(A2) If two consecutive file blocks $x-1$ and x are on the same or adjacent cylinder, requests to access these two blocks are serviced consecutively. Otherwise, after accessing block $x-1$, the disk head may move to service block x from any other cylinder i, with a probability distribution independent of blocks x or $x-1$ and proportional to the long term frequency of access to cylinder i.

The second part of this assumption is rather pessimistic due to the locality property of access requests and the use of elevator strategies. Now, let:

p_x = *the probability of an access request being for block x*
i_x = *the cylinder on which block x is located*
r_i = *the probability of an access request being for cylinder i*
$s(i,j)$ = *avg. seek time to cylinder j given the disk head is on cylinder i*
$h(x)$ = *avg. unnecessary seek time to access block x*

Then

$$S = \sum_{\text{all files } f} \sum_{\text{all blocks } x \in f} p_x h(x)$$

Following assumptions (A1) and (A2),

$$h(x) = 0 \qquad \text{if preceding logical block x-1 is on the same or adjacent cylinder}$$

$$= \sum_{\text{all cylinders } i} r_i\, s(i,i_x) \qquad \text{otherwise}$$

The density functions p_x and r_i are derived from the measurement data by making the assumption that

(A3) r_i is independent of the previous accesses and is equal to the frequency of access to cylinder i obtained from the long term measurements. p_x is also assumed to be independent of the previous access and is derived from r_i by assuming that the allocated blocks within a cylinder have an equal probability of being accessed.

The seek time between two cylinders i_y and i_x, $s(i_y,i_x)$, is assumed to be a function of d, the number of cylinders (distance) between the two. The following two formulae were used to evaluate $s(i_y,i_x)$, the average seek time.

(A4)

$$s_1(i_y,i_x) = a_1+b_1*d$$

$$s_2(i_y,i_x) = a_2+b_2*\sqrt{d}$$

where

$$d = abs(i_x-i_y)$$
$$= \textit{the seek distance (in cylinders) between two cylinders } i_x \text{and} i_y$$

The values for a_k and b_k, k=1,2, are computed in such a way that they satisfy the maximum (entire volume) and minimum (one cylinder) seek time values as reported in the disk drive's manual. In one seek time evaluation function, the disk head moves with constant velocity across cylinders. In the other, it moves with constant acceleration. Our experiments showed that the final results are not too sensitive to the choice of the formula.

To evaluate the unnecessary latency per accessed block, L, we have (from (A1, A2, A3)):

$$L = \sum_{all\ x} p_x\ l(x-1,x)$$

where $l(x-1,x)$ is the latency to access logical block x given preceding logical block $x-1$ was accessed last. Letting blk(x) to be the physical block number corresponding to x,

$$l(x-1,x) = 0 \quad \textit{if } x \textit{ is the first block of the file}$$

$$= ((blk(x-1)\oplus gap)\ominus blk(x))* \textit{(rotational time over one block)}$$
$$\textit{otherwise}$$

Here $x\oplus y$ and $x\ominus y$ are defined as $(x+y)\ mod\ (blocks/cylinder)$ and $(x-y+blocks/cylinder)\ mod\ (blocks/cylinder)$ respectively. *Gap* is the optimal rotational distance between two consecutive file blocks, and *blocks/cylinder* is the number of blocks on a cylinder. These two values are parameters of the file system construction and reorganization commands and depend on the type of the disk drive.

Once C is computed, it is used to predict disk utilization after reorganization. For this, the measurement data from the system activity report (*sar(1M)*) is used. This command reports measured disk utilization (ρ) and computed average service time ($\bar{x}$) during a measurement period. The approximate disk utilization after reorganization (ρ'), is obtained from:

$$\rho' = \rho\frac{\bar{x}'}{\bar{x}}$$

where

ρ = *disk utilization before reorganization*
$\bar{x}$ = *average service time before reorganization*
$\bar{x}' = \bar{x}-Cq$ = *average service time after reorganization*
q = *ratio of file system i/o to the total disk i/o*

2.1 MODEL PARAMETERS

The model parameters need to be measured or extracted from the system measurement data. In this section it is shown how these parameter are obtained and the assumptions that have to be made because of the unavailability of more accurate data.

To obtain the seek distance in the number of cylinders, and the latency in the number of blocks, a program has been developed that reads all file block numbers and produces a mapping[3] from the file blocks to the disk blocks. In addition, it counts the number of allocated blocks on every cylinder. This count is used to distribute the disk profile data to finer granularity (explained below). The program also looks at the directory blocks to measure the number of directory blocks that will be saved as a result of reorganization.

The cylinder and block access frequencies are obtained from the System Activity Disk Profile (*sadp*(1M)) data. This utility samples the number of accesses to 8-cylinder groups. It has been assumed that:

(A5) A cylinder on any 8-cylinder group is accessed proportional to the number of allocated blocks on that cylinder. Furthermore, if there is an

3. The file headers (*inodes*) provide file system block numbers for all blocks in the file. These numbers can be mapped to physical block locations by considering file system block size and the starting block of the disk partition on which the file system is located

access request for a cylinder, the blocks within that cylinder have an equal probability of being accessed.

There is an exception to this rule, and that is in the case where the boundary of two file systems lies inside an 8-cylinder group. Typically, the cylinders at the beginning of the file system have higher access frequency than those at the end. Hence,

(A6) Each subgroup on a boundary 8-cylinder group is first assigned a part of the disk activity profile proportional to the disk profile of its adjacent 8-cylinder group. Then, within each subgroup, the profile is distributed according to (A5).

The modules for data preparation and model evaluation are packaged together into a utility command that uses the system measurement data and produces the predictions. The run time of the program depends on the size of the file system. It could be a time consuming operation depending on how many blocks are allocated. On a file system of size 30K blocks, 60% full, the total cpu time on a 1 MIPS machine is about 6 seconds.

3. EXPERIMENTAL RESULTS

Experiments were conducted to verify the validity of the model. Note that the model included a number of assumptions and approximations that are rather coarse. However, we are interested in predictions that are accurate enough that can differentiate between a badly organized file system and one that is not too fragmented. The experimental results show that the predictions can provide us with some insight into the effectiveness of reorganization. In this section the results of two experiments in controlled and real environments are presented.

The first experiment consists of running an i/o-intensive benchmark on a dedicated machine - one with no interfering workload. The benchmark's i/o requests are mainly directed to an unorganized file system . This file system was fragmented by running the reorganization utility with wrong values for *gap* and *blocks/cylinder*. The system activity measurement (*sar*) and the disk activity profile (*sadp*) during the benchmark period were recorded.[4] Using the data from the run, the model was used to predict the disk utilization after reorganization. The result is given in Figure 1.

In this figure, *col_day* and *col_time* are the date and time when the data (disk activity profile) was collected. *Eval_day* and *eval_time* are the date and time of evaluation of the file system. *Cq*, the reductions in disk service time, is given in milliseconds. ρ is the measured disk utilization reported at *col_time* by *sar*, and ρ' is the predicted utilization after reorganization. Finally, *nullblk* is the total number of directory blocks saved as a result of reorganizations.

The file system is then reorganized using *dcopy*. The same benchmark is run on the two file systems. The *sar* results from both the first and second benchmark runs appear in Figure 2. In this figure *%busy* is the measured disk utilization (ρ), *avque* is the average queue length given the disk drive is busy, *r+w/s* and *blks/s* give the number of i/o requests per second, *avwait* and *avserv* are the average waiting and service times on the disk drive respectively. The model predicted that the utilization will reduce to 51% after reorganization. The actual measurements after running the same benchmark on the organized file system (Figure 2) show that the disk utilization reduced to 48%.

Finally, in Figure 3 we show the results of running the model with the data collected when the benchmark was running on the organized file system. Minimal performance improvements are expected if the file system is reorganized.

The second experiment was conducted on a real system. The file system under study was naturally fragmented. That is, unlike the previous model, its organization was not modified for the purpose of the experiment. A similar benchmark was run on this system and the system measurement data was collected. Note that we had to run a benchmark, since we cannot compare the after and after measurements if the workloads are not similar. However, we did let the real workload interfere with our measurements.

The file system was then reorganized and the same benchmark was run on the system. The *sar* results

Figure 5. Predicted Disk Utilization after Reorganizing a File System on dsk-6

from before and after the change are shown in Figure 4. The file system under study is placed on dsk-6[5]. The results of the prediction model are shown in Figure 5. The predicted utilization was 46%, while the measured utilization after the change was 43%. Note that in Figure 4 the average queue length at lower utilization is higher than that at higher utilization. This is because the average queue length is conditional on the disk being busy.

The difference between the predicted utilization and the measurements after the change is partly due to the fact that the number of i/o requests to the disk ($r+w/s$ column) are not the same during both benchmark runs. More i/o activities occurred during the first run of the benchmark. The model, therefore, based its knowledge on that i/o traffic, predicted a higher utilization. Nevertheless, the results are close enough that they validate the predictions.

4. RELATED ISSUES

The motivations for this model arose in the development of TUNEX, an expert system for UNIX system tuning. Initially TUNEX incorporated the system tuning and administration rules to find performance problems and recommend tuning solutions. However, it was soon found out that the rules are too general and in order to make quantitative recommendations, we need to perform quantitative analysis that need more specific information on the state of the system. This model is developed for TUNEX to ascertain whether i/o performance can be improved by reorganizing the file systems.

Once included in TUNEX, many other issues arise that need to be dealt with. For example, the quantity Cq (Figure 5) is a measure of how unorganized a file system is. However, ρ' tells us how effective the reorganization will be. Note that if ρ, the disk utilization, is small, no matter how unorganized the file system is, performance improvements will not be noticeable after reorganization. TUNEX recommends a reorganization when the disk utilization is above a threshold value and predicted utilization is below that value.

Another issue is the duration of time before the file system becomes unorganized. In a very dynamic environment an organized file system can become unorganized fast enough that a reorganization may not be cost effective. For this, TUNEX needs to track a history of the file system state, so that it can make a recommendation if a reorganization is worthwhile. This feature has not yet been implemented in TUNEX.

Given the predictive model, there is a question on which measurement data to use for the model. Data collected at different points in time result in different predictions about the extent of performance improvement. Organizing the same file system may be predicted to improve disk utilization by 5% or 10% depending on the time the input data was collected. TUNEX lists the range of predicted improvements resulting from the input data taken over periods of time when the disk drive was very busy (over 50% utilized).

5. SUMMARY

We presented a model for evaluating extent of fragmentation on a System V file system. Model's predictions in terms of performance gains help administrators make proper judgement on running a normally time consuming maintenance operation. We showed some experimental results that validate the model and discussed how this module was included and used by an automated tuning tool.

CAPACITY ANALYSIS OF PBX SYSTEMS

T. L. LO and J. PENG
McDonnell Douglas
Aerospace Information Services Company

ABSTRACT

A private branch exchange (PBX) is an electronic switching system that provides connections for voice communications. Recent PBX technology development allows the integration of voice and data traffic on PBX systems without compromising the quality of communications. This paper describes several capacity analysis algorithms for determining proper processing capacity of a PBX system based on processing environment, requirements and growth. Two case studies are provided to demonstrate the applicability of those algorithms.

INTRODUCTION

The private branch exchange (PBX) technology has evolved to parallel the computer technology in size, complexity, and importance. For years data has been carried on voice lines via sophisticated voice networks which has evolved since the inception of the telephone. Recent introduction of digital PBX and integrated voice and data services are perceived as an economic alternation in networking. The digital PBX technology provides interface capability to local area networks (LANs) and office automation. Unfortunately, most of today's voice and data integration of networks is external to the PBX with 90% of the PBX's installed still utilizing voice-only capabilities.

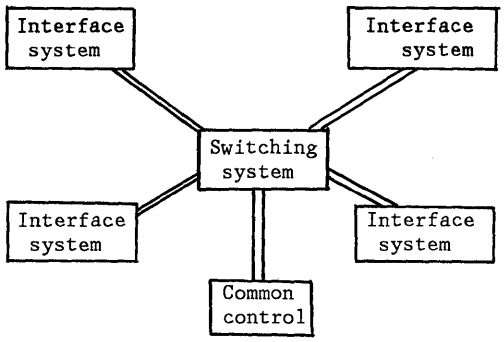
To select a proper PBX to accommodate present and future processing requirements is similar to selecting a computer system since capacity, service goals, cost and workload requirements all need to be considered. Only the evaluation criteria are different. For example, least-cost routing, speed dialing, call blocking probability and call handling capacity are the most popular PBX selection criteria whereas CPU MIPS, channel data rate, memory and cache size are pertinent parameters for computer selection.

This paper describes several algorithms for selecting a PBX system based on the requirements. The first section reviews fundamental properties of a modern PBX system. The second section discusses general PBX selection considerations and the third section presents several models to deal with performance prediction. Case studies are provided to illustrate the application of these models.

PBX ARCHITECTURE & TECHNOLOGY

PBX ARCHITECTURE

A PBX system is composed of three basic elements: common control, switching matrix and interface unit.



The common control governs the operation of the entire PBX system. It determines the allocation of internal resources for the function to be performed. It usually employs one or more microprocessors (CPUs) with random access memory (RAM) and read-only memory (ROM), backup disk or tape unit, and separate stand-alone software for call data recording and processing. The switching matrix provides the communication paths required for the interconnection of the interface units. It can be operated under three switching techniques: space division, time division and frequency division multiplexing, (SDM, FDM and TDM respectively). The speed of the switching matrix determines the traffic capacity of each PBX. The inclusion of data traffic impacts what is available to voice and alters the statistical behavior of the switch. The interface unit normally consists of "lines" from users to switching matrix (line cards) and "trunks" to outside switches (Trunk cards). The unit interfaces with all external equipment and is modularized to accommodate different line size requirements. The inclusion of protocol converters and LAN interfaces, as well as high speed trunks, make the interface unit more adapted to support distributed processing.

PBX SWITCHING TECHNOLOGY

The basic PBX switching technique deals with signal transmission in two distinct types: analog and digital. Analog transmission means that the signal transmitted is a direct analog of the actual signal. For example, in a voice signalling, an analog signal looks like a continuous wave which is modified as the voice frequency changes. In other words, analog signal changes in amplitude, increases in frequency, or drops to zero, depending upon the voice frequency gets louder, higher or stops. Digital signals are not continuously variables. They exist as a series of pulses, each represents one of a finite number of values at any instant.

The major difference between analog and digital signalling, therefore, is in their means of transmission. Analog signals are amplified as they are transmitted and amplification usually does not distinguish between the original signal and noise which may have cropped up on the line during the transmission. Digital signals do not have to be amplified, but are generated such that new signals are created, based on the measured values, to simulate the old ones. Thus all external noises are dropped during the regeneration.

A true digital switch PBX is a PBX with an internal switching matrix that switches voice (analog) and data (digital) signals in digital form. But a "computerized" PBX only implies the digital common control, not necessarily the switching matrix. Therefore, an "automated time division multiplexing PBX" may very well switch analog signals. PBX technology, especially switching technique, evolves following VLSI and ULSI development trends. PBX technology can generally be categorized into four development generations:

- First generation (1960's) - electronic and mechanical hard-wired logic-based switches using diodes and transistors. It was totally analog transmission with time-division multiplexing, but not computerized.

- Second generation (late 1960's -early 1970's) - primarily analog transmission with space division multiplexing, but with some digital capabilities requiring the assistance from external devices such as modems. It is microprocessor based and features stored program intelligence such as least-cost routing, security control, and automatic distribution of calls.

- 2.5 generation (late 1970's) - second generation PBXs with enhancements to accommodate data switching is the key feature of this half generation PBX development. PBXs utilize analog signalling between phone handset and PBX; data signals are converted to analog signals at the switch by a coder-decoder (CODEC) facility.

- Third generation (early 1980's) - most PBXs were digital-based to integrate voice and data at the phone handset rather than at the switch matrix. The switching technique utilizes pulse-code modulation (PCM) digital time division multiplexing and is characterized by "distributed" stored program intelligence.

- 3.5 generation (mid 1980's) - Several third generation PBXs with cabled-based local area networks (LANs) capability can be considered as one step closer toward the fourth generation PBX technology. In addition to the LAN interface, these PBXs can dynamically switch traffic using high speed bandwidth, such as T1 and satellite circuits, as well as the support of X.25 packet switching network interface.

- Fourth generation (late 1980's - early 1990's) - fiber optics and microwave links will be widely used to provide very large bandwidth (e.g. 500 mbps) for every workstation and each station will have the capability to perform teleconferencing, file manipulation, and complex graphics.

PBX CAPACITY ANALYSIS CONSIDERATIONS

SWITCHING CAPACITY

The most common PBX capacity indicator is "one hundred (Roman numeral C) Call Second, or CCS." CCS capacity is similar to MIPS (millions instructions per second) as it relates to computer processing capacity. Therefore, CCS can be used as a common denominator to provide some indication of performance capacity for each PBX. For example, 36 CCS can be represented as the capacity per hour per path, derived by 60 minutes X 60 second divided by 100. Most PBXs require a 6 CCS per call as a minimum capacity for a normal voice system. If data is introduced through the PBX, 24 CCS per call would be required to statistically handle the traffic since a data call has approximately four times more impact on PBX capacity than a voice call. A typical mix of voice/data in today's PBX environment is 75% voice and 25 % data (OPDE85).

To determine a particular PBX's capacity, the CCS can be interpreted in terms of number of simultaneous calls per hour. For example, AT & T System 75 PBX has a rated 8,676 CCS capacity. A worst case scenario of 36 CCS per call with full-time data use would offer 241 simultaneous calls per hour. A best case with 6 CCS per call, with voice only requirement, would support 1,446 calls per hour capacity. If we use a typical 75/25 voice/data mixed workload, the System 75 capacity can approximately support 600 voice only and 200 voice/data stations (600 + 4*200 < 1,446).

Although CCS is a common PBX capacity indicator, it is only one of many variables which must be considered when selecting a PBX for a particular processing environment.

TRAFFIC STATISTICS

Since the majority of today's PBXs are voice-based, voice traffic statistics, such as number of distribution of incoming and outgoing calls, number of long distance calls, and call duration, are prominent. An average phone user's profile can be derived from these statistics, which can also be used to determine future usages.

In addition to traffic statistics, the probability of call blocking is also of importance. That is, when a user needs to access the phone, there is a chance that he/she will not be able to use the phone due to all-line-busy condition. A probability of 0 means a non-blocking capacity. The U.S. telephone industry uses a block probability of 0.01 (one out of every 100 calls is likely to be blocked) whereas a 0.005 is used by European telephone industry.

The probability of call blocking is indirectly affected by the number of trunk lines that a PBX can support. The trunk lines can be grouped via a TIE, FX, WATS or DOD/DID line. A TIE line is a leased line connects two PBXs without having to dial normal phone number. A FX (foreign exchange) line provides telephone service from a central office (CO) which is outside the caller's exchange area. A caller may, in the simplest form, dial one or two digits to obtain a dial tone for subsequent calls. A Wide Area Telecommunication Service (WATS) line allows calls to specified geographic areas with potential lower cost long distance services. WATS lines essentially come in two types: INWATS and OUTWATS. The Direct Outward Dialing (DOD) and Direct

Inward Dialing (DID) lines allow callers to dial an extension without the need for assistance from the PBX attendant. They are connected via PBX to local COs.

COMMUNICATIONS REQUIREMENTS

The third factor for determining a PBX capacity is the voice communication requirements. The most desirable features are automatic route selection, signal transmission, centralized attendant, traffic statistics recording, voice/data integration, maintenance and control, and user programmable features.

The automatic route selection (ARS) feature allows a PBX to determine the route for calls as THE user begins to dial the first few digits. Queuing should be considered as part of ARS. There are generally two types of queuing: off-hook and call-back. An off-hook queuing calculates the average time that a caller must wait, in an all-line-busy condition, for the first trunk line to become free. This queuing time should not be more than 10 seconds. A call-back queuing allows a caller to place himself in a queue and hang up. The PBX system will inform the caller within a specified time interval, normally less than 10 minutes.

Signal transmission feature requires a PBX to switch signals on trunk lines to avoid unnecessary turnaround delay especially in a TIE-trunk network which connects two PBXs with dedicated lines for fast communications between the two PBXs. Since the analog signaling will probably be the voice communication standard for a long time, a connection from an originating to a terminating PBX should follow the "VLN+4" rule. This rule introduces "loss" into a line to reduce the echo and the loss required is called Via Net Loss (VNL). In order to make echo level low enough, an extra amount of loss, approximately 4 decibels (dB) is required, divided up to 2 dB in each end of the line.

Centralized attendant - short TIE trunks which are used to distribute incoming calls from the attendant switchboard to nearby PBXs, are inexpensive and the swap of TIE trunk cost for attendant salary makes economic sense. Furthermore, desk-to-desk dialing is offered by most PBXs, thus reducing the dependency on switchboard attendants.

Traffic statistics recording - most PBXs provide the call dial recording (CDR) capability. In addition, the dialing and ringing times, non-productive intervals and aborts, and queuing time and length are desirable statistics. For capacity planning purpose, queuing, trunk call distribution, and processor utilization are pertinent information to record. Once the information is collected, PBXs should provide the post-processing functions to report system resource usages and calling statistics.

Voice/data integration - the primary motivation for integrating voice and data is to reduce switching and transmission costs, consolidate facilities, and improve administrative efficiency. The developments of local area network technology, intercity digital switching (e.g. integrated services digital network), and voice/data workstations all make voice/data integration affordable and attractive.

Maintenance and control - one of the most frustrating parts of telephone system management is getting changes and additions made. The PBX internal system should be able to display information such as which phone is on which pick-up group, who hunts to whom, which users are assigned to which extensions, and which phone sets are assigned to what switch matrix input.

User friendly features - most modern PBXs provide users with programmable features through the stored-program control intelligence. Features such as call forwarding, ring again, night attendant, call waiting indication, and inter-desk dialing, are the most welcome ones.

MATHEMATICAL MODELS FOR PBX CAPACITY ANALYSIS

ERLANG-B MODEL

The common approach to analyze PBX capacity is to use analytic modeling. These models are of particular interest: Poisson, Erlang-B, and Molina. All three deal with three types of input variables: number of trunk lines, traffic volume, and probability of call blocking. Knowing the values of any two, the value of the third one can be readily determined. Since Erlang-B model is the most widely used model in telephone industry, it is discussed here.

The "number of line" variable implies the number of trunk lines that a PBX needs to support. The "traffic volume" variable requires two types of input information: average number of calls per unit of time per phone, and average call duration which is defined as the elapsed time between phone handset off- and on-hook. The product of these two is called an Erlang. That is,

$$\text{Erlang} = (\#\text{ of call/time/phone}) * (\text{call duration/phone})$$

The probability of call blocking indicates the chance that a phone call is blocked because of all-line-busy condition. The general equation to determine the probability of blocking, assuming the number of trunk line and traffic volume are given, is based on recursive relations,

$$P(n) = (P(n-1) * A)/(I + P(n-1) * A)$$

where $I = 1,\ldots,T$ (T is number of trunk line)
$n = 2,\ldots, T+1$ (representing the recursive relation)
A = average traffic volume in Erlang
$P(1) = 1$ is the starting value

For example, if A is 4.51 Erlangs and T = 6 lines, then the probabilities of blocking would be:

X	P(X)
1	1.0
2	0.8185
3	0.6486
4	0.4937
5	0.3576
6	0.2439
7	0.1549

The result can be interpreted as follows. Given 6 trunk lines with the average traffic volume of 4.51 Erlangs, the probability of blocking any access to trunk line is 15.49%; or roughly one out of every six accesses is likely to be blocked due to trunk line shortage. The general practice of finding a desirable probability of blocking is to increase the number of trunk lines with traffic volume held as constants until the desirable probabilities are found.

MULTISERVER QUEUING MODEL

In a telephone information inquiry system, the number of attendants is of primary concern since it determines how long a caller must wait for an available attendant if the call can not be handled right away. The multi-server queuing models (MART72) can be used to determine the proper number of attendants required to meet the minimum service goal.

The model assumes the following:

* the system is in steady-state condition.
* incoming calls arrive in a random pattern.
* the service time (the length of time that an attendant spends servicing an inquiry) is independent of the service time of previous inquiry.
* all attendants are capable of providing the same type of service.
* the service policy is first-come-first-served.

Let

U = server utilization
N = average arrival rate
Ts = average service time
M = number of servers in parallel on a multiserver system
Tq = average queuing time
Q = average queue length
Tt = total time spent in the system
B = probability that all servers are busy
T = total number of inquires in the system

Therefore,

$$U = N * Ts/M$$
$$B = X/Y$$
$$X = 1 - K$$
$$Y = 1 - U*K$$

$$K = \sum_{N=0}^{M-1} \frac{(MU)^N}{N!} \Big/ \sum_{N=0}^{M} \frac{(MU)^N}{N!}$$

$$Q = B * (U/(1 - U))$$
$$T = B * (U/(1 - U)) + M*U$$

$$Tq = \frac{B * Ts}{M(1 - U)}$$

$$Tt = \frac{B * Ts}{M(1 - U)} + Ts$$

CASE STUDIES

Two case studies are presented here. The first one concerns the PBX system selection in a manufacturing environment based on current traffic volume, user profile analysis, special feature requirements, and future growth. The major concern is the number of trunk lines required to support a specific probability of call blocking. The second case study analyzes the capacity of a health care information inquiry system with the goal of minimizing the time to service an incoming inquiry. The main concern is how many attendants should be used to handle various loads at different working periods (i.e. three working shifts, weekends, holidays, etc.).

CASE STUDY #1

A division of a manufacturing company is planning a relocation project which will move the entire division to a new facility fifty miles east of current facility. The division will operate their own data center which is linked to corporate data network via corporate PBX system. The existing voice communications service is provided by the corporate PBX network on a monthly rental basis. One of the major concerns is whether the division should continue to use corporate PBX network or operate their own PBX system.

Three factors need to be considered in order to make the "owning or renting" decision: traffic volume, current and future feature requirements, and the cost. The traffic statistics can be gathered from accounting records; feature requirements can be obtained from a user survey; and the cost is determined on current corporate billing invoices and future traffic volume and feature requirements.

Basic Traffic and Cost Statistics

There are eight departments in the division; they are grouped into two segments, called group X and group Y for this study. The voice traffic analysis is based on 178 phone extensions, some of them are dial-ups and some are data center operators. Following tables show the most recent six months (November 86 to April 87) cost information, including equipment cost and actual calling cost, and calling statistics.

Month	Group X ($)		Group Y($)		Equipment($)		Grand
	L.D.	Local	L. D.	Local	X	Y	total($)
Nov.	1,920	2,971	1,931	286	6,969	2,168	15,417
Dec.	1,061	4,085	3,562	255	6,730	2,168	18,262
Jan.	1,156	4,216	3,145	304	6,739	2,476	18,262
Feb.	1,112	3,843	2,766	310	7,118	2,573	17,722
Mar.	1,269	3,764	2,720	319	6,499	2,591	17,162
Apr.	1,763	5,524	1,225	303	6,994	3,346	21,072

Table 1 Six Months Cost Information

Table 3 Cost Per Individual Phone Statistics

Month	Long Dist X	Long Dist Y	Local call X	Local call Y	Dept. avg. X	Dept. avg. Y	Total average
Nov.	4.70	4.39	4.69	3.62	4.67	4.05	4.36
Dec.	4.82	3.94	4.76	3.10	4.73	3.66	4.20
Jan.	5.17	4.06	4.80	3.33	4.91	3.84	4.37
Feb.	5.15	4.15	4.77	3.51	4.87	4.05	4.45
Mar.	5.86	3.98	5.71	4.11	5.62	4.07	4.85
Apr.	7.11	3.95	7.33	3.31	6.89	3.81	5.35
avg.	5.47	4.08	5.34	3.50	5.28	3.91	4.60

Table 4 Individual Call Duration Statistics

From these tables, a phone user's profile can be interpreted as follows:

* A caller makes 67 calls a month
* Each phone costs $115 including equipment cost of $59 and phone call cost of $56
* Each phone call lasts 4.6 minutes and group X users tend to use the phone longer than group Y users (5.28 vs 3.91 minutes)
* Each call costs $0.84 on the average
* Each caller spends 47% on local calls and 53% on long distance calls, including 35% on corporate PBX and 18% on local telephone company's long distance services

Future Feature Requirements

A survey form was sent to each individual of the division in order to solicit information on desirable features and calling frequency and duration. The most desirable features, ranked by their voting popularity, are listed below.

* Call transfer
* Call forward in all case
* Conference call
* Call hold
* Busy override
* Data line for data/file transmission
* Call waiting indicator
* Automatic callback
* Call attendant
* Speaker phone
* Trunk queuing with auto routing
* Night answering

Tables 5 below lists the summary of call duration statistics.

	CALL DURATION (minutes) 1-3	3-15	15-60	60+	Total
# call-out	6,199.0	14,778.0	718.0	15.0	
# call-out/phone	40.5	96.6	4.69	0.1	
#call-out/phone/day	1.85	4.4	0.21	-	6.44
#call-in	6,289.0	14,656.0	976.0	21.0	
#call-in/phone	41.1	95.6	6.38	0.14	
#call-in/phone/day	1.87	4.35	0.29	-	6.51

Table 5 Forecasted Call Duration Data

The number of calls per phone per day is derived from the assumption that there are 22 working days in a month. The mean values for 1-3, 3-15, 15-60, and 60+ intervals are 2, 8, 45, and 61 minutes respectively. The weighted average call duration is 7.22 minutes. Therefore, an average phone user makes 6.44 outgoing calls per day and receives 6.51 incoming calls per day; or a person plans to use the phone 13 times a day with a weighted average call duration of 7.22 minutes.

PBX Capacity Analysis

A PBX's capacity is determined by the number of trunk lines it can support subject to a specific call blocking probability. A call blocking probability, as defined previously, is the chance that a phone usage is likely to be blocked due to an all-line-busy condition.

The common approach to analyze a PBX's capacity is to use the Erlang-B analytic model. An Erlang is the product of two variables: the number of calls per phone per unit of time and the call duration. Since April's statistics is 15% higher than the six-month average, it is used as a worst case scenario to determine the Erlang of current system. The forecasted data is used to estimate the Erlangs for future system. Both types of Erlangs are listed below.

	Call duration Current	Call duration Future	# call/min Current	# call/min Future	Erlangs Current	Erlangs Future
Long distance via corp. PBX	4.66	-	0.42	-	1.957	-
Long distance via phone co.	9.64	-	0.213	-	2.053	-
Local calls	7.33	-	0.58	-	4.251	-
Avg/total	7.21	7.72	1.213	1.44	8.742	10.468

Table 6 Current & Future Capacity Requirements

Based on Erlang-B model, the Erlangs and number of lines can determine the call blocking probability. The following table shows the call blocking probability based on 8.742 Erlang traffic.

# of trunks	Probability (%)
9	21.16
10	15.62
11	11.05
12	7.46
13	4.86
14	2.90
15	1.66
16	0.90
17	0.46
18	0.22
19	0.103
20	0.045
21	0.019
22	0.007
23	0.003
24	0.001
25	0.0004
26	0.0001
27	0

Table 7 Call Blocking Probability with 8.742 Erlangs

Modeled results indicate that for the traffic of 8.742 Erlangs; therefore, 27 trunk lines are required to support a non-blocking system. For retaining telephone industry's 0.01 standard, 16 trunk lines are necessary. Similarly, for the forecasted traffic of 10.468 Erlangs, 33 and 20 trunk lines are required to support a non-blocking and 0.01 blocking system, respectively.

Since the above modeled results are based on a combined total Erlang traffic, a different approach was used based on each individual Erlang traffic. Table 8 shows the modeled results.

Type of call	Long dist. via PBX	Long dist. phone co.	local calls
Erlangs	1.957	2.053	4.251
# of trunks	Prob. (%)	Prob. (%)	Prob. (%)
2	39.08	41.16	63.75
4	8.93	10.30	33.44
5	3.35	4.09	22.13
6	1.07	1.39	13.56
7	0.297	0.41	7.61
9	0.016	0.025	1.80
10	0.003	0.005	0.76
12	0.0001	0.0002	0.104
13	0	0	0.034
15			0.003
16			0.0008
17			0.0002
18			0

Table 8 Call Blocking Prob. from individual Erlang

Results from Table 8 indicate that in order to maintain a non-blocking probability system, a total of 44 trunk lines are required. For a 0.01 blocking system, 23 trunk lines are necessary.

Results from Tables 7 and 8 raise an interesting question. When all three types of calls are combined together, they require 27 trunk lines; when they are analyzed separately, the sum of trunk lines of each group is much larger than the combined requirement (44 vs 27). Why ? The combined situation implies that a group of trunk lines are available to be accessed regardless the type of calls made. The separate situation implies that a group of lines are dedicated only to a group of users. Therefore, the probability of blocking is higher in a separate situation than in a combined case. This brings up a decision making question and one must decide how to configure the trunk lines for achieving desirable call blocking probability. As discussed earlier, the trunk lines can be grouped together using either TIE, FX, WATS, or DOD/DID lines to realize the most cost effective routes.

Once the capacity requirements of a PBX are determined, the desirable features need to be considered for selecting a proper PBX system. Most telecommunications research reports can provide detail PBX description and functional comparisons.

CASE STUDY #2

A health care information services company provides a telephone inquiry services to the public. The current system consists of 16 lines and 10 attendants to answer inquiries, and 2 on-line CICS terminals for retrieving information. The inquiry system is operated as follows. If an incoming inquiry is not answered within 8 seconds, the call is placed in a pool answered by a first-come-first-service policy. There are two electronic priority indicators showing the next line to be answered. If a call is answered, the attendant may continue the conversation or retrieve information. The information retrieval is operated in two modes: manual and automatic. In a manual retrieval mode, an attendant goes to the hard copy looking for information; in an automatic mode, the attendant uses a terminal to access the CICS data base. Queuing occurs when an attendant confronts an all-terminals busy condition.

The desirable service goal is 10 minutes per inquiry including queuing and processing times. Since this goal is not 100% attainable, the management has ordered a PBX capacity analysis study to address following questions:

- What is the current system capacity ?
- If the system is to provide a 10 minute service per inquiry including a 3-minute initial waiting and 5-7 minute processing time, what is the necessary configuration to meet this goal ?
- How many CICS terminals are required for on-line inquiry processing in order to reduce queuing time on terminals ?
- How many attendants are required to handle the weekend and non-prime hours inquiries ?

Current Statistics

The inquiry system is monitored by a Code-A-Phone Sequence V monitor which operates in three modes: answer-only, answer-hold and idle. It provides detail telephone information on number of incoming and outgoing calls, number of abandon calls, and busy minutes. It also displays the number of calls answered by the monitor with a prerecorded announcement if the call is not answered after 8 seconds. The monitor also updates the status of queued calls. The measured statistics are:

	# inquiry/hr	Service time/inquiry
Weekday prime hours	75	6.74 min
Weekday non-prime hours	21	5.25 min
Weekend prime hours	8	5.25 min
Weekend non-prime hours	6	5.25 min

Table 9 Measured Inquiry System Statistics

The observed queuing statistics consist of three categories:

Avg. queue time for an available terminal	65 seconds
Avg. time difference between on-line and manual processing per inquiry	24 seconds
Avg. % of attendant waiting for a terminal	33%

The current system is capable of handling 60 inquiries an hour. The averaged prime shift hourly inquiry rate was 75 and approximately 25% of the incoming inquiries are placed in queues. This number is likely to increase as time evolves since the incoming rate is greater than the service rate.

Model Application

The telephone inquiry system is a classic multiple-server queuing system where callers enter a common queue if they are not answered immediately, and wait for the next available server (attendant). The input parameters to the model are: the average service time, number of available attendants (servers) to answer the inquiry, and the number of calls per minute (or hour). The model provides the following output information:

* Server utilization (how many minutes that an attendant is busy in an hour).
* Caller's queuing time.
* Number of callers in queue.
* Number of callers being serviced (answered).
* Total processing time per call including queuing and processing time.
* The probability that all servers (attendants) are busy.

The model is executed in iterative mode with varying number of attendants so that the results can be plotted for quick reference.

Modeled Result Analysis

As indicated earlier, the multi-server model can estimate the queuing and processing times corresponding to various load conditions in terms of number of inquiry per hour. Table 10 below shows these calculated values, in minutes, for the weekday prime shift hours with an average service time of 6.74 minutes.

# people	P = 10		P = 12		P = 14		P = 16	
Inquiry per hr	wait time	total time	wait time	total time	wait time	total time	wait time	total time
60	2.97	9.71	0.38	7.12	0.06	6.80		
61	3.56	10.31						
62	4.08	10.83						
63	4.82	11.56						
66	8.93	15.66						
69	24.43	31.14						
70	56.31	63.06						
72			1.51	8.25	0.26	6.99		
78			3.27	10.01				
84			9.61	16.35	0.89	7.63		
87			27.28	34.02				
88			70.66	77.39				
90					1.69	8.43	0.32	7.06
96					3.52	10.26		
102					10.28	17.02	1.00	7.74
107					30.65	37.39		
111							2.99	9.95
114							3.75	10.49
120							137.73	144.47

Table 10 Modeled System Capacities for Prime Hours

Data indicate that the current system can handle 60 inquiries an hour to meet the desirable goal: 3 minutes waiting and 7 minutes processing. To add 6 more attendants, the system capacity is increased to 111 inquiries an hour. Figure 1 summarizes the data in graphic form.

Since there are times that an attendant may have to wait for the terminal, the management needs to know how many terminals should be added in order to improve information retrieval time. The model assumes that no more than 1/2 of all attendants access the terminal at the same time; it then estimates the expected queuing times using the number of available terminals and number of simultaneous access, as shown in Table 11.

# simultaneous access	Number of terminals: 8	7	6	5	4	3	2
8	0	0	0	5.29	27.5	*	*
7	0	0	0	2.78	11.9	534.5	*
6	0	0	0	0	5.7	38.9	*
5	0	0	0	0	0	14.1	*
4	0	0	0	0	0	5.9	62.7
3	0	0	0	0	0	0	16.9
2	0	0	0	0	0	0	0

Table 11 Modeled Terminal Wait Time

Note that an asterisk indicates that the queuing time is extremely high. The observed terminal wait time is 65 seconds in a 10-attendants and 2-terminals configuration. The modeled terminal wait time of the similar configuration is 62.7 seconds, a very close approximation. Based on these estimates, a total of 5 terminals would reduce the average terminal wait time to only about 5 seconds. Figure 2 summarizes the results of terminal wait time analysis.

From Tables 10 and 11, the recommended system configuration consists of 16 attendants and 5 terminals, and the capacity is 148 inquiries per hour with an average wait time of 3.1 minutes and processing time of 5.25 minutes. Figure 3 plots the calculated system capacities versus the number of available attendants.

The weekday non-prime hours and weekend prime and non-prime hours have the monitored hourly rates of 21, 8, and 6 inquiries respectively, and the current number of attendant is 3. The terminal wait time in those cases should be close to zero. The model calculates the capacities for those periods in a similar manner as it did for the weekday prime hours, but with different service time value. Table 12 lists various system capacities corresponding to those periods.

# people	P = 1		P = 2		P = 3		P = 4	
Inq. per hr	Wait time	total time	Wait time	total time	wait time	total time	Wait time	Total time
6	0.49	5.74	0.061	5.31				
8	0.82	6.07	0.097	5.35				
11	1.51	6.76						
12	1.99	7.25	0.276	5.53	0.043	5.29		
18	8.57	13.82	0.97	6.22	0.187	5.44	0.03	5.28
21	28.43	33.67	1.76	7.01	0.28	5.53	0.07	5.32
22	87.39	92.63						
24			2.87	8.12				
30			10.83	16.08	1.39	6.64	0.16	5.41
33			43.4	48.65				
36					3.54	8.79		
42					13.34	18.59	1.19	6.44
45					81.10	86.36		
48							3.72	8.97
54							25.26	30.51

Table 12 Modeled Non-Prime & Weekends system capacity

Based on these results, two attendants should be sufficient to handle weekend and holiday load up to 14 inquiries an hour. Three attendants are required to support the non-prime weekday hours with a processing capacity of 24 inquiries an hour. Figure 4 shows the weekend and non-prime system capacities.

In summary, six attendants are required to handle the weekday prime hour inquiry demand. Two to three terminals should be added to reduce terminal queuing time. Two attendants can support the weekend and holiday inquiry demand and three attendants are necessary to handle weekday non-prime hour inquiry demand.

CONCLUDING REMARKS

We have shown that the same analytic models used for performance analysis and capacity planning in data processing and data communications can be applied to voice communications. In the PBX capacity selection case, a simple Erlang-B model, together with surveyed feature requirements and cost information, can provide very useful capacity planning guideline. In the telephone information inquiry system, the classic multi-server queuing model can be applied to determined the processing capacity based on a specific threshold on total processing time.

CONCEPTUAL ISSUES IN MEASURING THE BEHAVIOR OF A DISTRIBUTED REAL–TIME PROCESS–CONTROL COMPUTER SYSTEM[1]

J. Dennis Lawrence
Lawrence Livermore National Laboratory

ABSTRACT

Measuring the performance, reliability and availability of a distributed real-time process-control fault-tolerant computer system presents a variety of interesting problems. A method is described by which this task can be organized efficiently, and by which appropriate measures can be provided for a variety of different user groups. This involves constructing a system structure graph that organizes all of the hardware and software of the computer system. Subgraphs are identified that provide information to the various users. A particularly important type of user is the equipment, or process, being controlled. Some of the problems that one can expect to encounter are discussed.

1. GENERAL PRINCIPLES OF COMPUTER SYSTEM BEHAVIOR

The behavior of any computer system can be understood quantitatively by providing certain measures of that behavior. This is true both for analyzing and explaining current behavior, and for predicting future behavior. However, behavior is only useful in the context of the tasks the system is expected to perform, and the objectives of the people who interact with the system. As a consequence of this, measures are context dependent, useful only with respect to the differing goals of the computer system users.

For example, consider measures of performance for a general-purpose timesharing system. A person sitting at a terminal is most interested in response time, while a person who runs batch jobs cares more about turn-around time. The system manager, intent on maximizing resource usage, will be quite interested in CPU utilization.

Now, suppose we have two people at interactive terminals. The first person is using the text editor and Fortran compiler to debug a large program, and the second person is directing time-consuming queries at a database management system (DBMS). The operating system (OS) stays up all day, but the DBMS goes down once an hour, and stays down for half an hour each time. How do our two users view this day?

To the first person, response time varies from fast to slow during the day, and seems to change a couple of times an hour. Still, the system availability is 100%, and reliability is perfect for the day. To the second person, however, response time is medium whenever he can get on, but availability is 50% and the mean time between failures is one hour.

You will notice that the goals of the three people in the first example are in conflict, since improving any one of the measures is likely to have a negative impact of the other two. Furthermore, performance, availability and reliability goals interact: an increase in reliability may result in improved availability and degraded performance. Or vice versa. As can be seen in the second example, even the perception of the system's behavior can vary widely among the users.

How can such goals and perceptions be reconciled? The answer to this question, in the setting of a distributed real-time process-control (RT–PC) computer system, is the subject of this paper.

We will be concerned with various aspects of three classes of behavior: performance, availability and reliability (frequently abbreviated to PAR). We begin by defining these terms, developing some general methods of measuring behavior, and providing an example. We will then go into each of these aspects in turn, considering measures appropriate to a distributed RT–PC computer system. In the process of doing this, we discover that there are important interactions that must be considered, and discuss methods of understanding these. Throughout, the emphasis is on obtaining practical answers to practical problems.

1.1. Definitions

The term *behavior* is sufficiently vague to refer to any aspect of a system that can be measured and is of interest to the observer. For this paper, however, we will limit the term to various aspects of performance, reliability and availability.

We will use the term *user* to include anyone or anything that interacts with the computer system. This includes persons that use the computer system as a tool to accomplish other work (frequently referred to as end users), and to persons (such as operators and systems programmers) who are directly concerned with the computer system itself. These will usually be referred to as *external users* and *internal users*; the distinction becomes important when we assign appropriate measures of PAR to different classes of users. A third type of user is the equipment being controlled by the RT–PC system.

Roughly speaking, performance refers to the speed with which the system responds to user demands; reliability, to its ability to operate without failure; and availability, to its ability to complete work for users, by satisfying resource requirements. While somewhat more precise verbal definitions can be given, it is necessary (to be useful) to specify these concepts in terms of mathematical equations that can be evaluated (ultimately) from observable measurements. For this paper, the following informal definitions are sufficient.

- *Performance* measures the efficiency with which a device or system satisfies service requests from (human or mechanical) users. A computer system can be understood as a collection of various hardware and software resources, connected together into a network. Activities consist of various tasks that are routed among the resources, requesting service. Each resource is limited in the number of tasks that can simultaneously receive service; other tasks may be queued, awaiting their turn for service. Performance measures the efficiency of all this activity.
- *Reliability* is the probability that a device or system will operate for a given period of time without failure under given operating conditions [1]. The reliability of a system is thus a measure of the success with which the system conforms to some authoritative specification of its behavior, and cannot be measured without such a specification [2].
- *Availability* is a measure of the ability of a device or system to complete a mission without excessive down time [1]. It is the expected fraction of time that the system is available to perform useful work.

See [3] for more precise definitions of reliability and availability.

[1]This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract No. W–7405–Eng–48.

1.2. Classes of Measures

A first step in classifying measures (of all three types) results from separating external from internal measures. End users are generally most interested in external measures; systems management, in internal measures; and equipment, in both.

External, or *black–box*, measures are calculated by examining the behavior of the system from the outside, with no knowledge of the internal composition or configuration. These measures reflect how well the system is meeting current end user objectives, and thus should reflect current user satisfaction.

Internal, or *white–box*, measures are calculated by an examination of the structure of the system, and the behavior of the various subsystems and components into which the system can be divided. These measures have a variety of uses. Notice that each of these goals has application in each of the three aspects of PAR.

- to assist system management in reorganizing the computer system to better meet user objectives;
- to calculate how much additional stress the system can tolerate before user objectives can no longer be met;
- to predict and control system degradation as stress increases;
- to understand and predict the effects of changes in PAR on the equipment being controlled;
- to predict when new system resources will have to be acquired in order to improve behavior;
- to perform sensitivity analyses, so as to determine whether minor changes in system structure exist that can have major impact of system behavior; and
- to help find system bottlenecks and points of vulnerability, so effort can be directed towards critical areas.

You can see from this that external measures are primarily concerned with current behavior, while internal measures look more to the future, with the intent of decreasing uncertainty and improving management and operational decisions. External measures can be determined by actual measurement of the computer system, while internal measures combine these measurements with additional measurements internal to the system, estimates of future workloads, and anticipated future user requirements in order to predict and control future system behavior. This is generally done by constructing models of possible configurations, solving the models for various known or hypothetical workloads, analyzing the solutions to obtain insight into behavior, and using the insight to guide the actual evaluation and evolution of the system.

A brief example may indicate why we separate external from internal measures. Suppose we have a process-control system, which has two CPUs that control the equipment. Either CPU is capable of performing this control by itself, so if the primary CPU fails, the backup CPU takes over with no loss of control. Now, suppose CPU–1 fails. Repair takes some period of time, during which CPU–2 controls the equipment. When repair has been completed, CPU–1 becomes the new backup CPU.

Now, from the viewpoint of the external users, availability is 100% throughout this period of time. However, from the viewpoint of the internal users, only half of the potentially available system is actually there during the repair interval. The equipment continues to operate, but at increased vulnerability to failures. Both internal and external viewpoints are valid, and both are important. They cannot be combined; hence, we keep both external and internal measures when describing the system behavior.

1.3. Components, Systems and Views

A computer system can be considered to be a hierarchy of (sub)-systems and components. Here, a *component* is considered to be atomic – it is repaired or replaced as a unit, and we do not look inside it to measure behavior within. You can see that what one person thinks of as a component may be a complex system to someone else. In such conflicts, let us assume that agreement can be reached, so (in effect) a component is a piece of the system that nobody wishes to subdivide in order to consider PAR.

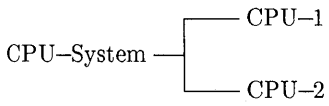
Components are combined with other components (and, possibly, with subsystems) to form subsystems. These in turn can be combined to form other subsystems, etc., until we arrive at the top of the hierarchy with a single system including everything. We permit components and subsystems to belong to more than one (sub)system; the resulting structure is a directed acyclic graph. We call this graph the *system structure graph* (SSG).

In practice, a component is either a hardware device or a software module. A hardware component would then be the smallest device that is removed as a unit for repair; this is meant to imply that resistors are not usually considered to be components (although we could, if we wanted to). A software component could be a single subroutine or a single program, depending on how deep into the system structure we wish to go. Keep in mind that our purpose is to obtain practical measures of PAR; reliability of a single resistor, or performance of a single line of code, is generally not helpful to the users of a computer system.

It would also be possible to add users (people and equipment) to the list of components, since their actions may well affect PAR. This idea is not pursued further here; we view people as demanding levels of service, and the system as attempting to provide those levels. If a user causes a system crash, we measure the crash, and assign fault to the component or subsystem that failed, not to the user.[2]

Now, suppose that there is some measure b of behavior that we wish to calculate for an SSG. Typically, certain measurements are carried out at some level within the graph. For example, if b measures reliability, we could begin by measuring reliability of individual components. These measurements are then combined, bottom to top, so as to obtain a measure that quantifies this behavior for the entire graph. Note that the evaluation of b at an internal node of the graph will ideally require information only from nodes below that node, but not nodes above it or in other branches. Unfortunately, this ideal is not always satisfied; behavior in remote portions of the SSG will frequently have an impact on the internal node for which measures are being calculated.

Different measures, of course, will require different algorithms. Recall the two-CPU example from the last section:



If our measure is external availability, A_E we have A_E(CPU–1) = 0.0, A_E(CPU–2) = 1.0, and A_E(CPU–system) = 1.0. However, if our measure is internal availability (defined as percentage of total capacity), we have A_I(CPU–1) = 0.0, A_I(CPU–2) = 1.0, but A_I(CPU–system) = 0.5.

An additional complication may occur if a measure can be determined at an internal node of the SSG, but not at any subordinate nodes. As an example, consider a communication system made up of several distinct links, each of which is

[2]The opposite point of view is quite legitimate, but is outside the scope of this paper.

tracked for reliability. It may happen that noise on one of the links causes end-to-end communication failure, but (for some reason) we cannot determine which link actually failed.

Typically, any given user is concerned with only a portion of the full SSG. If you make no plots, for example, then the reliability of the plotter is uninteresting. For this user, we can construct a subgraph of the SSG known as a *view*. The view contains only those portions of the SSG that are required for the actions desired by this particular user. As was pointed out in an earlier paragraph, calculation of measure b for this view will generally require reference to portions of the SSG that are not in the view. Views that correspond to portions of the equipment being controlled are, of course, particularly important.

When constructing subgraphs for internal users, it is possible to create *artificial* users to represent critical portions of the SSG that are not visible externally, and that do not directly involve the equipment being controlled. For example, we could define such a user to represent a critically important portion of the communication system, in order to track the performance and reliability of this resource over time.

There are a number of advantages to the technique outlined in this section.

- It accounts for legitimate variations among the various users. Since each user receives a separate set of measurements, it is possible for Management to objectively detect users that are receiving inadequate service, and to direct scarce resources to improving the situation.
- System Management can examine trends for different users, and project these trends into the future. In this way, it should be possible to predict degradations in PAR before they occur (in many cases), and to take remedial action in a timely fashion.
- By considering the equipment being controlled as a type of user, we can use the same technique to isolate portions of the system that are critical to the real time control system. In an RT–PC system, we cannot afford to lose track of these areas!
- The method should be efficient computationally, since there will be large areas of the SSG in common among different users. With proper organization and preparation, much of the data collection and the calculation of measures can be automated. Note, however, the importance of planning.
- The concept is very flexible. It is easy to add new external users, to redefine views as the needs of a user change, and to add new artificial users to isolate and study portions of the system that suddenly become critical.
- By maintaining historical data on the SSG, one can perform retrospective studies as well. This can be useful, for example, in understanding the background of a newly emerging problem area.

2. A TYPICAL EXAMPLE

An example may clarify the discussion in the last section. This example consists of a network of Digital Equipment (DEC)[3] VAX computers that manage a large number of DEC microcomputers (LSI–11's) that control individual pieces of equipment. In this system, each LSI–11 devotes itself to controlling its own portion of the overall process, providing status information to the VAX network, and accepting commands from the VAXs.

[3]DEC, DECnet, DECserver, MicroVAX, and VAX are trademarks of Digital Equipment Corp. Ethernet is a trademark of Xerox Corp. XYPLEX is a trademark of Xyplex, Inc.

The VAXs are used to coordinate the activities of the LSI–11's, subject to internally programmed criteria and commands from operators. There are a number of operators, each responsible for some aspect of the equipment that is being controlled. The VAXs provide detailed or summary information to operators, and accept commands from operators; these commands may, in turn, result in further commands from VAXs to many microcomputers, subject to the programmed constraints already mentioned.

The hardware for this example is sketched in Figure 1, a simplified version of an actual network at LLNL. A portion of the SSG is shown in Figure 2. Detailed information about the various devices can be found in references [4–6]. This description is intended merely as an example of a typical real time system [7], not as characteristic of all RT–PC's.

The actual network from which this example was derived currently consists of three dozen microcomputers; twelve controlling VAXs; eight Ethernet cables connected together by repeaters and (in some cases) fiber optic lines; over thirty direct-coupled terminals, many with touch panels attached; and numerous disks, printers and other peripherals. In addition, there are several dozen other computers on the same Ethernet (with a wide variety of uses) and over 400 terminals attached via terminal servers.

3. PERFORMANCE MEASURES

3.1. Introduction

Performance modeling of computer systems has received a considerable amount of attention over the past decade or so, and remains an area of active research [8]. Most of this work is directed at two common problems: general purpose time sharing systems and communication systems [9]. Almost all of the theoretical studies and computer modeling programs are based on queueing network theory – and the current study is no exception. For an alternative approach based on Petri Nets, see [10].

The general approach to modeling performance of a computer system is, at least in theory, straightforward and well understood [11]. The first step is to understand the structure and dynamics of the system; this results in a characterization of the workload and a queueing model of the system activity. Once the model has been developed, it must be solved for measures of interest, such as response time and utilization of the different components and subsystems. The general approach for a RT–PC system follows this model, but with some differences in emphasis, as discussed in the next subsection.

3.2. Comparing Real–Time Systems to Other Types of Computer Systems

Real-time process-control (RT–PC) systems differ, in a number of areas important to modeling, from time-sharing (TSS), and communication (CS) systems. In some cases, these differences lead to an easier problem to solve; in others, the reverse. Note that these differences are matters of degree, not of kind, and that many of the statements made below are generalizations. The existence of exceptions should be understood, even where not stated explicitly.

- System Usage.
  - Modeling emphasis for TSS is, of course, on interactive and batch use of a central computer complex. Jobs are submitted to the computer from remote terminals and/or batch stations at the whim of the end user.
  - Modeling emphasis for CS is on message traffic over a network. For this kind of problem, the computers on the network are generally of interest only as sources and sinks for messages. Message generation and routing are at the discretion of the end users.

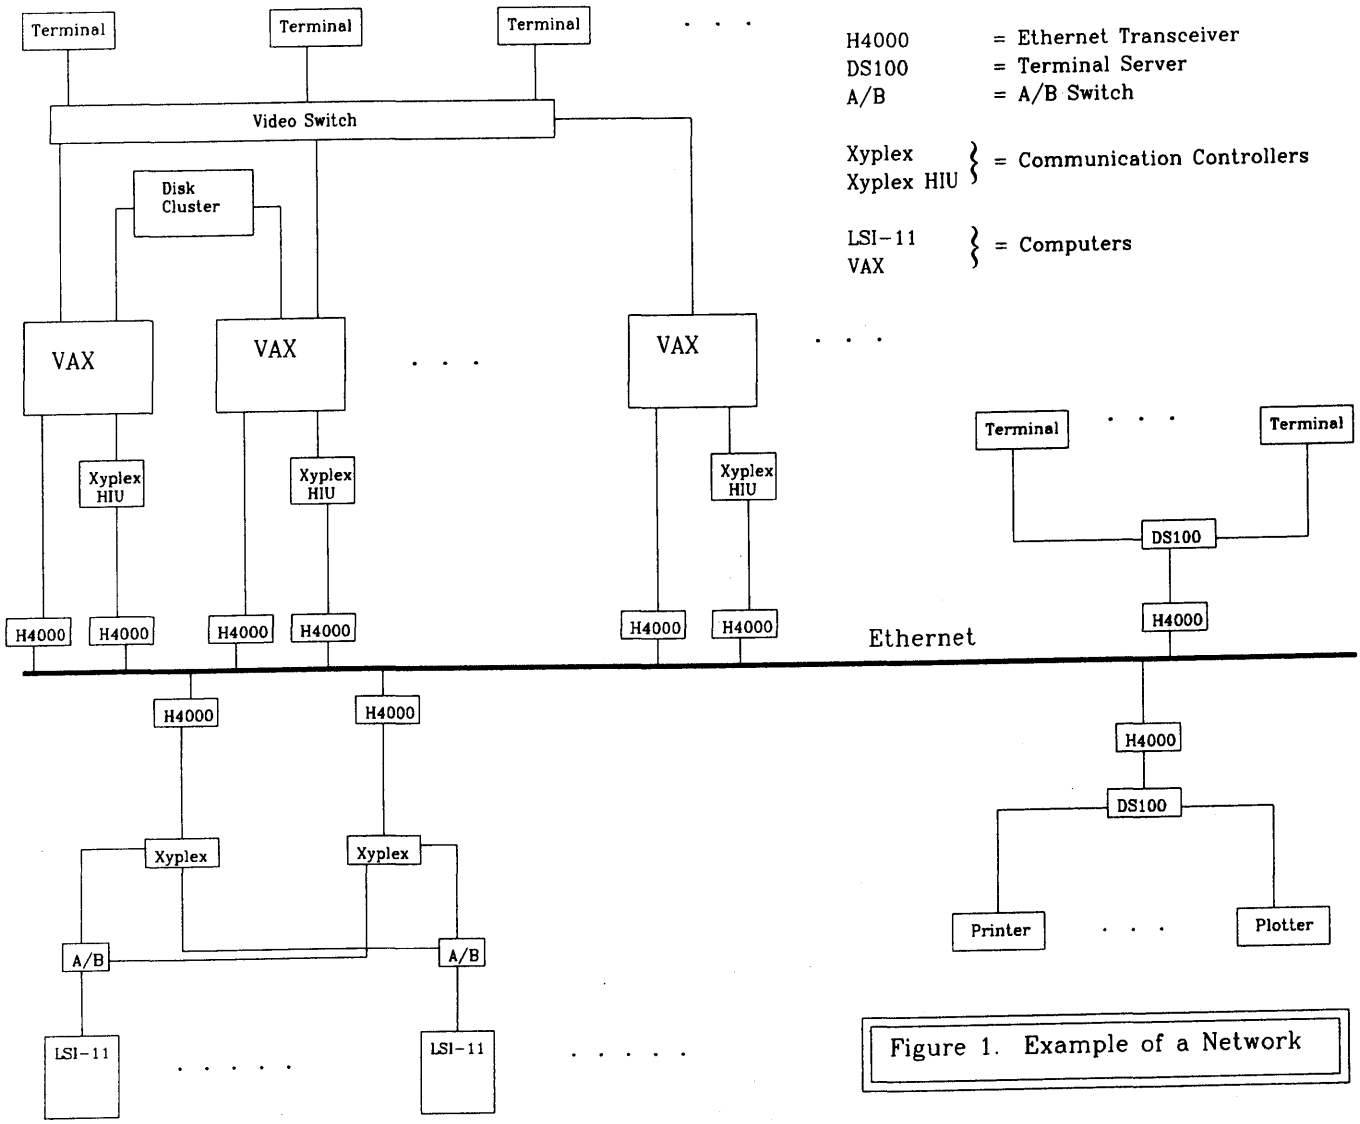


Figure 1. Example of a Network

– In a model of a RT–PC system, all aspects of the computer system are important. However, most of the actual programs run by the computer are fixed, and can be analyzed quite thoroughly.

System Structure.

– A standard TSS model is a single central CPU; I/O devices such as disks and tapes; and interaction devices such as terminals, card readers, and printers. This is sometimes referred to as the central server problem.

– A CS consists of a network connected to multiple CPUs and (possibly) terminals. The types of networks can range from local area networks, such as an Ethernet system, to very long range systems involving land lines and satellite communications. Arpanet is an example of the latter.

– A RT–PC problem of the type being considered here includes all of these aspects: multiple CPUs, possibly of different types; local area networks; analog and digital sensors and actuators; disks and (sometimes) tapes; terminals and other interactive devices, and (possibly) long range networks.

Time Span of Attention.

– Analysis of a TSS or CS system is generally aimed at long range averages. The model is designed to answer such questions as, "What is the average response time during peak hours of the day?" The unpredictable nature of the workload generally precludes detailed analysis, although this is sometimes of interest.

– Analysis of a RT–PC system is aimed much more at short range issues. The predictable nature of the workload, plus the necessity of keeping up with the equipment being controlled, make this both possible and necessary. A matter of particular concern is understanding the performance of the system during times when part of the system has failed, and during times of unusual stress from the underlying equipment.

Workload Characteristics.

– Workloads for TSS and CS problems tend to be both highly variable, and unpredictable in detail. This variability can be over a variety of time periods. For example, workloads tend to peak during certain periods of the day (say, 10 am to 4 pm), week (low weekend loads), month (end of the month processing), or year (tax time). Knowledge of such workloads is almost always statistical in nature.

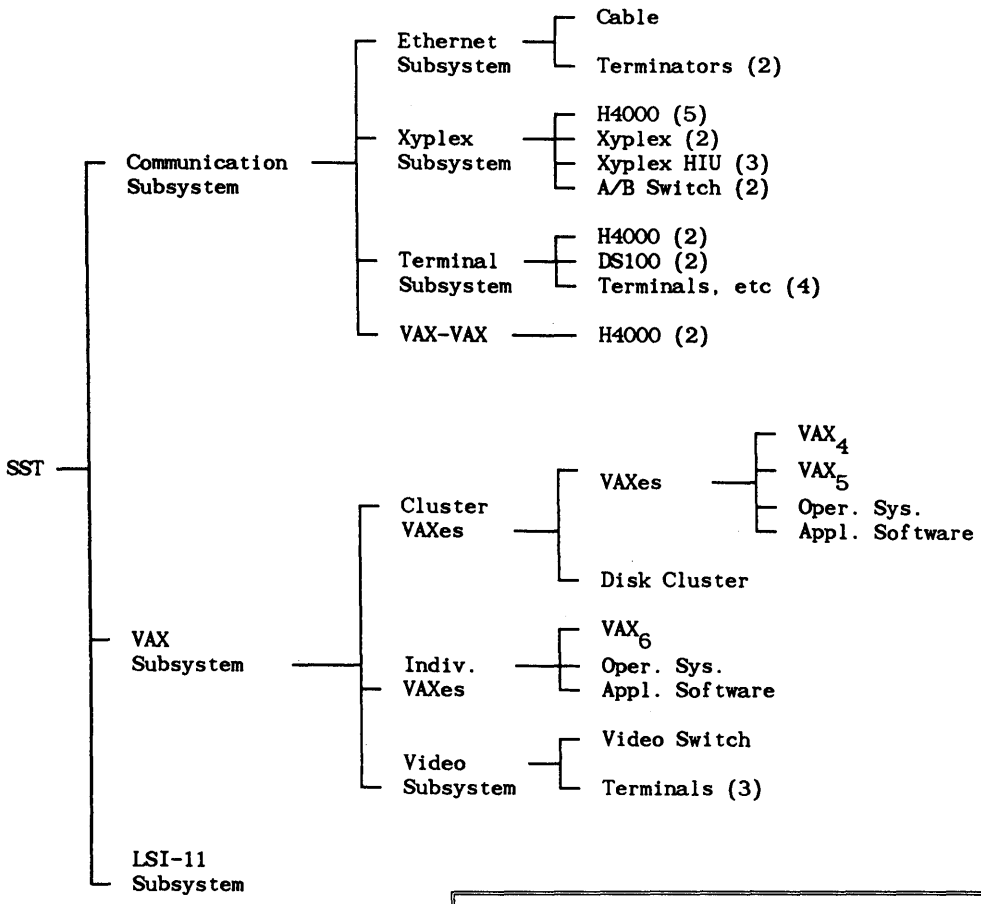

Figure 2. Example of a System Structure Graph

- Workloads for RT–PC systems frequently can be analyzed much more precisely. Any changes in workload will be caused by changes in the underlying equipment, by failures in some portion of the computer system, or by well-controlled changes to the computer hardware or software. Such changes can, therefore, frequently be predicted as precisely as necessary. In the extreme, one can look at the actual instructions of the various code modules.

- Type of Statistic.
  - Analyses of TSS and CS systems tend to be limited to means and variances of measured quantities.
  - Predictability is of prime importance in an RT–PC system. As a consequence, while means and (especially) variances are quite interesting, the analyst must be vitally concerned about worst-case behavior. The 90^{th} percentile may well be more useful than a mean.

3.3. Example

Let us examine some of the objects in Figure 1, in order to describe how performance might be measured.

- Ethernet. The primary measures of interest are: the number of collisions per unit of time, wait times (due to the detection of collisions and the binary exponential backoff algorithm used to schedule retransmission), and channel utilization [12–13]. Commercially available products exist for measuring traffic and collisions. Results can be used to create input to a modeling program such as PLANS [14–15], in order to estimate future loads.
- H4000 transceiver and A/B Switches. These devices are totally transparent to messages, and can therefore be completely ignored when analyzing performance. Note that this is not true when analyzing reliability.
- DS100 terminal server. This device has one connection to an H4000 and up to eight connections to serial devices such as terminals. Primary functions are: message buffering, speed adjustments, detecting and resolving Ethernet collisions, and format changes between streams of characters (to/from the serial devices) and Ethernet packets. If modeling is necessary at all, it is quite straightforward, and quite conventional.
- VAX. There is nothing conceptually unusual about building a model of a VAX, other than to say that the factors discussed in the last subsection must be considered. (This is not meant to imply that it is trivial.)

Once the performance of the individual hardware and software components is understood, we can use the SSG to construct more global models. Typically, a model can be developed at each internal node that represents the activity carried out at that node. Models developed for subordinate nodes can be included as "subroutines." The process continues until everything in the graph is included. At this point, the performance of the various views can be evaluated for the various users.

All this appears to involve quite a bit of work. Many models must be constructed, and various sorts of workloads analyzed. However, the models tend to be small, and the workloads would have to be analyzed in any case. As with many other problem areas (for example, writing computer programs), careful planning, formal design, and a subdivision of the problem into a hierarchy of sub-problems can lead to an elegant, efficient and manageable solution.

4. RELIABILITY MEASURES

4.1. Introduction

The difference between reliability and availability, and the importance of each, can be illustrated by an example. The drum of a cement mixer must be kept in rotation, or the cement mixture hardens, and a new vehicle must be purchased. As a consequence, reliability is an important consideration in purchasing decisions for cement mixers.

Now, suppose the vehicle is connected to Headquarters via a microwave radio. As the truck moves about the city, radio blind-spots are occasionally encountered; during these, transmission fades for a few seconds. You can see that this communication system has low reliability (in the order of minutes), but high availability, since dead times usually don't last long. If the radio is used only to give routing instructions to the driver, this may well be a cost effective means of communication, and would be preferred to one with high reliability (months) that cannot be fixed, so must be discarded upon failure.

But, suppose the rotation of the drum is controlled by the radio link. No signal, no rotation. For actually driving about the city, this is probably ok, since inertia will keep the drum going during the brief dead spots. But, what happens if the truck stops for a traffic signal in a blind spot? A more reliable communication system may be preferred!

A RT–PC computer system has attributes of both aspects of this example. The portion of the system that directly controls the equipment must generally have very high reliability and availability. However, if a sufficient number of terminals are available to the operators, no one terminal will have such stringent requirements. A database system that collects status information at periodic intervals could require high availability (so that the probability is high of being available when such an interval occurs), but not such high reliability (since the status information is not collected continually).

4.2. Problems in Determining Reliability and Availability

A number of difficulties arise in attempting to measure reliability and availability of any computer system, including RT–PC systems. Once again, the differences between TSS and CS systems on the one hand, and RT–PC systems on the other, are more a matter of emphasis than of kind. Standard methods of reliability block diagrams and fault tree analysis are useful [16]. See [17–18] for more detail on computer-related reliability issues. The problems listed here are representative.

- Transient failures are a significant problem. Longbottom [17] points out that about half of the failures in a computer system are transient. It is frequently difficult to isolate the cause (since all components will show correct behavior when tested); however, the system has failed, and this must be accounted for somewhere.

- It can be very difficult to trace the cause of some failures. A series of apparently unrelated errors may eventually (after days or weeks of effort) be traced to a single fault. A particularly difficult aspect of this involves interactions among hardware, software, operations personnel, and the immediate environment, since faults in any one of these areas can sometimes show up as errors in any other area.

- The statistical theory of reliability depends on a number of assumptions, some of which are not satisfied in computer systems. The effect of such violations on accurately calculating reliability and availability measures can be obscure.

  - All failures are assumed to be statistically independent. In fact, however, computer failures tend to bunch. That is, after one computer failure, there is a significantly increased probability of additional failures for a short period of time.

  - It is assumed that the operating times from all instances of a component can be combined in order to calculate total hours of operation and total number of failures.

  - It is assumed that operational hours can be measured with reasonable accuracy. For purely electronic components, this presents no particular problems. However, there are difficulties in defining "operational" for mixed electronic-mechanical components, such as tape drives and printers, and more severe difficulties for software. Is a printer operational when turned on, but not printing? Is a program operational when not being run?

  - The action of repairing a component is assumed to have no effect on future failure rates. That is, a repaired component can be considered new.

  - Finally, sufficient failures of each type of component are assumed to occur to permit a failure distribution to be calculated, or (at least) to determine if an exponential distribution is a reasonable hypothesis for a distribution function.

- It is not always obvious how to include environmental failures caused by events outside the computer system, such as electric power failure, or interference by unrelated computers that happen to share the network.

- Faults may be detected by many components within the man-machine system. For example: a computer operator detects an operating system crash, the operating system detects an error in a disk read command, an application program module notices that a value from a sensor is impossible, a communication module finds a parity error in a message, and so on. Fault detection is a distributed activity.

A common method of improving the reliability of a RT–PC system is to use fault tolerant techniques throughout the system [19]. The intent of such techniques is to improve the external reliability of the system, by removing as many single points of failure as possible. This, of course, adds considerably to the overall complexity of the system, and to its analysis. As a result of this, computer help is required in order to construct and analyze a reliability model [20]. One promising technique, which can be used to analyze and understand hardware, software, operational and environmental reliability is that of fault tree analysis [16, 21–22].

In a conventional computer or communication system which makes no attempt to tolerate faults, the impact of reliability on performance is pretty obvious. Once fault tolerance becomes an important aspect of the system, the problem becomes more complex. It is in the very nature of a fault tolerant system to hide failures from end users, although degraded performance may be permitted. As a result, the performance model should be augmented to account for failures of different devices. An example of this is given in [23].

The system structure graph, and its various user-dependent subgraphs, is a useful tool in organizing the collection and analysis of failure data. The occurrence of a fault can be attached to any node of the graph, not just the leaves. This is useful in those cases where an error is seen in some subsystem of the RT–PC system, but cannot be assigned to any particular component. For example, suppose a message must be sent from a control computer to an actuator attached to one of the embedded microcomputers in Figure 1. It doesn't arrive on time, due to collisions on the Ethernet; this is detected by the microcomputer, and an appropriate message is sent back to the controller. We have a fault, but no one component has failed. The *subsystem* has failed, and that's where the fault should be attached for reliability measurement.

In many cases, there will be too few instances of failure of a particular type of component to permit accurate prediction of component failure rates. However, it may well happen that enough failures occur in some subsystem that includes the component (as well as many more) to permit determination of a failure rate distribution for the subsystem. In this case, we can measure the MTBF for the subsystem, but cannot predict why the different failures will occur. Here, too, the SSG is a useful organizing tool.

4.3. Example

Many examples of reliability measurements have been given above; only a few are added here. If we examine Figure 1 in order to measure reliability and availability, we will notice a number of differences from Subsection 3.3.

- Ethernet and other cables. Possible sources for reliability problems include: broken cable, short circuits in devices connected to a cable, and radio frequency noise in the environment. (There are others, of course.) The first two are hard failures, while the last may well be transient. A broken cable will prevent message traffic, while the short circuit could show up as spurious messages. Even in a simple cable, a variety of problems can occur, with a variety of symptoms.

- H4000, A/B switches and DS100. These devices may fail, so a MTBF exists, and can be measured if enough failures occur.

- Application Software. As we all know, application programs occasionally fail. Depending on the nature of the failure, and on the recovery method being used, the failure may have little noticeable effect, the entire system may crash, or anything in between.

- Operators. There are two broad categories of operator failure: (1) the procedures which the operator is expected to follow are correct, but the operator does something else (for any of a number of good or bad reasons); or, (2) the procedures are incorrect, and the operator may or may not follow them. A particularly interesting problem here is the case where the operational procedures are wrong, the operator detects this fact, the operator carries out a correct procedure, and then fails to notify anyone of the error.

- Environment. The variety of ways that the environment can interact with our RT–PC system, coupled with the infrequency of most of them, can lead one to neglect this aspect of failure analysis. In some cases (such as an explosion that levels the plant), it is perfectly proper to ignore the environment. However, in many other cases, an environmental analysis should be included. This is particularly true for power failure or surges, broken pipes, fire, and so on.

5. CONCLUSIONS

We have presented a general technique for analyzing the performance and reliability of a real-time process-control computer system, and discussed some of the conceptual problems involved in analyzing such systems. The primary ideas expressed in the paper are:

- There exist a wide variety of (human, equipment and artificial) users, with very different requirements. An analysis of a RT–PC system must be prepared to recognize each of them.

- Reliability, availability and performance of a RT–PC system must be considered jointly.

- The system structure graph is a useful device for organizing the information and calculations necessary to measuring the performance, reliability and availability of a RT–PC system.

COMPREHENSIVE PROCESS FOR PROJECTING COMPUTER RESOURCES

John Wandzilak & Ray Murphy
Empire Blue Cross Blue Shield

ABSTRACT

The process used to predict computer resource requirements at Empire Blue Cross Blue Shield has evolved over the last eight years. It has proven to be a highly reliable and accurate methodology that drives our annually updated five year equipment plan. This paper offers in essence a "how to" approach to the computer resource planning process. Although the process was created in a health insurance corporation environment, the fundamental steps are applicable to all businesses. Figure 1 illustrates the necessary functions to support the process. Basically the process is 1) the translation of business indicators into related data processing workload demands, 2) the conversion of workload demands into alternative computing equipment configurations to meet service levels, 3) management approval of an equipment configuration based upon performance and financial considerations. The body of this paper follows the flow of Fig. 1.

BUSINESS FORECASTS

The first step is to develop a business forecast.

1. Generate business trends from a baseline of historical information for the past five years. The data should contain the basic profiles of marketing, operational and financial statistics. This data base will provide a ramp for launching future projections enabling the workload analyst to fully understand the inter-relationships of the business functions.

2. Some corporations have five year business plans indicating sales by product and area, production schedules, worker populations, etc. Such plans facilitate the business forecast. Unfortunately, many companies do not have long range quantifiable data. Quite often business plans are available only for the current budget year, but can form the bridge to an estimate for outer years.

3. In the absence of hard forecasting data, trends can be generated based upon the historical database. Industry trends, economic conditions, unquantified but stated corporate goals, budgeted projects and products that influence the shape of the business projections and their relationships must be understood.

4. Develop a model of the business based on the data collected. The model should be simple with only a few of the major business indicators. At Empire key business drivers are contract volumes by type, members per contract, and related claims volume. An analysis of this data is required to substantiate basic business relationships (e.g. claims volume do not necessarily linearly track contract size). It is vital to explore the effect of one business parameter on another.

5. Establish basic business assumptions, draft a numerical forecast, and then meet with the corporate business experts in marketing, finance and operating areas to validate the data.

6. Prepare a final draft of the business forecast.

WORKLOAD PROJECTIONS

The workload projection step is very similar to that of the business forecast.

1. Develop a baseline of data processing workload information. A five year historical file of data processing utilization metrics should contain:

   a) On-Line transactions

   By type, volume (prime and other shifts), response time

We use a customized software package to capture on-line transaction volumes by type, volume by response time, by hour of day. (See Fig. 2)

   b) CPU hours
   By application type, test and production, on-line and batch, by shift, by machine.

The CPU hours are collected by an accounting package which processes SMF daily logs. A key factor to the success of our workload forecasting process is the establishment and on-going control of appropriate job codes for each application, by production batch, production on-line, test batch, test on-line and support categories.

2. The creation of the resource utilization data base is followed by the difficult task of relating computing metrics to business drivers. Relationships are derived from the merging of the business data base with that of computer resources used for production functions:

   -business drivers to CPU hours, to on-line CPU hours, and to the number of on-line transactions.
   -on-line transactions to on-line CPU hours.

Fig. 3 shows how a particular type of claims volume e.g. medical claims relates to the CPU used in a batch mode by the medical claims system. Fig. 4 displays on-line transaction volume vs CPU time. These types of relationships need to be determined for every batch and on-line production system.

Relationships also need to be determined for testing. Although testing usage for a development project level varies greatly with the point of the project life cycle, maintenance efforts take on a more fixed relationship. Year after year we have concluded that the total envelope of testing utilization is related to population of application systems staff with adjustment for major high priority projects.

Figure 2.

3. We now can proceed with developing a future demand profile. Each on-line transaction volume is sized dependent upon the related business driver and adjusted for any anticipated increased functionality. Validation is accomplished through separate meetings with user area representatives and application systems project leaders by the workload analyst. Similarly, CPU hours are projected by sizing the impact of business drivers as well as system functionality. Changes to the computing environment, such as upgrades in CPU's which require the normalization of CPU hours, and new software (SNA moved some network functions and related CPU hours from the CPU to the communications controllers), must also be weighed. Test demands are estimated by reviewing near term and long term project schedules and staffing, and using historical data as benchmarks.

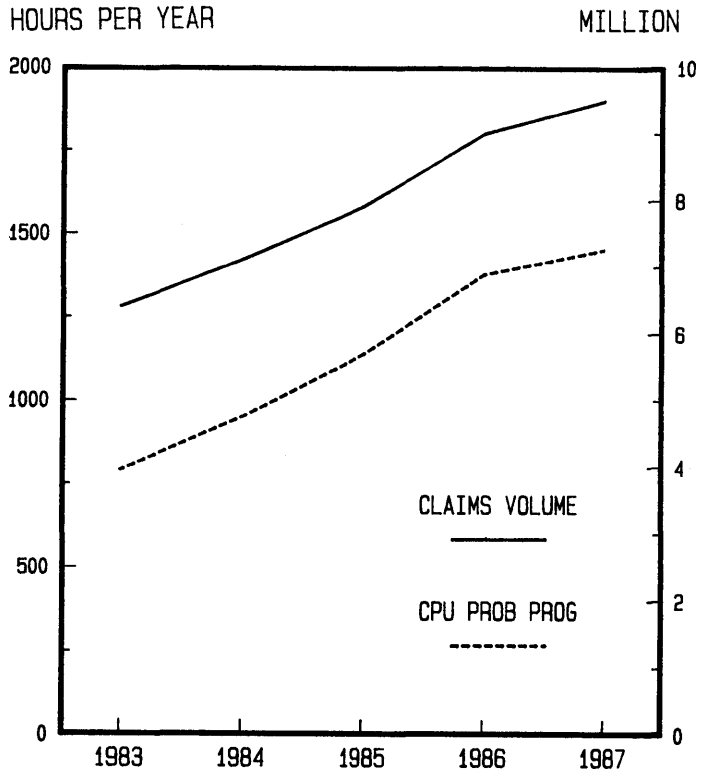
4. The workload forecast is then created by summarizing all of the details by category:

   - on-line production
   - batch production
   - on-line testing
   - batch testing
   - support e.g. technical services functions, quality assurance etc.

SERVICE LEVELS

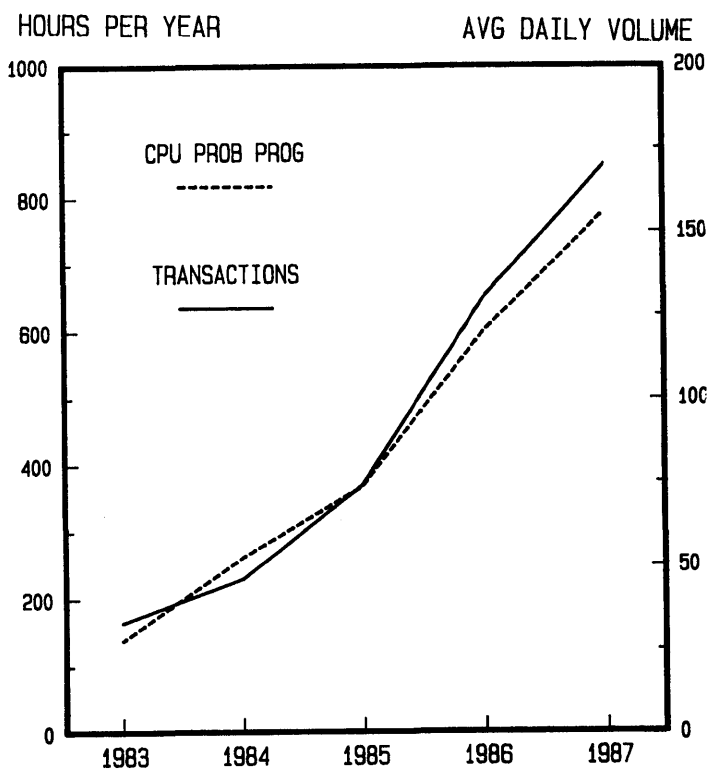
The projection of workloads based on accurate business and utilization data establishes a demand profile only at a particular service level. If on-line transaction levels are needed by the user community at a faster response time than currently experienced, then compliance with higher service level will change the demand profile. It is important to understand the details of all service changes. For instance, an increase in an on-line application's volume, functionality and/or service level may not have any impact if it occurs in the early evening. However, a small change during the prime shift may create significant service problems. A formal service level agreement (SLA) program is in effect with all of our major users. Service level performance vs goals are continuously monitored and the resulting data is used to form a basis for user/data processing performance reviews.

New service level requirements are incorporated into the overall demand profile.



MEDICALS CLAIMS VS MCS BATCH CPU

Figure 3.



MCS ON-LINE

Figure 4.

EQUIPMENT PLANNING PROCESS

Four different elements feed the development of alternatives for addressing the demand. The demand profile, as previously discussed provides a basis for determining future requirements. However, service levels, which are formally defined by SLA's, also influence the alternatives. Frequently, the service levels which are in place in current SLA's may not be adequate for the five year planning period. Improvements in service may be desirable (See Fig. 5) and, if so, must be factored into the demand profile at this point. (Any commitment to improve service over the planning period will by necessity increase the demand requirements). It is essential that service commitments which form the basis of the plan be agreed to by responsible senior management early in this process. The current workload must be broken down into classifications, and growth projected separately in each classification, to determine total requirements for the planning period (See Fig. 6). Finally, a technology forecast is undertaken. Each major processor vendor is contacted and discussions regarding present and future product plans are held. These directions are formally documented in the plan and become key in developing alternate processor schedules.

DEVELOPMENT OF ALTERNATIVES

At this point, demand projections and service level requirements are translated into peak period MIP requirements for each year of the planning period. The translation to peak requirements is key. While measurements and projections of demand are often made on a shift or 24 hour basis, the equipment must be configured to handle the demand of sustained 15 minute peaks in the 10:00 a.m. - 12:00 noon and 2:00 p.m. - 4:00 p.m. periods.

After peak MIP requirements are developed, (See Fig. 7), alternative processor strategies to meet this demand are generated. The technology forecast must be used to insure appropriate technological direction and proper use of vendor offerings in each strategy. Some basic criteria (cost, vendor viability, match with demand, etc.) are applied to reduce the number of alternatives to three which will be further evaluated.

MIPS REQUIREMENTS FOR IMPROVED SERVICE

(Alternative A, 1986-1991)

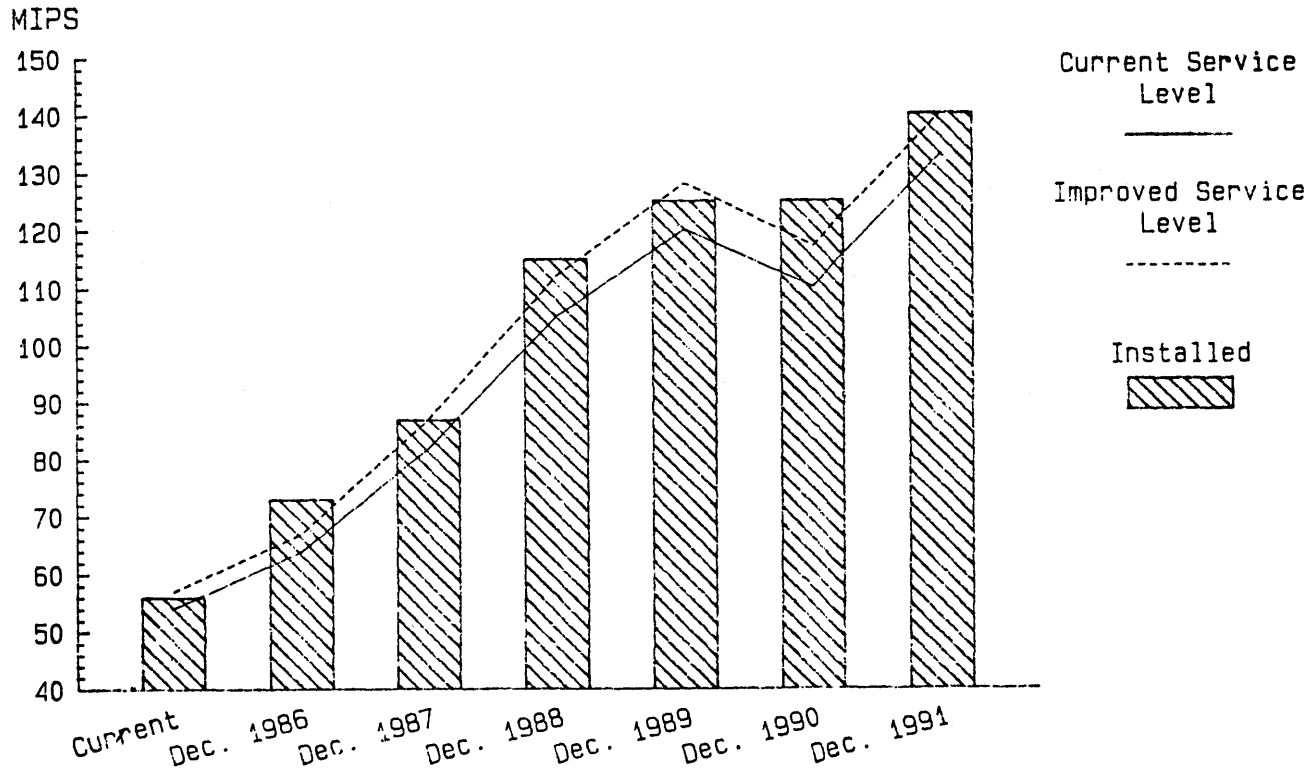


Figure 5.

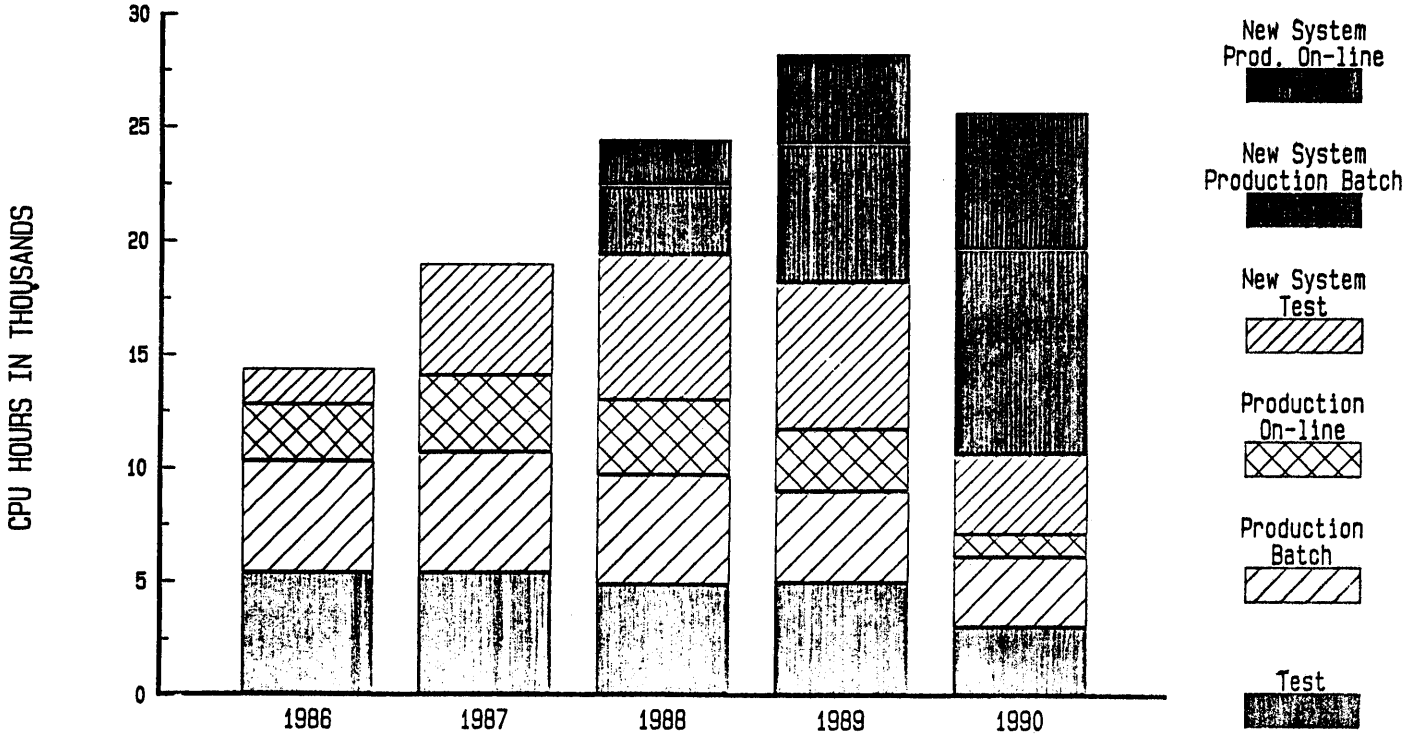

Figure 6.

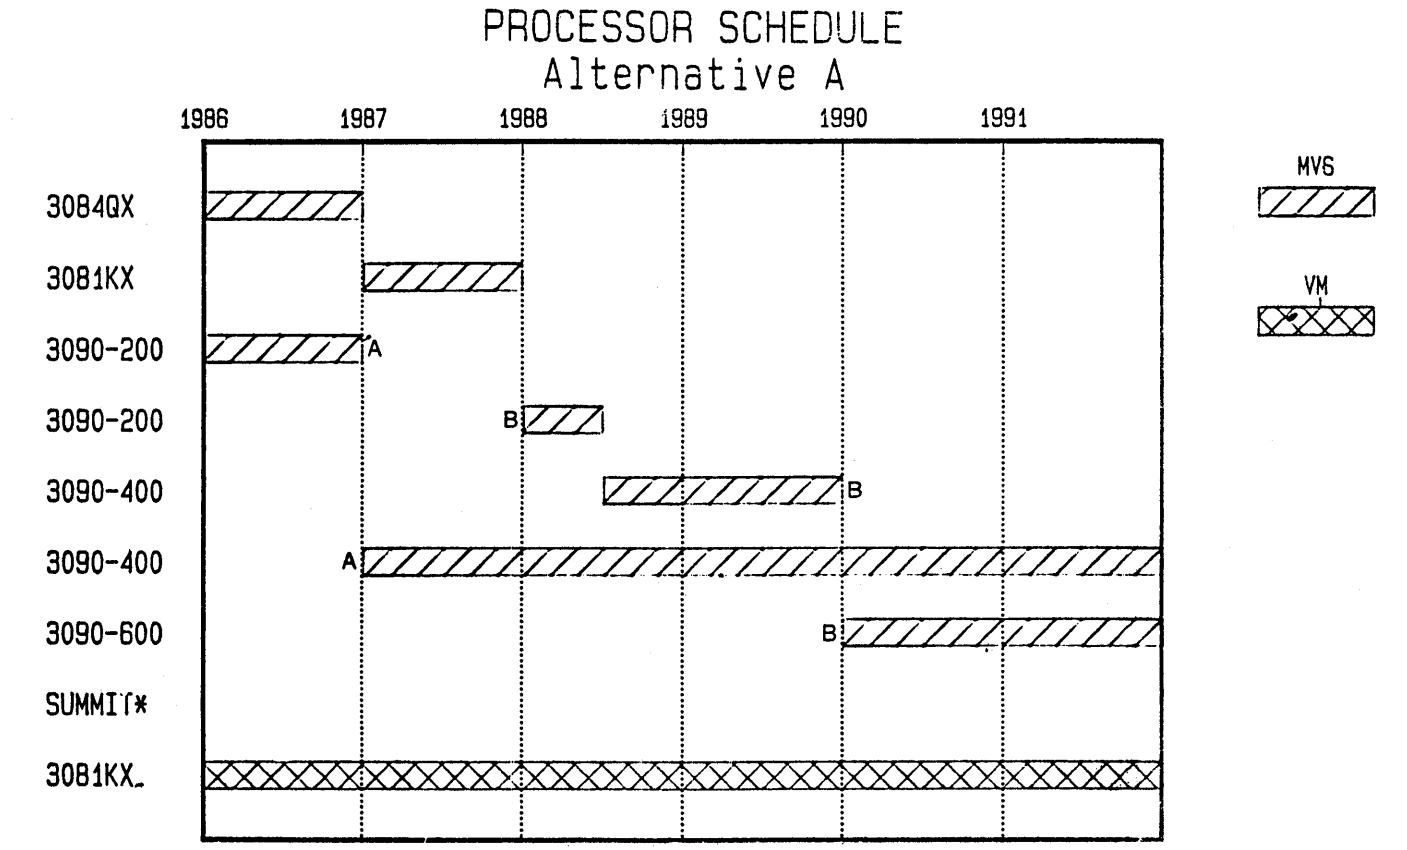

*SUMMIT is an IBM unannounced 90-100 MIPS processor; forecast in 12/91.

Figure 7.

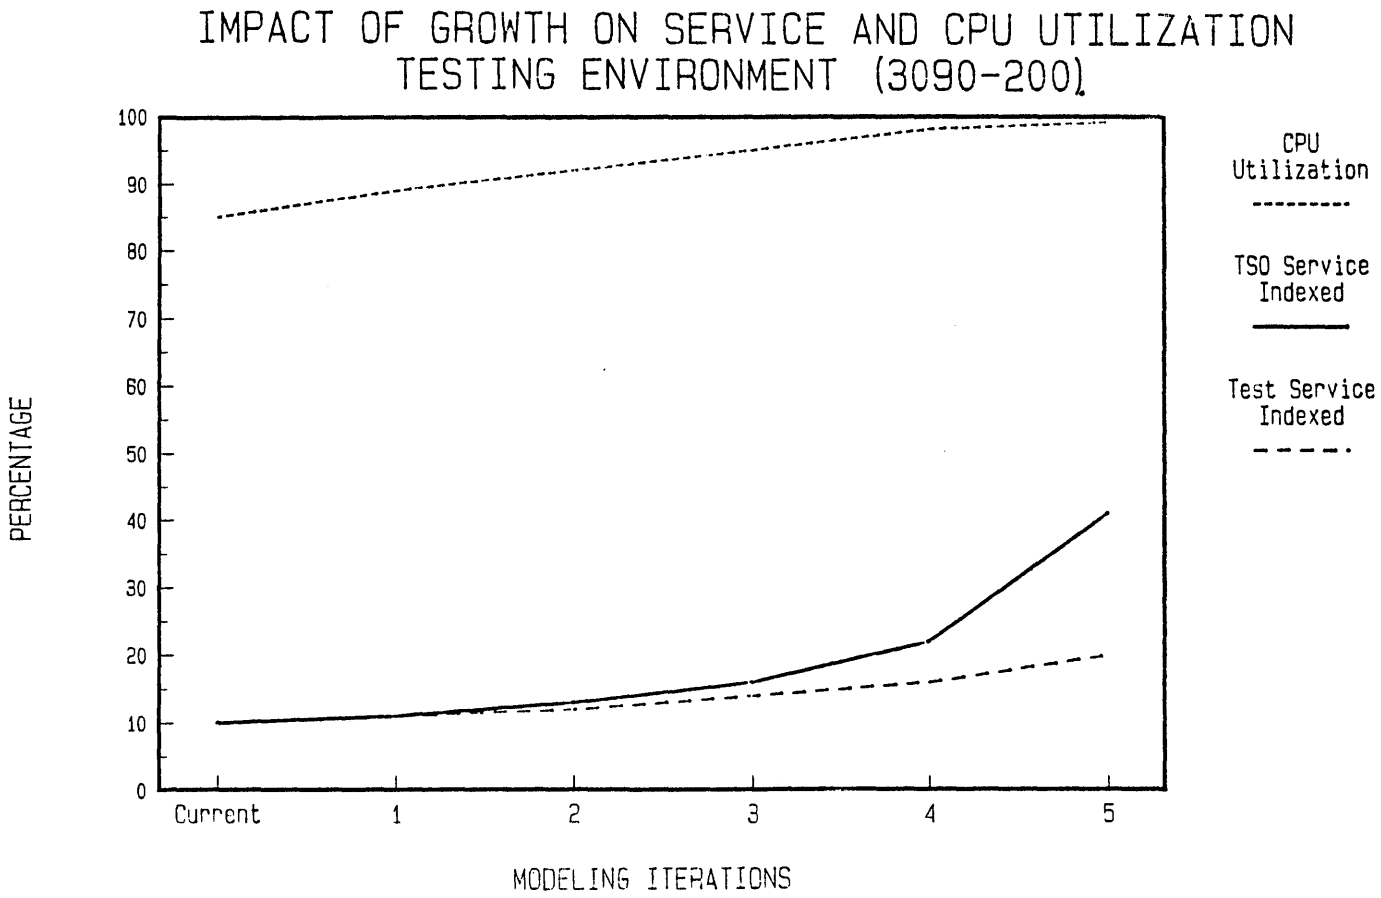

Figure 8.

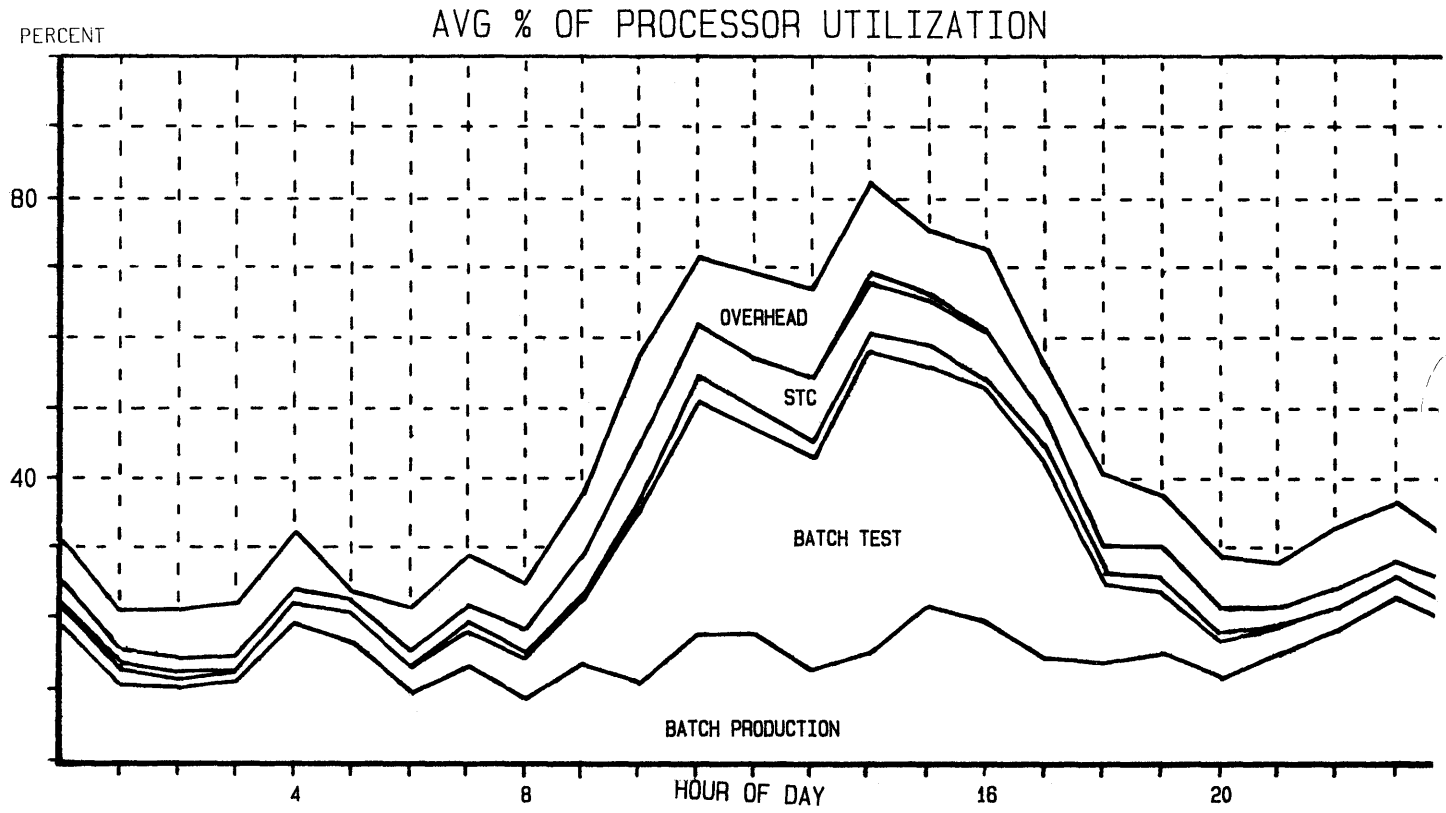

Figure 9.

PERFORMANCE MODELING

Parallel to the process of alternative generation, a model of the present computer systems environment should be built and calibrated. Each processor is modeled separately with the model reflecting current workload and utilization for these workloads.

After calibration, the workloads may be increased in 5% increments and the impact on service examined (See Fig. 8). The key service indicator for on-line services (TSO, CICS) is response time and for batch workloads it is relative elapsed time of the workload. In all cases, results are shown relative to today's service level. The modeling iterations can be done for the first 12-18 months of the planning period, depending on the growth curve. Steeper curves will introduce modeling inaccuracies earlier in the process. The models allow prediction of service levels for the early part of the plan period for each alternative. These become a key element in the formulation of a process recommendation.

FINANCIAL MODELING

In addition to service level projections, cost is the other element which has a major influence on the recommendation of an equipment strategy. All major equipment related cost elements (rent/lease, depreciation, maintenance, environmental cost, etc.) shall be factored into the cost model

Total costs for each alternative over the five year period are developed. Business realities dictate that both the total five year cost and the subsequent year budget cost are equally important in determining cost effectiveness. Both of these figures must be analyzed in determining the alternative to recommend to management.

RECOMMENDATION AND APPROVAL

Although the process of selecting the alternative is somewhat subjective, the availability of concrete data regarding service impact, cost and technological fitness, clarifies the decision making process. The next step is the presentation to senior management. Success can be achieved by structuring the presentation consistent with the steps in this paper. By beginning with business requirements, deriving the demand forecast, noting current status, service impact and cost for each alternative, and concluding with a recommendation, a direct link between business requirements and the equipment plan can be shown. Through this link, final approval by senior management can be achieved.

MONITORING

The development of a new five year plan is a yearly occurrence but the monitoring of the process is ongoing. The objective of the process is to ensure that the enterprise achieves expected levels of service. Performance is measured against service agreement goals each day; response time by type of transaction, on-time output delivery by individual report, availability of computing hardware, network and software components. The service is reviewed weekly with Senior EDP Management. Fig. 9 shows workload by category over a 24 hour monitoring period. Business drivers are analyzed monthly in terms of contracts, claims volumes, new products and regulations. The forecast of individual business indicators, transaction volumes and CPU utilization by application, are reviewed quarterly against actual data. Deviations from projections are explained.

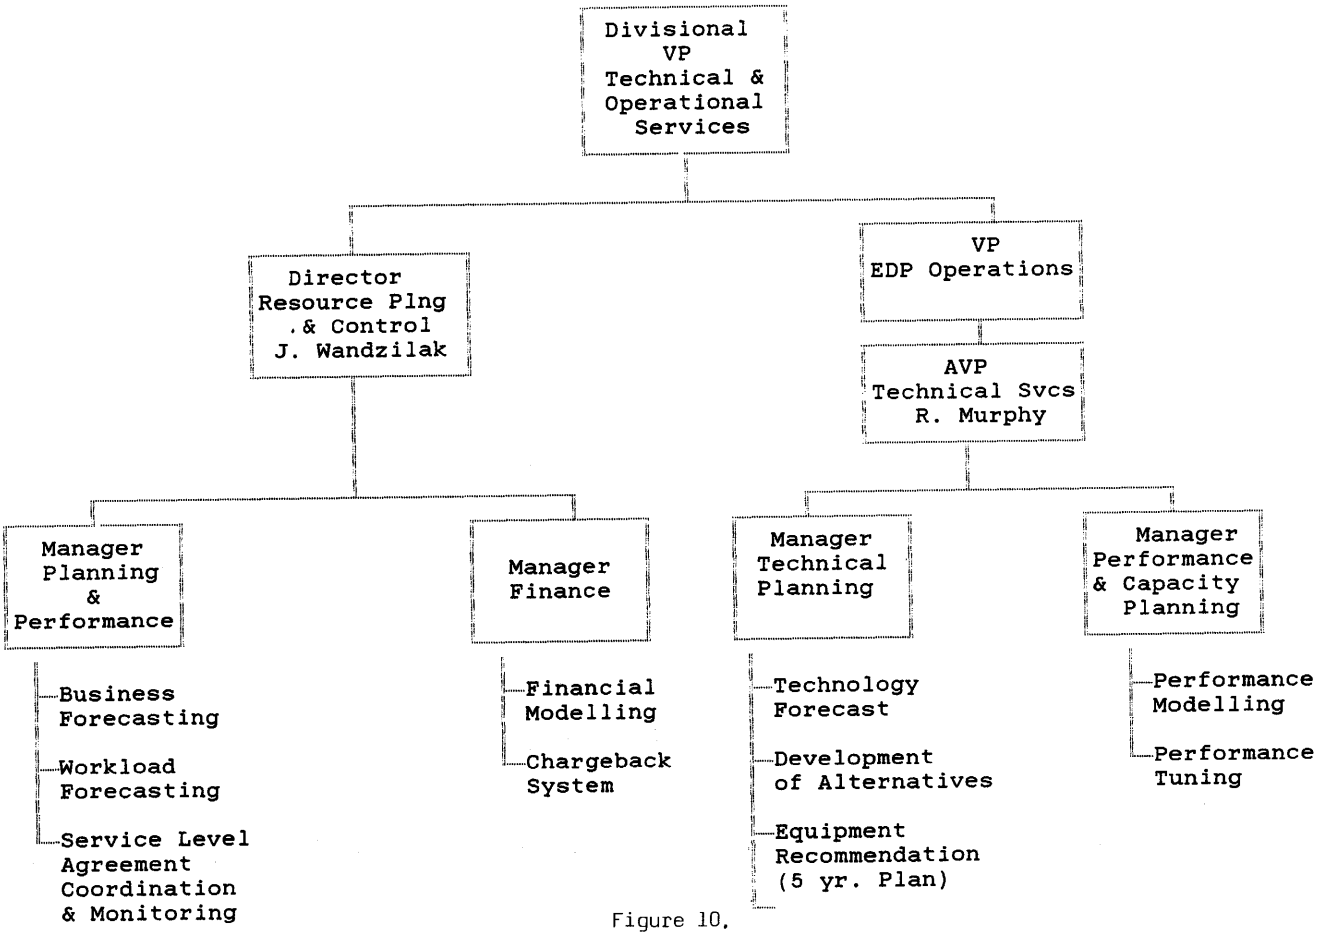

Figure 10.

ORGANIZATION & PERSONNEL

The organization of personnel to administer the aforementioned process is structured as shown in Fig. 10. The organization chart only shows the chain of command related to this paper, as are the functions identified next to the organizational unit. The responsibilities for the process are divided between the Resource Planning and Control group and the Technical Services area. In addition to the authors, approximately three analysts from each area are engaged in the computer resource projection process. The process starts in February and concludes before the July budgeting process for the following year.

RESULTS & SUMMARY

The results of our process for the past 4 years are shown in Figures 11 and 12. The business forecast, with claims volume as the major drivers, has been predicted within 3% of actual experience. The projections of On-line production transaction volumes have been within 5% of actual amounts. See Fig. 11. CPU hours are shown in bar graph form in Fig. 12 and show predications within a range of 1.5 to 9.5% of actual.

In summary, we have found a very detailed "grass roots" workload forecasting technique coupled with a rigorous performance and equipment capacity modeling process to yield dependable results for generating computer resource plans. We recommend this process to other planners not only for its reliability, but also as a technique to give management visibility to technical planning in business terms.

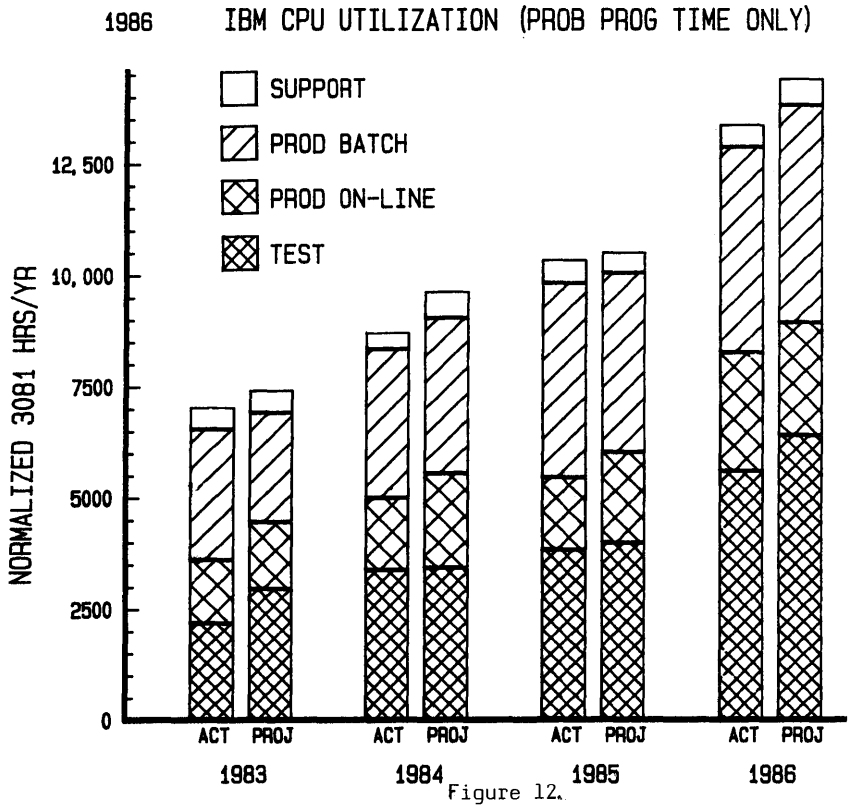

Figure 12.

CAPACITY PLANNING AS A BUSINESS PROCESS

Jerry L. Rosenberg
SRM Associates, Ltd.

ABSTRACT

It is becoming more apparent to capacity planners that they can no longer accomplish their jobs from the relative safety of the Data Processing community. Granted, it is less threatening to deal in jargon that we know, with people to whom we can easily relate, and in concepts with which we are readily conversant. That is exactly what we have historically done. But while we have been gathering data on I/O's per second and paging rates, data processing has grown into a major component of our enterprise. In fact, if management is totally honest, they will admit that the corporation can no longer function without data processing support. Because of this, corporate management is very concerned with understanding how they can best utilize "computing" to meet their goals and needs. Capacity planning should be the process that supplies these insights. This can only be accomplished if capacity planning is structured as a business process and not just a data processing function.

This paper will highlight the steps that should be taken to convert capacity planning into a viable corporate process. To accomplish this, we will be concerned with a method of defining the reasonable goals and expectations that the corporation should have for capacity planning. And just to be fair, we will review those goals and expectations that capacity planners should have of the corporation. These will include data requirements, time frames, support structures, and reporting needs. Of major impact will be the ever-present underlying requirement to understand and relate to the corporate "bottom line".

Introduction

Most Capacity Planners have accepted the fact that the process that they are engaged in must evolve into a business based function. This has been evidenced by discussions over the past several years concerning such items as Natural Forecasting Units (NFU) and Key Volume Indicators (KVI). It should be safe then to make the assumption that we are committed to posturing capacity management as a viable contributing component of the overall corporate entity. The author believes that any capacity planner that does not follow this path will find it increasingly more difficult to function effectively over the next few years. Given this first premise, it safe to also assume that we accept the requirement of understanding the rudiments of the industry in which our individual corporations are engaged. This knowledge should help us to identify those business elements of the industry that can effect the utilization of data processing resources.

These two issues: incorporating business concepts into capacity planning; and making capacity planning more responsive and useful to the corporation through the development of KVI's and NFU's, have been discussed over the past decade. The problem is that many of us are no closer to implementing them than we were ten years ago.

Since we have opened the door just a crack and let in some non-technical, non-data processing thoughts, perhaps it will not be considered too radical to suggest that we actually take a lesson from the business side of the company in structuring the foundation of a better capacity management process. In the strictest sense, data processing can be viewed as a business with a customer base and a deliverable product and/or service. This is equally true for the sub-component of data processing that we call capacity management. The establishment or advancement of this process should therefore be enhanced by the application of proven techniques from the general business community.

A Business Approach

In the sectors of the company that deal with the delivery of products to our ultimate customer base, there are definite guidelines for approaching the introduction of a new product or the major modification of an existing one. The first step is most often an analysis of the potential market to gauge the needs and interests of the customers. This concept of "market research", and its application to capacity planning, could help to supply us with some insights into the creation of a methodology that is more responsive to the needs of the corporation.

Define The Product

Any good market analysis must begin by establishing a concrete understanding of the product being offered. In our case, the service that is supplied by capacity planning is typically defined as:

The process required to ensure an environment with sufficient resources to deliver satisfactory service in a cost-effective manner.

There have been numerous volumes written on the expansion of this definition and the enumeration of all the component tasks that must be addressed, from workload characterization to management reporting. These issues are very important but are not the subject of this investigation. We are going to delve into this definition from the standpoint of what it can tell us about our potential market.

Define The Customer Base

In reviewing the definition, we can extract at least three specific areas of concern. "Sufficient resources" suggests CPU's, I/O devices, channels, network components, memory, etc. These are all within the province of the data processing departments of the company. "Satisfactory service" implies response times, transactions per hour, claims per day, accounts processed, customers serviced, etc. and relate to the end users of DP services. These are generally the operating departments that perform the actual functions of the company. "Cost-effective" is measured by return on investment, budget, fiscal strategy, etc. and are usually the concerns of the "executive branch" of the organization.

By reviewing the definition of the "product" that we are contemplating, we have identified three distinct customer types that we must satisfy. Each has a

different requirement from the process that we are developing. Graphically, we can consider this situation as follows:

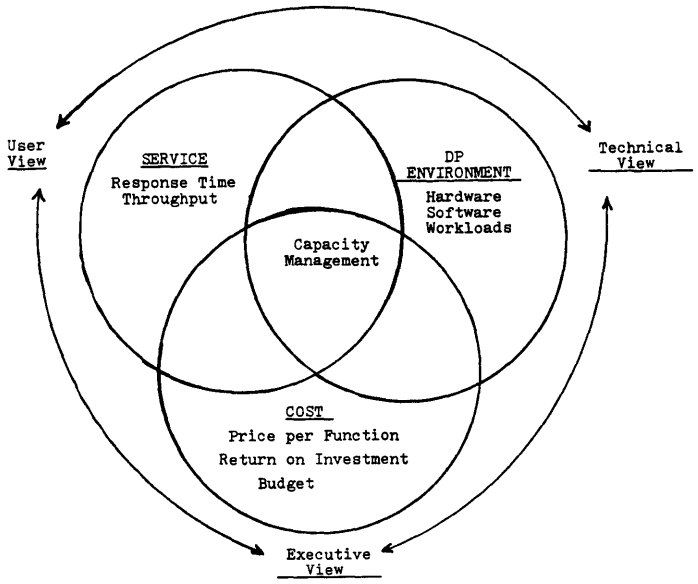

FIGURE 1

As seen, this illustration highlights three different views of capacity management; each with different needs, expectations, goals and resources. These are, in fact, the three major "customer types" for the capacity management process. In order to perform a market survey, we need to analyze each of these market segments, understand it in relation to the process and define the best approach to meet their singular and collective requirements.

Keep in mind that this is a very simplified view of reality. There are undoubtedly, in each corporation, many more subdivisions than these. For example, within the user community, there are executives as well who have different needs than line users. Also, within the data processing area we have executives and users in the form of TSO and CMS applications developers who need service to perform their jobs. Each list of "customers" will be slighty different. It should represent the clusters of homogeneous users who require capacity management support. For the sake of illustrating the process, we will work with these three broad catagories.

The Analysis

The "market research" activity should be viewed as an orderly progression that helps us to build a capacity management process that is useful to the organization by being beneficial to the segments that make up the corporation. In order to accomplish this task, we need only follow some simple steps:

1. Define the customer segments
2. Develop a "Concerns Inventory"
3. Expand these into a "Reduction Matrix"
4. Prioritize the resulting tasks
5. Proceed with the tasks

Since I am sure that this is not crystal clear at this point, let's explain each step.

1. Define the Customer Segments

As stated above, we must identify those groups in the corporation that require the services of capacity management. In the example, we will be considering the simplified case of a three segment environment - users, DP, and executives.

+ USERS

These are the people who depend on DP to provide them with services in support of their own corporate functions. They generally include a wide variety of business functions from payroll to engineering design. They all share some common requirements from data processing: accurate results that are available in a timely, reliable, cost-effective manner. They all desire as much service and functionality as possible.

+ DATA PROCESSING

This is the community that must establish and maintain the environment that supports the users in the manner that they require. In many instances, the "requirement" is actually different from the level "desired" by the users. As a result, one of the functions of the process will have to be the reconciliation of user desire to DP capability. In order to meet as many requests as possible, DP wants as much state-of-the-art hardware and software as it can get.

+ EXECUTIVES

This group is concerned with the overall goals of the corporation. They are faced with balancing the need for expanded capabilty and functionality against the budgetary bottom-line. They need to be convinced that expenditures will have a long-term return on investment.

These are the three segments that we will be addressing in our example. The danger in this approach of segregating customers is in falling prey to the belief that an adversary relationship needs to exist between these groups. This need not be the case. Unfortunately, it has become the status quo in many organizations. Our goal is to enhance the activities of the entire enterprise. Capacity management must be approached as a vehicle for helping each component work best in the common interest.

2. Develop a Concerns Inventory

This task requires the itemization of those detailed points that need to be researched within each customer segment to insure a sound process. While there may be some additions for specific environments, a reasonable starting point would include:

+ Expectations

What does each customer think he should be getting from the capacity management function? In a market survey for a new product, this activity would require the use of questionnaires and interviews. This same methodology should be utilized to obtain all of the information needed. It is impossible to develop a product to meet the needs of the community at large unless you find out what they really want.

For each segment, list those items that are critical to the performance of their respective functions. This task should yield some insight into the groups "measure of success". In short, how does this group know that it is doing well. This can be measured quantifiably in number of claims processed or items delivered or it can be more subjective, such as "met budgetary goals". In any case, it will help us to determine the "bottom line" for each user community and help us to develop a process that best serves these needs.

+ Inputs to the Process
Itemize the specific input sources needed in the capacity management process that are available from each segment. The information in this area should include the specific source, the type of data, its use in capacity planning, the storage medium (hardcopy, DASD, tape, word of mouth, etc.), and the time frames associated with data availability and updates.

+ Committments/Communications
The key personnel in each group should be identified and the level of committment required to insure cooperation from all parties must be clearly delineated. Without committment and cooperation, the capacity management effort is doomed to failure. Since the process is very dependent on a strong degree of inter-departmental cooperation, each segment must be "in step" during the establishment and maintenence of the process.

In order to insure the on-going viability of the methodology, the lines of communications should be clearly defined. An aid to understanding the "channels" is to obtain an up-to-date organizational chart.

+ Benefits/Opportunities
Remembering that we are conducting a business-like market study, let's continue the analogy to its likely conclusion. Eventually, we are going to have to sell our product. In order to ensure that we can accomplish this goal, it is highly advisable to list all of the potential benefits to be derived by our customers. The primary advantage is that we can eventually use this information to convince reluctant customers to subscribe to our process. It is often helpful to make people feel that they are active contributors to the development of the process. As a secondary dividend, in listing the benefits to users we might uncover some additional report or service that we can provide that enhances that value of the function. Even if we cannot easily include these capabilities now, they can be considered for later enhancements or additions.

+ Timeframes
For any issues that have a time dependency, notations must be made and related to the process. Late delivery is often worse than no delivery. It is also embarrassing to promise delivery of a report that requires data that is not available until after the report date. It is vital that the process be built around these time constraints.

+ Deliverables
As a result of producing entries in each of the above areas, we should be able to develop a list of expected outputs that meet the needs of the customer base. Effectively, we are distilling all the requests into a series of manageable end products.

+ Limitations
Also as result of the analysis of all the above, we should list all of the concerns that cannot be addressed at this time with reasons and ultimate solutions. This section will help to direct future activities and will also help you to answer the customer who asks "why not?".

* Summary of Matrix

It should be apparent that a series of interviews and questionnaires are required to accumulate the points that make up the matrix. This approach does not eliminate the need to talk to the customers. In fact it is dependent on it. What we hope this procedure will provide is a means of summarizing the acquired data into a manageable format.

It is often of interest for the analyst to anticipate the contents of the matrix before beginning the data acquisition phase. Comparing the initial guesses with the final results can be used as a measure of how well the capacity planner understands the business and the user community. Of course it is important not to allow our initial belief to cloud the objectivity required in the interview process.

3. Expand these into an "Analysis Matrix"

Given the results of a reasonable interview process, we can now use the matrix to reduce the data into summary format. At that point, we will be able to summarize each row and column to obtain a list of tasks.

In our particular example, the matrix will appear as follows:

	USERS	DP	EXECS	SUMMARY
Expectations				
Inputs				
Commitment				
Benefits				
Timeframes				
Deliverables				
Limitations				

As previously mentioned, this matrix is not all inclusive and should be used as a framework for customizing a set of concerns for each specific environment. Often the development of this matrix will help to uncover other unique concerns within your organization that should be specifically included and addressed. As an example, we will be filling in this matrix later in the paper to illustrate the process.

4. Prioritize the Resulting Tasks

Once the matrix has been developed and the data acquired has been summarized into it, a review of the right most column and the bottom two rows (Summary, Deliverables, and Limitations) should easily result in the production of a list of tasks. Essentially what we are doing is using the matrix format to simplify the analysis. By reviewing each row, we should be able to develop a summary for that key item. By doing the same for each column, a list of desires and requirements from each user group shoud evolve. The intersect of these processes should yield the two boxes at the lower right of the matrix that have the distilled information that we need.

The capacity planner will now be able to discern the relative priority of each task dependent, of course, on the appropriate scheme in vogue in your corporation. Some of the more common prioritization techniques are: Technical value, Monetary concerns, Delivery of service, The highest ranking person always gets his way, etc. In point of fact, the system in place is usually some combination of the above. Since I don't have enough time or paper to cover the topic of the political realities of the business world, all I can say is - be alert and best of luck with this one.

5. Proceed with the Tasks

Having a prioritized list of tasks should help in keeping the process on track. Before you proceed , it is a good idea to review this with some of the customers who supplied the information (particulary those identified in the Committment section). This allows us to verify that we correctly interpreted the data we received.

* Summary of the Process

The key rationale for utilizing this, or any other technique, is to establish and maintain a perspective of the task at hand. Following this approach will force the analyst to proceed in an orderly pattern through the steps of data collection, reduction, analysis and result formulation.

The technique employs a standard business approach of surveying users concerning critical issues to help produce the most effective product. In this case, the product is a capacity management process that will be most responsive to the business needs of the enterprise. In order to step through the matrix, the analyst will conduct meaningful discussions with other departments in the corporation that will make him aware of the business of the corporation. In addition, he will discover the goals and needs of computer users, critical time considerations, available data sources, financial concerns and political realities. If he absorbs only a portion of these items, he will be much more valuable in his function as a capcity planner.

Matrix Example

In order to best illustrate how this matrix format can help to summarize data from seemingly disparate customer types, we will complete the matrix already used as an example.

Let us assume that we have distributed questionnaires that asked for clarification of the issues that we identified on the matrix. As a result of the responses to these inquiries, we followed up with interviews of several key persons in each community.

Due to lack of a spread sheet format in the proceedings, we will view the matrix one column at a time.

	USERS
Expectations	+ Understanding of resource comsumption by activity. For example, what resources are needed to process a particular function? + Accurate measures of service. How do we report response and delivery? + Clear service level agreements
Inputs	+ Projected volumes + Business plans + Details of anticipated new applications
Commitment	This segment will contain a list of key personnel that would be interviewed in detail.
Benefits	+ Better service + Better information for service level negotiations + Insights into scheduling + Information for the budget process
Timeframes	+ Volume schedules + New application schedules + Output delivery times + Response time needs

Perhaps as a result of reviewing this column, we could summarize as follows:

Deliverables	+ Reports related to service level delivery and cost of service
Limitations	+ We need to acquire data related to: -Business plans -Application plans

Let's move on to the next column:

	DP
Expectations	+ Utilization breakdowns by worlkoad + Future hardward and software needs + Bottleneck determinations + Clear service level agreements
Inputs	+ Classical monitor data + Technical information + DP plans
Commitment	This segment will contain a list of key personnel that would be interviewed in detail.
Benefits	+ System tuning + Adequate resources to meet user needs + Tracking methodology
Timeframes	+ Peak periods + Due out constraints + Workload overlaps

Perhaps as a result of reviewing this column, we could summarize as follows:

Deliverables	+ Workload characterizations + Reports on: Service by Workload Bottlenecks Future h/w needs
Limitations	+ Data may not be available readily for specific subsystems, i.e., CICS

We're ready to view the last column:

	EXECS
Expectations	+ Breakdown by line of business + Cost of DP by type + Optimal solutions to DP service
Inputs	+ Corporate plans + New lines of business + Potential legislative impacts
Commitment	This segment will contain a list of key personnel that would be interviewed in detail.
Benefits	+ Cost effectiveness + Return on investment analysis + Budgetary insights
Timeframes	+ Schedules for corporate planning process + Budgetary timelines
Deliverables	+ Reports on: Cost of DP Future alternatives with costs
Limitations	+ We need access to corporate plans, budgetary issues, state of the industry data, etc.

As a result of these three columns, we might summarize this way:

	SUMMARY
Expectations	+ Need to develop requirements by workload with associated costs + Must address the area of NFU's and KVI's
Inputs	+ Data is required from SMF/RMF, other subsystem monitors (CICS, IMS, etc.) + In addition, we need non-monitor data related to business volumes and plans
Commitment	This segment will contain a list of key personnel that would be interviewed in detail.
Benefits	+ Here we would detail how the process could be sold in each area
Timeframes	+ Here we would summarize the time requirements specific to each area

Based on this sample matrix (which has been kept very brief for the sake of discussion), the following tasks might be listed:

- Establish procedures for collecting and analyzing existing utilization data;
- Investigate and implement a monitoring tool for the requisite subsystems (CICS, IMS, Data Base);
- Regularly acquire and review both corporate and user department planning documents;
- Develop the relationship between business elements and DP usage. Establish a "cost per element"; and
- Design and publish reports that address the delivery of service both currently and in the future. Develop models that are capable of anticipating future system performance.

This list is by no means complete. Each item can be expanded into many sub-components. It should, however, be clear that involving the "customers" in the development effort will allow for a process that is more sensitive to their needs. The basic benefits of following this approach are:

- The involvement of all areas of the corporation in the development of the capacity management process will help insure support in the endeavor;
- It supplies a format for reducing and managing volumes of data into a few pages; and
- It supports a methodology for highlighting the critical tasks that must be performed to make the process successful.

Perhaps this is a good time to suggest the use of another business technique. Before you invest a lot of time and effort in the process, use the concept of "test markets" to see how well your product will be received. Start small and use the reactions that you get to help improve the output.

General Comments

Since we are interested in bringing capacity management into the mainstream of "the business enterprise", it is important that we always conduct qurselves in a business-like manner. To achieve this goal here are some general rules of thumb to keeep in mind:

- Know Your Customers

In a broader sense, know what your company does for a living. Unless you have this ubderstanding, it will be very difficult to relate to the needs of each segment of the company. This may require that the analyst occassionally review trade publications and establish relationships with peers in non-DP functions within the organization.

Optimally, this will be a two way process in which you will learn about the "business" and will help to educate others in the value of DP. It is also important to understand the organizational structure and the corporate decision making process. This will assist the capacity planner in determining the best point in the company to present information for optimal results.

- Satisfy Your Customer

This is an age-old axiom in business which still holds true. In the process of knowing your customers , it is key that you gain insight into his needs and requirements. Success is tied to satisfying those needs. As a part of satisfying the customer, concerns such as timeliness, accuracy, reliability and cost must be addressed.

- Gain the Customer's Confidence Through Positive Achievements

Nothing succeeds like success. Take a positive attitude and approach to performing your tasks. Exert some effort in trying to help the organization derive the maximum utilization from available resources. Develop an effective reporting system. Suggest alternatives that eliminate bottlenecks. Prove that the capacity management function is worth the investment. And do it in a positive cooperative manner.

- Present Multiple Solutions

Whenever possible, present more than one alternative for consideration. This is especially important when dealing with higher levels of management. Each option should be clearly delineated with benefits and impacts, costs and timeframes. This will help to get others personally involved and committed to the resulting decision. (please read on)

- Take a Chance (within reason)

While we advise you to present multiple options, do not be afraid to support the one that you think is best. Also, if you feel strongly, present original ideas and solutions. Gambles which are based on sound foundations come to be known as investments.

- Establish Defined Plans

Never appear haphazard and disorganized. Keep your tasks in perspective and document each milestone. The matrix approach presented in this paper has this concept as one of its cornerstones.

- Make Decisions

Management is not impressed by indecisiveness. If you hope to advance, you must exhibit leadership qualities.

- Constantly Review

Always remember that any process left to its own will eventually atrophy. Set up a viable feedback system that points out the strengths and weaknesses of the process. Correct the weaknesses and publish the strengths. Continually improve the process.

Perhaps it is time that capacity planners "do as the Romans do" and use some of the tools of the trade and the guidelines that have been employed by other segments of the business community for years. At the very least, if we start investigating how businessmen think, we will have a better chance of understanding their needs and helping them to succeed. If we accomplish that, then we succeed.

A CAPACITY PLANNING METHODOLOGY THAT IS DESTINED TO SUCCEED

Ruu-Tian Lawrence
First Bank System Information Services, Inc.

ABSTRACT

This paper was written to share with you how you can successfully establish capacity management function in your organization. The key issues this paper address are:

- A capacity management methodology that is destined to succeed.
- The organizational savvy that planners need to be effective.

To end the paper I will show you a recent quarterly capacity plan I developed. Please feel free to adopt ideas that are of value to you. I hope you will enjoy the success that I have enjoyed.

1. INTRODUCTION

This paper was written with the intent of sharing my experience as a Capacity Planner in two St. Paul organizations over the past four and one-half years. I can proudly say that in both situations the capacity management methodology was implemented with great success.

However, success was not obtained without pain. The pain I experienced came while learning two valuable lessons. One lesson concerned capacity management methodology. The other concerned technical knowledge and organization savvy that planners need to be effective. Both lessons can help you to successfully establish the capacity management function in your organization as well.

It has been a decade since the capacity management concept was conceived and its importance generally recognized. We capacity planners have come a long way. Nowadays capacity management is a very common and prevalent discipline which can be found in most medium and large data centers. This fact is illustrated by the rapid growth of attendance in annual Computer Measurement Group national conferences. The capacity management function has transformed from an art form to more of a scientific discipline.

There are numerous software packages on the market today which claim to help capacity planners do a convincing job in planning future computing requirements for their organizations. All these scientific, user-friendly, and expensive tools can help planners to increase the precision of their forecasts if they are used appropriately. Higher precision may ultimately bolster planners' credibility. Yet we planners often place too much emphasis on the tools we need before the capacity management function has been soundly established. We fail to recognize that a sound capacity management methodology is what provides the foundation that a planner needs to succeed during the start-up phase. Attempting to use an expensive analytical model without this basic foundation will result in high capital investment with low return. In fact, a good planner can initially establish the capacity management function with great success without any analytical models.

2. LESSON ONE: THE METHODOLOGY

A sound capacity planning methodology is no more than talking to the right people, placing accountabilities where they belong, forecasting frequently, and taking full responsibility for the recommendations. It is absolutely essential for planners to accomplish all four tasks to make his methodology effective.

2.1 TALKING TO THE RIGHT PEOPLE

Good forecasters use good indicators. They search for strong indicators. They normally have a good understanding of where they can find good information to base their forecasts on. Good planners need to do the same thing. We planners are forecasters. We need to know where to get accurate and reliable information so efforts spent gathering and validating data can be minimized.

I have relied on three primary sources. The first source is the systems development staff. These managers, analysts, and programmers are normally the first line interface with users. Because of their combined knowledge of both business and technology, they can greatly help in assessing the impact of new or enhanced computer systems.

The second source I rely on heavily is corporate planners and marketing staff. They normally possess a wealth of knowledge of business seasonality, trends, customer behavior, product promotions, etc. With their assistance we often can identify and explain patterned usage variations. At times we can even explain odd, unique, and non-recurring behavior.

To give you an example: during 1985 for a period of one month, Automatic Teller Machine (ATM) transaction volume increased by 40%. I was puzzled by that fact. After talking with one of the marketers I realized a campaign had been started to encourage customers to use Instant Cash Cards by randomly offering cash prizes. This promotion resulted in a 40% increase in ATM transactions on the mainframe. Luckily the mainframe was not saturated and there was no negative impact on the service level. However, Had I known in advance of this upcoming promotion, I would have been better prepared to deal with its impact--especially if the mainframe had been close to saturation.

The last source of information usually comes from diligently reading internal communications and following market changes and business related issues, such as bills to be decided during legislative sessions, etc. We planners need to follow closely all the issues which may affect the way our organization does business.

In the banking industry for example, state reciprocal banking law allows banks to acquire banks in other states that have corresponding reciprocal agreements. In 1986 when the law passed in Minnesota, my organization was suddenly in the position of being able to

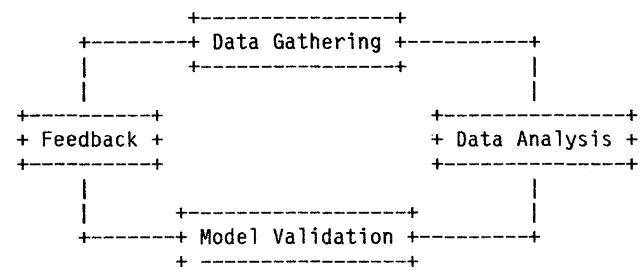
acquire a number of other banks. This could have instantly required increased computing resource requirements of many times our current capacity.

2.2 ACCOUNTABILITY

Capacity planners should not be the only ones responsible for the capacity plan. In order to explain why, I will start by looking at the objectives of capacity management and the planning process itself.

The objective of capacity planning is to assure adequate computing resources to meet future demands in a cost-effective way. The ultimate goal is to maintain the level of service which is agreed on or acceptable to the users. Service level objectives consist of availability, responsiveness, and reliability. Providing high quality and stable service in essence may increase employee productivity and maintain a good customer image. Since the impact of capacity management is corporate wide, to achieve its goal in essence is to achieve a corporate goal. Consequently, all employees need to share this responsibility.

The planning process itself consists of four major components. They are data gathering, data analysis, model validation, and feedback. It is a closed-loop, continuous process.



We all know the acronym 'GIGO' which means Garbage In Garbage Out. Accurate input information is critical to the reliability of the outcome.

Capacity planners, generally speaking, are not chartered to work with users directly on developing new systems or enhancing existing systems. Many times they are not kept current on all upcoming projects that may affect resource requirements. However, they are chartered to plan and predict future resource requirements for the organization. Therefore planners must get periodic updates on upcoming workloads to make the planning process complete.

As I indicated previously there are three sources from which I obtain information on upcoming workloads. They are the system development staff, marketers and corporate planners, and my own tracking of important business issues. In my organization, the system development staff provides by far the most information on medium term (six to eighteen months) resource requirements.

The systems development staff interface with users directly to define data processing needs and suggest ways to satisfy the needs. They most likely maintain and support some existing data processing applications for the users as well. They are close to their users and they best understand users' needs.

Frequently capacity planners need to actually beg for information on potential upcoming projects in order to forecast future resource requirements. This practice requires unnecessary effort on the part of capacity planners. The responsibility for ensuring that sufficient capacity exists to support new systems lies fully with the system developers who have promised a particular level of support to users. It is therefore imperative that the system development staff be accountable for providing projected requirements in a timely manner.

To carry this logic one step further, the organization probably should also hold the marketers and corporate planners accountable for providing information to capacity management staff and for working with them to derive accurate predictions. However, in reality this theory may not work. These groups are usually managed by a different division head whose responsibility is primarily outward focused. Their data processing expertise is often low. They normally do not share the same concern for data processing service levels.

Therefore, holding them accountable for providing input to the planning process may be impractical. There are other ways of obtaining this information which will be discussed in Lesson Two: Technical Knowledge and Organizational Savvy.

Capacity planners are responsible for developing the planning methodology. We are likewise responsible for marketing the methodology to management. We are responsible for convincing management that accountability in the process needs to be adequately placed. Capacity planners also need to assist our planning partners to better understand their current workload. By furnishing them with information on historical trends and resource consumptions for the systems under their responsibility, we will enable them to polish their forecasting skills and make them better forecasters. Competent planning partners, it goes without saying, give us a better chance to derive accurate forecasts.

By holding the system development staff accountable for input information, we already have them agreeing with the planning assumptions. By helping our planning partners to forecast better and by truly developing a partnership in the planning process, we planners will have allied ourselves with them all. When the final plan is presented, the capacity planners can assume there will be no one to challenge the validity of assumptions.

The planning process is a joint venture. The more planners that can assist, the better the result will be. The key is to offer our assistance and to work with the system development staff and other planning partners to create a win-win situation.

2.3 FREQUENT FORECASTS

Good forecasters forecast often. Where I worked, a quarterly planning cycle was adequate when supplemented by monthly comparison of actual versus forecast. A short planning cycle precludes us from being too far wrong. Periodic validating of our assumptions and predictions is extremely important due to the fact that plans and priorities inevitably change with time. When changes take place it is natural that predictions as a result should change accordingly.

However, when changes occur, it is critical for planners to be able to explain the difference between actual and prediction. All managers know that it is important either to operate within budget or be able to explain the variances. The same rule applies to planners. We need to either be accurate in the forecasts or be able to explain why the actual is different

from forecast. This is the only way we planners can establish our credibility.

2.4 BE RESPONSIBLE

Often I hear planners say, "My management is not committed." I challenge this type of statement. If management is not committed, why would they have a capacity planner on their payroll? I believe we planners need to be responsible for the capacity planning methodology. We need to market our ideas and prove the value of our existence. We need to make ourselves understood by our management. We need to focus on issues that our management is concerned about. We need to present our cases in ways that provide management all the information it needs to make decisions. We need to make management recognize our contribution to the organization.

In addition to our upward responsibility, we are responsible for working with people who provide us information that feeds into the plan. We are responsible for assisting them in forecasting better. More importantly we are responsible for giving them feedback. We need to convince them that the effort in seeking better forecasts is for the benefit of the organization. We need to convince them that we are there to help them look smart in their users' eyes. We are there to build a winning team.

3. LESSON TWO: TECHNICAL KNOWLEDGE AND ORGANIZATIONAL SAVVY

A good planner requires good people skills. Understanding bits and bytes is not enough. Unlike performance analysts, capacity planners have more exposure to the world at large. We cannot work in an ivory tower alone and expect to be successful.

For example, the problem I stated earlier about not being able to rely on outside departments for information can be overcome by a planner's organizational savvy. He can use informal influence to gather this information from corporate planners and marketers. Such individuals often cannot express the details of their service requirements in terms that are directly usable in the planning process. By providing them with historical trends of their application work volumes, the planner can equip them with the knowledge they need to quantify the impact of potential projects.

Of course, a planner needs to be technically proficient. He needs to understand operating systems. He needs to be fully aware of the integration of all applications. The level of application integration often determines the portability of certain applications from one mainframe to another. In addition to knowledge of operating systems, mainframes, and applications, the planner also needs to be trained in statistics. This knowledge will allow the planner to better understand the data. It will also enable him to better present the information, especially when the confidence of projection is not high due to future uncertainties.

On top of all the above knowledge, the planner needs to draw all the information around him as input to the planning process. He needs to have a very good understanding of the business he is in. The understanding of business equips him to better communicate with his users. The planner also needs to be politically sensitive. He needs to understand the issues that relate to the financial well being of his organization. Recommendations he makes should be technically sound and make good business sense. Additionally he needs to be able to present his recommendation persuasively and effectively. For example, graphical presentation should be considered due to its proven effectiveness.

In short, a good planner needs to be a technician, a statistician, a communicator and a manager who is capable of managing processes as well as people.

4. EXAMPLE: A RECENT CAPACITY PLAN

I would like to end this paper by showing a recent quarterly capacity plan which I developed. The plan has four basic sections. They are assumptions, volume projections, forecasts, and recommendations. Please feel free to adopt any ideas you feel would be valuable. However, try to be creative. Do develop a format that best suits your management's preferences.

4.1 CAPACITY PLAN FIRST QUARTER 1987
FIRST BANK SYSTEM INFORMATION SERVICES, INC.
JANUARY 1987

- The plan is developed to accommodate daily peak demand.
- 85% of utilization is used as processor (CPU) threshold. Higher usage may cause performance degradation, therefore, decrease our ability to maintain the established service objectives.
- Real storage and virtual storage are also taken into consideration.

CAPACITY PLANNING ASSUMPTIONS

RETAIL

- Lobby Automation
  Implementation will continue. The Metro banks will totally be implemented by July 1987. Five region banks will be implemented by December 1987.

  Add Credit Scoring feature. Will test through April 1987. Will implement in May 1987. May take in credit bureaus' credit rating in December 1987.

  To allow Otts transaction be posted to CICS directly. Test through April 1987. Will implement in April 1987.

  Large Currency Reporting system will be implemented through February 1987. Will be in full production in March 1987.
- CIS Expansion
  Incorporated Credit Card information in June 1987. Trust information in July 1987. Insurance information in October 1987. Discount Brokerage in October 1987. Mortgage in October 1987.
- First Milwaukee
  Will convert all retail systems by March 1987.
- Due From Reconciliation
  Initial implementation includes Fed. Reserve accounts for FBMP and FBSP. Will implement online by March 1987. Accounts for other banks (ex: Chase Manhattan) in June 1987. Will include regions in July 1987.
- 1099 Window Tran
  1099 window transaction volume peak at year end.

- 1099 Year End Correction System
  Automate 1099 year-end-correction process by January 1987.

- Collection Management System
  Will implement Credit Card by January 1987. In production in February 1987.

- IL and DDH Deconversion
  IL and DDH will remain IDMS applications throughout December 1987.

- First Mortgage
  Testing the Risk Management module in the Encompass system by May 1987. Implement in June 1987. In production in July 1987.

- Others (Impact NOT assessed)

  Account Reconciliation System
  Currently we are evaluating an ARS system from DISC corporation. Expecting to make a decision on software package by April 1987. Testing by May 1987, and implementation in June 1987.

  APEX System
  Two alternatives are now being considered. They are IBM and Tandem softwares. Will complete software recommendation by January 1987. Will complete hardware recommendation by March 1987. If it is approved, then will test in third quarter 1987; and be in production in fourth quarter 1987.

  Check Processing System
  We are currently evaluating the whole check processing system with SI. The result of the project may or may not impact IBM mainframes. Regardless the result, we do not expect to see any implementation plan until the fourth quarter 1987 at the earliest.

  Saving/CD's/Retirement System
  A study will be conducted to determine what all needs to be done to improve the savings, CD's, and retirement systems.

  Checking Plus
  Enhance to handle larger retail loans in second quarter of 1987. This may enable the move of retail loans from CLII to Checking Plus systems.

  CIF Files Consolidating/Marketing Analysis System
  Develop a consolidated FBS customers' file. This will allow personal bankers easy accesses to a complete customer business profile. Along with this effort, we are currently evaluating softwares which will facilitate cleaning and standardizing data elements process of CIF files. Providing householding feature will be part of the project. We are developing the POD now. Will test consolidation in March 1987. Implement the consolidation system in May 1987. Automatic clean-up by July 1987. Manual clean-up will be part of the routine process; and householding feature is expected to be implemented in July 1987.

  Unistatements
  Possibly add more types of accounts and more relationships to the system. For example: adding credit card accounts to unistatements. This will be a batch system. Target to implement in the third quarter 1987.

  Float Pricing System
  Possibly modify the existing Burroughs system to provide SI more flexibility in controlling float pricing. Expecting a decision by May 1987. Implementation in September 1987.

  Routing System
  Possibly replace the regional transmission (X300) with RJE jobs. The new system will handle the input as well as print-back capabilities. POD is completed in January 1987. If approved, will test through June 1987; and will implement in July 1987.

  Sales Management System - Retail
  Will develop a system to monitor and track retail sales in 1987. This is to support incentive compensation pay for personal bankers. Will implement in February 1987; and in production in March 1987.

  Sales Management System - Small Business
  Will develop a system to monitor and track small business sales in second quarter 1987. Implementation in third quarter 1987; and in production in third quarter 1987. Mainly a batch system.

WHOLESALE

- AIM System
  50 administration assistants are using online AIM system. This usage will continue to grow. Will start CIS Monetary balances project in March 1987. Will test through October 1987. Implement in November 1987.

  Plan to modify the system to reduce online transactions. Test through June 1987. Implement in July 1987.

  Will develop a product information sub-system. Will complete specification by January 1987. Test through May 1987. Implement first phase in June 1987; and implement second phase in October 1987. This is mainly a batch system.

- Trust System
  Test the security movement package by December 1987. Will implement in 1988.

- Stock transfer
  The system will leave us by March 1987.

- Due From Reconciliation
  Develop a Due Rec system for Commercial loans. Complete POD by January 1987. Will test through March 1987; and will implement in April 1987. It will be a batch system.

- Others (Impact NOT Assessed)

  AIM System
  Enhance AIM system to be the wholesale CIS system.

  AIM Junior Project
  Will eliminate the information stored in the system for Small Business for Minneapolis and St. Paul. Will test in April 1987. Implement in June 1987.

  Commercial Loan II
  Automation of foreign exposure risk analysis may happen. If go, will incorporate IBG, MIDAS information into CLII database. In the second phase, will incorporate DDA, CD's information into

the CLII database. Expecting a go or no-go decision by March 1987. Test through June 1987; and implementation in July 1987.

London Project
This project is currently on hold.

SYSTEM

- Network Services
  HCF facility will be installed in first quarter 1987. This facility will allow FBS Mortgage system 36's to communicate with each other. HCF along with reverse passthru will also allow HP devices to communicate with the IBM mainframes.

- Advanced Function Printing
  AFP is available for use. Complete implementation plan by January 1987. Will implement in IS by March 1987. Implement production print throughout 1987.

- System Software
  Enhancements to system software are required to improve availability, support new hardware or provide software for new and larger applications. Resources required for this support are included in the forecast.

- Others (Impact Not Assessed)

  Implementation of Single System Image is not quantified.

DIVESTITURE

- Sturgis
  Deconversion is completed in December 1986.

- Bremer Banks
  Deconversion is now in progress. Target to complete by December 1987.

- Others
  Status change from affiliate to Corr between August 1986 to July 1987. At this time, they will leave the HR, Payroll and G/L systems. Six months after the status change they will leave FBS system completely.

  Mengedoth Banks - Status change in January 1988. Deconvert six months after the status change.

ENTERPRISE BUSINESS

- G/L Business Line of Reporting
  Full production in February 1987.

- Management Report/Funds Transfer Pricing
  Develop funds transfer pricing module in October 1986. Eliminate existing management reporting system in January 1987.

- Others (Impact NOT Assessed)

  Human Resources System
  The project is progressing slowly. No impact is assessed on the IBM host in 1987.

OFFICE OF TECHNOLOGY

- End User Computing
  Focus
  Have approximately 60 focus users in December 1986. Will have another 110 focus users by December 1987.

  Issco Graphics
  FBSSI and Trust will pilot until December 1986. They will be in production in January 1987. Have approximately six users in December 1986. Will have additional 24 Issco graphic users by December 1987.

- Others (Impact NOT Assessed)

  End User Computing
  Issco Plan - This is a project management facility. FBSSI will be the initial user of this product. However, how the use of this product proliferates is an unknown at this point of time.

  Office Automation
  The possibility of implementing any office automation facility is unknown currently.

ONLINE TRANSACTION VOLUME FORECASTS
(Peak Hour Only)

New Application Growth	12/86	Addition by 12/87
Lobby Automation	3,500	5,000
AIF Expansion	-	5,200
First Milwaukee	-	3,000
Collection	900	1,000
FBS Mortgage	750	100
Due From Reconciliation	-	100
G/L Regional	2,100	500
G/L Metro	1,200	500
1099 Correction	-	50

Existing Application Growth

An average of 3% annual growth is assessed in the forecasts.

END USER COMPUTING AND OFFICE AUTOMATION
(Number of Users)*

	12/86	Addition by 12/87
Focus	60	110
Issco Graphics	6	24

* This indicates the number of users who have access to the systems. However, the real driver of the usage is the number of logon (i.e., active) users. In the analysis, we assume that one out of every seven end users is active during the peak hours.

GRAPHS LAYOUTS

Major components of the Graphs are:

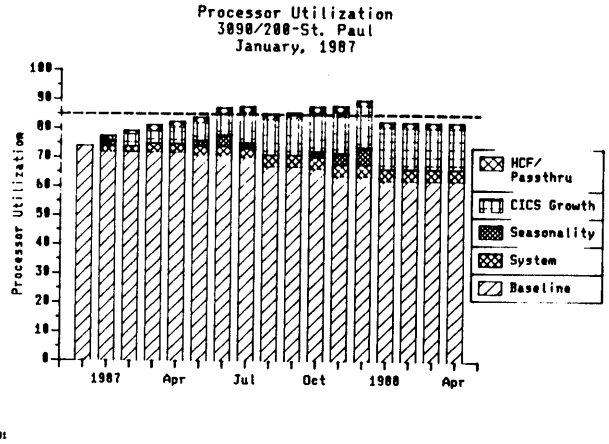
- Baseline - The processor utilization consumed by all existing workload which includes system and applications currently.

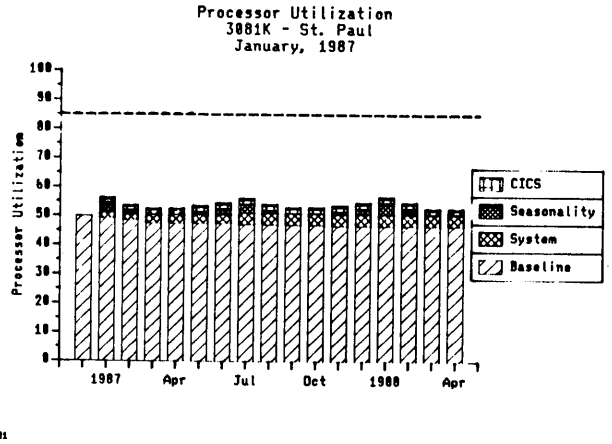
  Normally the declining baseline indicates the effect of divestitures of banks or applications.

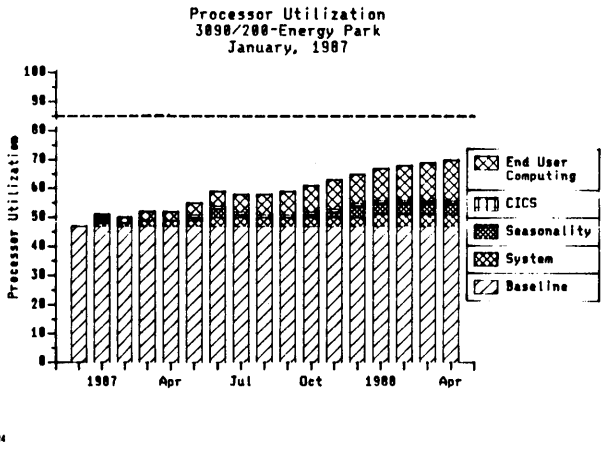
- System - Forecasted growth introduced by additional system utilities or enhanced versions of the existing system utilities.

- CICS Growth - Forecasted growth introduced by the new applications and the normal growth of the existing applications. However, new applications whose resource consumption are significant may be listed individually on the graphs.

- Seasonality - Forecasted additional usage due to the seasonal processing.
- Significant Events - New applications whose resource consumptions are of great significance are shown individually on the graphs.





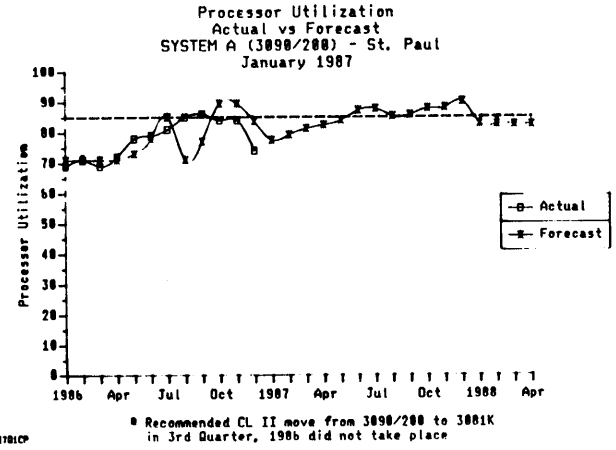


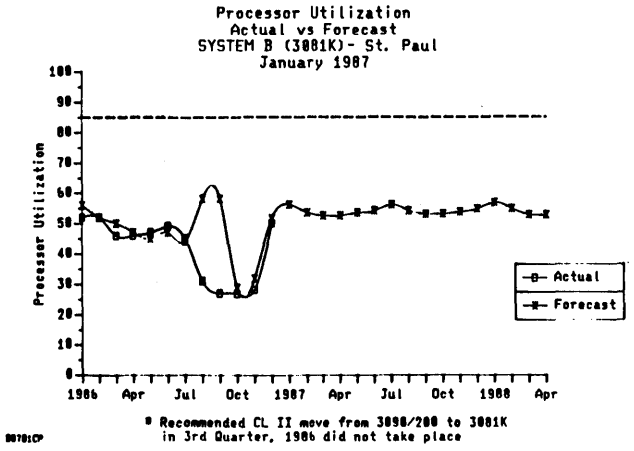
RECOMMENDATIONS

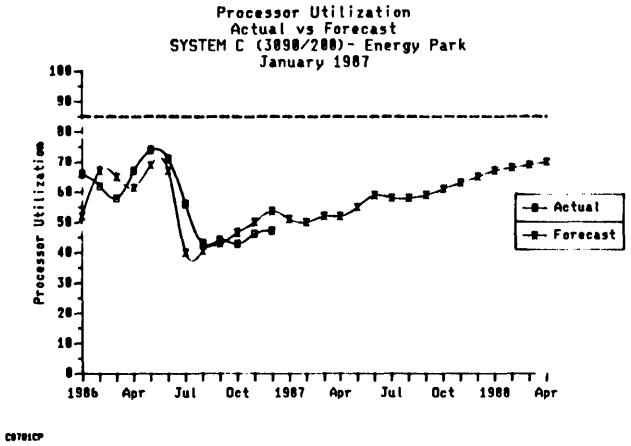
- If we implement new release of UCC General Ledger, two general ledger databases will merge in the first quarter of 1987. The merge will move the G/L database on the 3090/200 at St. Paul to the 3081K at St. Paul.
- Continue to explore the possibilities of implementing CICS Single System Image. This would allow users to access all three processors without being burdened to logon and logoff from one processor to the other.

  The Single System Image needs to be implemented by April 1987 either partially or in full. To alleviate capacity constraints in June 1987, we need to position to move Commercial Loan II and International Banking from 3090/200 to 3081K in St. Paul site and to move Personal Trust from 3081K to 3090/200 at St. Paul site.

  If Single System Image cannot be implemented by June 1987, then upgrade the 3090/200 to a 3090/400 at St. Paul site should be considered as an alternative.







4.2 DASD PLAN FIRST QUARTER 1987
FIRST BANK SYSTEM INFORMATION SERVICES, INC.
JANUARY 1987

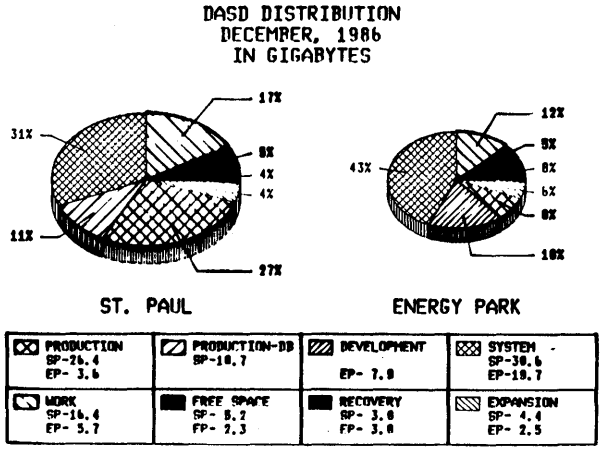
GRAPHS LAYOUT

- Production
  This is the disk space used by production systems which are non-IDMS.
- Production-Database
  This is the disk space used by IDMS production systems.
- Development
  This is the disk space used by application programmers for developing or maintaining systems.
- System
  This is the disk space used by Operating System, System Network facilities, program products installed in the systems, and some operational related files.
- Work
  This is the disk space required to support production and development work. Example: Sort space, temporary work space, etc.
- Free Space
  This is the space that is available to meet future or unexpected demands.
- Recovery
  This is the space required to do recovery in case of hardware malfunction.
- Expansion
  This is the space required on each logical units for potential file expansion and fragmentation.

  Generally speaking, the expansion spaces are small and fragmented. They can only be used to satisfy small demands. Disk management group always tries to minimize it. However, for planning purposes, we will treat Expansion as used space.

COMMENTS

- We are currently using 2.5 Giga Bytes as the threshold. This is equivalent to 4 3380D logical units.
- The Expansion Factor is 8% of all the production, development, and some system disk logical units.
- We are currently using 3.8 Giga Bytes for recovery. This is equivalent to 2 3380D and 2 3380E logical units.
- The Charts do include all the 3350 disk drives which are still in use. However, they will be phased out in February-March 1987 time frame. This is the result of the replacement of IBM 3350 disk drives with IBM 3380 disk drives project.



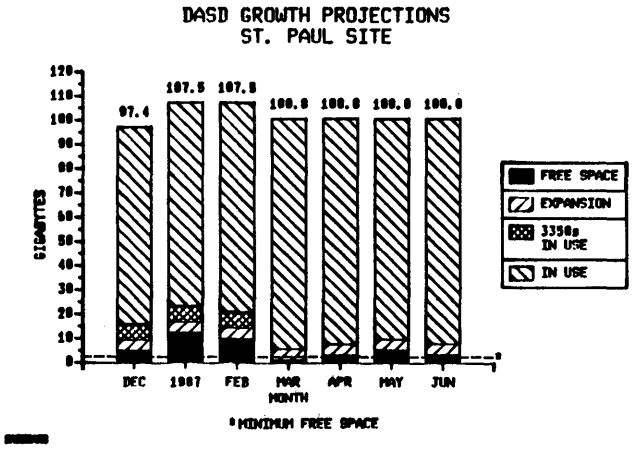
SUMMARY OF FUTURE DEMANDS

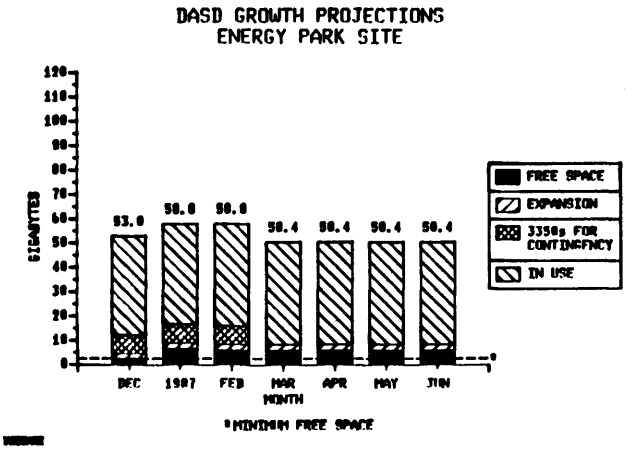
ST. PAUL SITE

Systems	Date Needed
• AIF File Expansion	1/87
• 1099 Correction System	1/87
• Mortgage File Expansion	1/87
• Collection Management	1/87
• Lobby Automation Support	1/87
• System/Database	2/87
• Billing File Expansion	2/87
• Human Resources System	2/87
• Personal Trust File Expansion	3/87
• Operation Print Project	3/87
• System/Database	3/87

ENERGY PARK SITE

Systems	Date Needed
• Human Resources - Focus	1/87
• System/Database	1/87
• Time Accounting System	1/87
• AIM File Expansion	2/87
• Focus/Gateway Expansion	2/87





WHAT WE CAN LEARN FROM OTHER CAPACITY PLANNERS: A SURVEY OF QUANTITATIVE METHODS

B. A. Ingraham
Pacific Bell

ABSTRACT

A variety of management science and operations research methods for planning under uncertainty or in complex situations are presented. The application of the methods to computer capacity planning is discussed.

1. INTRODUCTION

This paper is about a management philosophy in which quantitative methods are used to solve quantitative problems. This is NOT a tutorial which describes in detail how to implement quantitative techniques in specific situations.

The question "How is computer capacity planning carried out as a business function, rather than a technical function? ", has been raised repeatedly at the past few CMG conferences, in both presentations [3], and in the Executive Expectations of Capacity Planning panel discussions. At the root of this question lies one of the fundamental reasons why computer capacity planning has value to an enterprise. This reason is economics, the allocation of scarce resources to great or unlimited demands. Data processing competes for scarce resources, such as capital dollars, with other parts of the enterprise. If the other parts of the enterprise state their cases in business terms, and data processing states its case in technical data processing jargon, then data processing does not finish well in the competition.

Where can computer capacity planners learn to state a case in business terms? Capacity planning is not unique to computers and data processing. Capacity planning for the main productive systems is an indispensable business function in many large (and some not so large) enterprises, whether the output of the main productive systems is paint, insurance policies, or fast food. I refer to these non-DP capacity planners as "other capacity planners", for lack of a better choice of terms. (Some confusion is inevitable, as many computer capacity planners use the term "capacity planning" to mean "computer capacity planning".) Computer capacity planners can learn by studying other capacity planners to solve similar capacity planning problems with similar techniques instead of reinventing the wheel, or worse, expecting executives to learn data processing.

The paper is organized as follows: Section 2 looks at two different views of capacity planning. Section 3 examines where capacity planning falls on the planning continuum. In Section 4, a few important quantitative methods are discussed, namely forecasting, queueing theory, linear programming, and decision analysis. Implications for managing computer capacity planning are discussed in section 5.

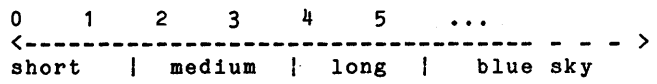
2. TWO PARADIGMS

There is a widely held belief that computer capacity planning is an outgrowth of systems programming and performance evaluation [12]. More specifically, it is held that experience as a systems programmer is a prerequisite to becoming a computer capacity planner, and that the tools used for performance evaluation are appropriate for solving computer capacity planning problems. Kune [13] calls such a set of shared beliefs about a discipline a paradigm. While the popularity of this paradigm attests to its success, the question posed in the introduction implies that there remain problems which are not solved to the satisfaction of executives making economic decisions.

There is another paradigm held by other capacity planners, in which capacity planning belongs to the business administration discipline of management of production and operations [9]. The tools of the trade in this paradigm are quantitative methods such as forecasting, decision theory, linear programming, and other management science techniques. I believe that we computer capacity planners can learn something from other capacity planners, in particular, how to apply quantitative methods within data processing to solve computer capacity planning problems. Seeing ourselves as business administrators rather than technicians will make the learning process easier.

3. THE PLANNING CONTINUUM

This section suggests a position for capacity planning on the planning continuum. The scope of planning can be anywhere from a few seconds to infinity. This is an awfully large range, so for practical purposes, it is helpful to break it up into smaller pieces. One way to split up the continuum is into tactical and strategic planning. Another way, which seems to fit the planning process better, is short, medium, and long.



The Planning Continuum

The scope of short-range planning is from the present to one or one and a half years out. The objective is to make detailed schedules for processing the work on the existing equipment. Medium-range planning covers the period from one or 1.5 years out to 3 or 5 years out. The objective here is to plan for enough equipment

to process the amount of work which will need to be done one to five years from the present. The focus is on aggregate planning, rather than details. The bulk of capacity planning, as a general business administration problem, ideally focuses on the middle range. Long range planning covers from 3 or 5 years and out. The objective is to make sure the physical facilities are in place to hold the equipment and people needed to process the amount of work which will need to be done 3 or 5 years from now and out. The sorts of things planned for are real estate and construction.

Note that as the planning horizon moves further out, complexity, uncertainty, the time available for analysis, the cost of mistakes, and the level of management approval all increase, while the degree of repetition decreases. For example, short-range planning may be done monthly, weekly, or even daily, medium-range planning is usually done at least yearly, but not more than quarterly, and long-range is ordinarily needed only on an ad hoc basis. All of these considerations effect the amount of time and money which will be spent on planning.

There must of course be communication among the short, medium and long range plans. I want to emphasize that the range of planning is a continuum, and there are big gray areas between short and medium, and between medium and long. When the time for capacity to be increased is near, then the aggregate and detailed plans must be reconciled. Capacity increases can sometimes be postponed by intensive efforts in short range planning. On the other end, the amount of computer hardware certainly effects the long-range plans for real estate and construction. However, a long-range capacity plan will not look much like a medium-range capacity plan. The problems, the solution techniques, and the people involved in long-range planning are all different from those in medium-range planning. The level of complexity, uncertainty, time available, and repetition in the medium range makes certain quantitative methods effective. The reason for this is, as we will see shortly, they were invented to help plan under uncertainty in complex situations.

4. QUANTITATIVE METHODS

This section will discuss some of the quantitative methods used for capacity planning. The list is by no means exhaustive, but is a survey intended to give a flavor of what is available and what it's good for.

4.1 FORECASTING

Forecasting is the foundation for all planning. Quantities which might be forecast in computer capacity planning include transactions per hour, CPU utilization, DASD space, tape drives, and print lines.

It appears to me that what many computer capacity planners expect from a forecast is one number for each forecast period, and absolute certainty that this one number will be correct. Many computer capacity planners also seem to fear that this is what management expects from forecasts. This is not a reasonable expectation. The future is uncertain. The goal of forecasting is to attempt to bound the uncertainty of the future as much as is reasonably possible. The bounds on the forecast are called X% confidence limits, and a forecast which includes X% confidence limits is called an interval forecast, as opposed to a point forecast. The value for X is typically 95. The interpretation of an interval forecast with 95% confidence limits is: based on past values, there is a 95% chance the actual future value will fall within the limits.

There are many forecasting techniques which will compute interval forecasts ([6], [10], [11]). They include stepwise autoregression, exponential smoothing, Holt-Winters, Box-Jenkins, statespace, and X11. The amount of time, skill, and historical data required varies with the method, as does the flexibility of the analysis and the quality of the forecast. The quality of the forecast also depends on the quality of the historical data: garbage in, garbage out.

A few comments about judging the quality of a forecast may be helpful. The accuracy of the forecast is not the only criterion. Confronted with two or more forecasts from which to choose, accuracy cannot be a criterion, since one would have to know the future already. Important criteria for evaluating models to use for a forecast are parsimony (the KISS principle), identifiability, goodness of fit, theoretical consistency, and lastly, accuracy [10].

In addition, a certain amount of sophistication is required when judging the accuracy of a forecast after the fact. Simply comparing the actuals with the forecast reveals little, since points are being compared with probability distributions. Techniques have been developed for testing whether the points fall where predicted [3].

4.2 QUEUEING THEORY

Queueing theory is an operations research method which relates waiting time in a queue to service time and server utilization ([2], [5]). It is used for determining numbers of bank tellers, studying runway congestion at airports, and for predicting the performance of computer systems. It has, based on the old computer capacity planning paradigm, been carried foreward as a computer capacity planning tool, especially for CPUs. The success of queueing models as performance predictors may encourage computer capacity planners to try out some of the other quantitative methods.

It is interesting to ponder whether queueing theory will continue to be as useful for CPU capacity planning as it has been in the past. A simple result from queueing theory, which is not discussed very much, is, as the service time decreases, the utilization at which the response time degrades approaches 100%. This means the shorter the service time, the higher you can drive the server utilization, whether the server is a CPU, I/O device, or anything else. There are three ways to reduce service time in a computer: optimize the application program, tune the system, and speed up the hardware. Great advances are being made in all three areas. At this point, it appears that current and future generations of large mainframes can be run at over 95% utilization without degrading response time [14]. No

additional information regarding the CPU can be gained from a queueing model, so the usefulness is diminished for planning for large mainframes. Queueing models are now more applicable as a computer capacity planning tool for slower CPUs, like superminis.

4.3 LINEAR PROGRAMMING

Linear programming is a constrained optimization technique with vast applications ([1], [5], [8], [9]). It is probably the best known and most widely used operations research method. The effectiveness of linear programming seems to come from its power to solve very large problems efficiently. In computer capacity planning, applications include DASD space planning, and the assignment of workloads to CPUs in multi-CPU data centers.

Linear programming was invented by George Dantzig in 1947, while working on a planning problem for the Air Force. I will let Dantzig speak for himself [1]:

> In a business setting one would hear, "Our goal is to make a profit." But you could never find any direct relationship between the stated goal and the actions to achieve the goal. If you looked closely at the next step, you would find some leader in his conceit had promulgated a bunch of ground rules to guide the way to the goal. This is a far cry from honestly looking at all alternative combinations of actions accross the board and picking the best combination. Those in charge often do a hand-wave and say, "I've considered all the alternatives," but this is so much garbage. They couldn't possibly look at all the possible combinations. Before 1947 the possibility that there could be a tool like linear programming that would enable one to examine millions of combinations was inconceivable. There was no algorithm or computational tool for doing so.

This sounds to me like the way a lot of computer capacity planning is still done today.

Linear programming turned out to be more effective than even Dantzig imagined. As an example, Joel Franklin [8] tells about his visit to a large oil company in 1958. The company had built a new multi-million dollar computer center. The computer was used mainly for linear programming, to make optimal production decisions which had previously been made by vice-presidents based on their experience. The computer center paid for itself in about two weeks. This gives some measure of the efficiency of linear programming compared with human judgment.

4.4 DECISION ANALYSIS

Decision analysis encompasses a number of methods for structuring the decision process ([5], [7], [9]). The techniques are helpful for planning under uncertainty and evaluating a large number of possible actions and outcomes. Some of the techniques are cost-benefit analysis, payoff tables, and decision trees. Among the quantities estimated and related in using these techniques are utility functions, payoffs, losses, risk behavior, expected value of perfect information, and the expected value of experimentation.

Here is a brief illustration. A decision tree may be used to structure the decision to buy a new CPU. Suppose there are three vendors to choose from. At the first decision level, there are four choices: buy from vendor 1, buy from vendor 2, buy from vendor 3, do not buy a CPU. For each vendor, there are several quantities to estimate: current price, price in the near future (Will there be a price cut? Is a VPA available?), new models available in the near future, reliability, life expectancy, salvage value, etc.. For the action of not buying now, some of the previous values are relevant, and in addition, the point of exhaustion, cost of degraded service, cost of additional tuning, etc., can be estimated. At the second decision level, the choices are, which of these estimates to make. The quantities involved at this level are the expected value of perfect information, the cost of each estimate, and so on. All of these possibilities and quantities can be structured on a decision tree, and the tree can then be "pruned" to find the decision with either the greatest expected payoff, or the least expected loss.

5. CONCLUSIONS

There are some obstacles to implementing quantitative methods in computer capacity planning. The first, not knowing they exist, I hope to have helped mitigate with this paper. The next is the required shift in paradigm, from seeing computer capacity planning as an extention of performance analysis, to seeing it as a subset of business administration. The time has come for us to remove our blinders so we can see what others are doing and learn from them.

There are also staffing and training considerations. If you are managing a capacity planning staff, you might begin steering your staff to take some training in quantitative methods. If you are hiring, you may want to consider someone with a background in management science or operations research, rather than systems programming or performance analysis. A good source of information may be the other capacity planners in the company you work for.

The potential payoffs are more efficient decisions built upon better forecasts and thorough analysis of alternatives. Computer capacity planning will be able to take advantage of the large body of knowledge concerning management science, operations research, and decision analysis, and thus avoid reinventing the solutions to problems which are already solved. Another benefit is computer capacity planners will communicate more clearly with business administrators, speaking in payoffs and costs rather than CPU seconds and megabytes. It seems clear from the last few CMG Conferences that this is the direction in which computer capacity planners want to go. A shift in paradigm and the use of quantitative methods are needed to establish computer capacity planning as an indispensable part of the business.

MANAGING DEPARTMENTAL MAINFRAME DEMAND THROUGH SHARED ACCOUNTABILITY

Kenneth C. Jones
GPU Service Corporation

ABSTRACT

As computer system usage has evolved from major applications developed and scheduled by an Information Systems function toward increasing client department development and scheduling of *ad hoc* programs and departmental systems, many organizations have felt they must better assist client departments in the effective management of their computer resource consumption.

Client departments and information centers have developed significant application and programming expertise as advanced languages make it easier to use computers without a technical understanding of the machines themselves. However, clients are less advanced in understanding the resources and costs required to support their activities. Thus, their use of computer resources sometimes seems to assume unlimited resources are available. At the same time, while other departments are retrenching they see IS continuing to expand – and do not realize that their own increased demands for automation are a key driving factor behind IS growth. It is therefore necessary for the technical experts within the IS function to translate computer resource consumption into terms which can be understood and effectively managed by the client community. IS has the data to support better management of this growth – now we must learn to market it to the rest of the corporation.

This paper reviews the techniques used by a mid-Atlantic utility firm to present information services usage and capacity data to non-IS management in a format which they can directly apply to managing their computer resource consumption. This reporting technique provides information by organizational and functional categories and uses non-IS terminology – dollars and names are provided, while technical measures are avoided for this audience. The reports have been very well received within the corporation, and continue to be expanded at the request of senior management.

WHY THIS PAPER?

Increasing development of computer skills throughout the corporation has led to greater demand for computer resources from outside the direct management scope of the Information Services (IS) function. As a result, there is a need for management outside IS to more actively manage their organizations' computer usage. This paper shares an approach to such management which has proved to be effective and well-received at General Public Utilities (GPU) Service Corporation.

Since the original development and distribution of the reports described here about 1-1/2 years ago, there has been a substantially increased awareness among non-IS management at our firm of the costs and sources of computer resource consumption. This has resulted in measurable changes in demand patterns, as well as in improved communications between IS and the rest of the company.

The reports are still growing and evolving at GPU, with the primary impetus for these changes coming from senior management – not from within the IS function. This paper was written to share our experiences with others in the field in the hope that they will be able to apply some of our lessons to their own organizations.

WHY ARE THESE TECHNIQUES NEEDED?

Increasing demand for computer resources which is driven directly by client departments – through *ad hoc* work in the batch, TSO[1], and/or CMS[1] environment – has resulted in a need to better manage this type of demand. This need is especially evident in the organization where this demand is a major – perhaps even **the** major – driving force requiring new capacity expenditures. However, IS cannot directly manage this growth since it is outside the scope of IS management control; thus, effective management requires communication and cooperation between IS and client departments.

In many organizations, the corporate image of IS professionals is that they are not a "real" part of the company. We are perceived as technical "wizards" who are remote from the real business of the organization. Our specialized skills are needed to provide computer services required to do the company's business – but for most of us, computing is **not** the company's primary business. Yet IS has had a historical tendency to grow at higher rates than the rest of the corporation.

Much of the image problem is due to poor communications. We must improve those communications and the level of cooperation between IS and the rest of the company. IS consumes a significant and growing portion of the corporate financial resources, and must be manageable. Ultimately, IS must do its share of the work necessary to understand the company's business and to help the rest of the company understand how their use of computer resources affects the major financial decisions made to provide those resources.

WHO ARE WE?

Before getting into the details of how we have addressed these requirements, the reader should understand the corporate structure in which these reports were developed. GPU Service Corporation exists as a separate corporation which provides centralized services for three operating electric utility companies under the overall GPU corporate structure. The Service Corporation functions include IS, materials & services, energy planning and finance, laboratory services, and similar functions which benefit from the economies of scale provided by centralization.

As a result of our location within the corporate structure, IS must be responsive to the needs both of the Service Corporation and of the operating utilities. A different corporate structure might require some adjustments to the details described below.

WHAT IS NEEDED TO IMPLEMENT THESE TECHNIQUES?

There are a number of types of data which must be available in order to implement this type of reporting within the corporation. First, it is essential to have information on computer resource usage at a detailed "who" and "when" level. In most organizations, this will come from a performance/capacity planning database (such as MICS[2]). For these reports, at least a month's worth of data must be maintained with enough detail to identify the individual responsible for a given session, job, etc.

In addition, these reports require corporate organizational data in the form of an "on-line organization chart" which will be used to group employees for reporting purposes. This information may be available through the security system, which frequently places userids into organizational groups to ease security definition.

There must be access to enough financial information to reasonably assign dollar costs to resource consumption. A chargeback system of some type is almost essential. Depending on corporate accounting practices, it may also be necessary to add some overheads to charges if they have not been included in the chargeback system. Without a chargeback system, it should still be possible to determine some estimated figures, "what chargeback would be", but this involves treading on rather shaky ground.

Finally, it will greatly improve the reports to be able to classify use into business applications such as "materials" or "customer accounting" rather than into IS applications such as "fast-class batch" or "TSO long transactions". When categorizing client-written code run interactively, the classifications should be understandable to the client as well, such as "graphics" or "SPF[1] edit/browse". If the ability to do business application classification is not available, consider developing it for better integration of IS into the corporation.

WHAT ARE THE FORMAT CONSIDERATIONS?

In order to have an impact with client department management, reports must be brief – one page per division, for example. Our reports list the top 40 clients on each page; the figure "40" was chosen because that is how many names will fit within the selected format.

It is important to develop a readable, attractive format. Because of the number of names per page, we chose not to use graphics in our reports. Graphics are appropriate to a large scale report, not a down-to-the-individual detail report. However, we did develop a boxed layout for ease of reading, and graphics are produced from some summary-level data. Remember, everything else being equal, a clean-looking report will have more impact than something that looks like "another computer listing". All the content in the world will not do any good if it is not accessible to the reader.

CHOICE OF REPORT TOPICS

The first point to remember when reports are generated is that the rest of the corporation expects and fears a "paper avalanche" from IS. Start small, and expand in response to feedback and requirements. Let the recipients adjust to one or two reports at a time.

Be careful to stick to topics for the report which can be understood and managed by client management. The client understands "12 job runs in the materials subsystem by J. A. Abernathy at an approximate cost of $294", not "12 BMPs accessing database family 381 submitted by userid K8934 with 46 minutes of CPU time and 125,000 database calls". Among the topics we have selected are job runs, TSO sessions and priority job executions.

Items selected for reporting must be manageable. The client cannot manage database calls, since it was IS that wrote the IMS[1] code. The client **can** manage transactions or jobs.

In addition to being manageable, the subjects must also be able to show an impact if they are better managed. In our 24-hour shop, the CPU is most highly utilized between 8 a.m. and 5 p.m. To maximize machine utilization, and return on investment, IS encourages shifting of use to evening and night hours whenever feasible. Our reports do not show usage during evening and night hours. At present, we do not really care who the non-prime users are – they do not drive our costs.

Above all, if the client cannot tell from your report how to manage the use – through names, applications, dollars, etc. – you may as well save the machine cycles and paper to produce it. The client cannot be accountable for managing things he cannot understand. Our job is to help him understand.

CHOICE OF REPORT TERMINOLOGY

This brings us to the overall key to any client reports which you expect to be used. If we continue to use "tech-speak", reports will have minimal impact.

The rest of the corporation manages in dollars. CPU time, main storage occupancy, I/O operations, database calls – none of these mean much outside IS. We need to translate into the language of business. Once we do that, client department management of dollars and sessions will result in savings in CPU, MSO, I/Os, and database calls.

In many organizations, dollars may simply be extracted from a chargeback system. At GPU, it was not quite that easy since computer chargeback figures enter the corporate accounting system and have a variety of overheads applied at summarized levels. It is not always easy to spread these back to the detailed reporting level.

If you have trouble assigning dollars, try anyway. When estimating, always do two things: (a) document the assumptions, and (b) make it clear to the recipient that this is an estimate. Bad dollar figures can destroy your credibility; no dollar figures **will** destroy your effectiveness. Assigning dollars may be difficult, but it must be done. The credibility problem may be ameliorated if you present early drafts as a first pass and invite feedback and corrections. Also, be sure that IS management has the first shot at reviewing the reports.

Determine what kind of dollars you are going to report, and make it clear what they are. For example, should the total match the IS hardware budget? the total IS budget? the total client bills? with or without corporate overheads? If you do not make clear what your figures can be compared to, they will be compared to everything – which means they will be wrong in every case but one.

It is also important to provide actual client names in as many places as possible. IS manages userids, the rest of the company manages people. In computer usage, there is a(n approximate) one-to-one correspondence. Do not make the client look that up.

Reports should be printed and summarized by corporate structure – division, department, etc. In this way, they can be targeted to the right management to see results. Incidentally, if your "on-line organization chart" has any errors, you will find out about it this way! Summarization by corporate unit

provides top-level management with visibility of the areas of highest, and perhaps inefficient, use. This is key in highlighting the areas where closer management attention can yield the biggest dividends.

GET TOP IS MANAGEMENT SUPPORT

Before going too far in developing this type of reporting project, obtain the involvement of top IS management. They will have input, much of which will help in those areas where technical people can tend to have a perspective problem. Their support is essential if you want to see results; as one of our managers would put it, "don't shoot uphill".

When the reports have been refined with input from top IS management, they will have their own "investment" in the project. At this point, they will want to sell it to the rest of the corporation. You need this involvement from IS management; they can sell it much better than you can.

APPLICATION OF THESE PRINCIPLES AT GPU

At GPU, we are still evolving in the process of applying these principles. We generate monthly TOP 40 reports, bundled by organizational unit and summarized at the overall company and corporate levels. We distribute the reports to the information centers, which work directly with the affected units in changing work habits where appropriate. We also send them to top management, for high visibility.

The actual reports we use are described below.

THE TOP 40 REPORTS

The first page is an overview (Figure 1) which shows how subsystems and corporate units share the total capacity of our installation. There was some technical unease in generating this, as we got into the details of sotware measurements vs. hardware measurements and so forth. However, what we publish is the best available **and it adds up.** As long as we are consistent in our technique, management has had no trouble buying into it. In fact, their perspective tends to be that they do not want to hear about the technical details, they just want a consistent report from month to month. We have documented our assumptions, and will notify all recipients of any changes.

We learned early that the percentages on this report must check fairly closely with all other reports for management acceptance. For example, if a corporate summary batch report is compared with a TSO report, the ratio for total CPU time must check with the overview page. This is true wherever it is reasonable to

Figure 3. 40 Most Used TSO Functions by Division

compare figures. The fastest way to lose credibility is to have figures which do not check.

Our next reports focus on TSO consumption, which has been our fastest growing workload. One is by client (Figure 2); it uses such key concepts as client names (not userids), dollars as well as CPU time, and business category breakdowns. The other breaks down usage by function (Figure 3), so that a manager can see what his personnel are doing in a more detailed fashion.

We also have a demand batch report (Figure 4). In our environment, "demand batch" is defined to be all batch which is run at the request of a TSO session; this includes non-scheduled production work as well as code written by the client. This definition was selected because resource requests can be related to who "demands" it for management control. It is difficult to categorize this work into business functions, since much of the code is client-written. In this case, the client should be able to relate to a software product name such as RAMIS[3] or SAS[4], or to a category such as graphics or spreadsheet.

We produce a scheduled batch report as well, but it is the least-used of the set. In our environment, this cannot presently be broken down to the department level, which makes it harder to manage. We provide a job description, which helps in management. This was an area where some descriptions were inaccurate; our reporting of them led to corrections and better documentation standards compliance. On this report, the key control factor is number of runs, since run frequency is the manageable variable.

Another report we generate covers DASD occupancy (Figure 5). DASD is a very expensive resource, with total installation costs approaching the costs for mainframes. At the same time, it tends to be undermanaged throughout the industry, as the attendance at CMG DASD management sessions implies – everyone is looking for the key.

Our report is by client name, with the measurement and control variable a function of space occupied and time occupied. We intend to investigate the impact of time-of-day on this report. Would it make sense to convert this to a prime-shift-only report as we do with CPU-based reports?

We have also added a priority batch report to show the biggest users of priorities within the installation. This identifies clients and departments which most frequently bump themselves to the head of the queue. It has become somewhat controversial at GPU, since it allows each department to see how others are using priority. It brings the "priority wars" out in the open!

Our final report summarizes the dollar figures on the earlier reports (Figure 6). Management finds this to be very useful in identifying those clients with an overall high consumption pattern.

We conclude the report with a client index, showing the organizational information used for every client listed. This was added at the request of the receiving management.

Figure 6. TOP 40 Clients of D.P. Services by Department

CONCLUSIONS

Based on the response within our organization to the reporting techniques discussed here, I believe it is essential to work toward implementing and refining some version in any organization where the IS function is a service function for the overall business. Computer resources consume an impressive portion of the overall corporate dollar, and non-IS management generally do not understand their units' use of these resources well enough to manage it for maximum effectiveness. It is up to the technical wizards in IS to come at least halfway to help client department management to manage their IS resource usage. As direct consumption of these resources by client departments continues to grow, IS cannot manage them alone. Better management by IS requires client department participation.

Through better communication and cooperation between IS and client department management, this type of reporting can improve IS' standing in the corporation. At the same time, managing the installed capacity will be made easier through sharing the load. Both IS and the rest of the corporation will be the ultimate winners.

Management Reporting: An Approach To Availability and Service Reporting

Michael Marcus
Freddie Mac

ABSTRACT

Management needs and wants timely information about service and availability of the online systems. This paper presents a definition of availability, traces the history of the different reporting methods developed over the years, and reports on a recently developed availability management reporting system. For any installation not currently doing this type of reporting, the information presented can be used as a starting point for developing a set of management reports.

INTRODUCTION

One of the problems of providing reports to management is reporting technical information in a form that is easy to understand and does not overwhelm the reader. Sometimes trial and error prevail in the development of reporting systems. The following availability and service reporting system has evolved in part by trial and error and in part by a need for better reporting. The current set of reports and graphs have been used at all levels of management. What this paper is attempting to do is give some examples of what has been done in this area of reporting to provide a starting point for developing a set of reports and graphs for use in any installation.

When availability and service are at "acceptable" levels, management has not always demanded reports about service indicators. Until there are many interruptions in availability or service becomes degraded, management does not need this information. This is especially true of organizations that are "new" to online data processing. When this happens, management has a need to know what is happening and why. To be able to provide this information, data from multiple sources needs to be collected and maintained.

AVAILABILTIY

Before producing a report on availability, a concise definition of availability is needed. Our definition for availability is the measure of time a given service is available to end users within established service hours. If a given computer service is scheduled for 12 hours and is in operation for 14 hours, it is only considered for tracking purposes to be available for 12 hours. There is no bonus given if an outage occurs and service is extended to compensate for the outage. If an outage is scheduled during normal service hours, there is no penalty provided service is restored within the scheduled time. For single image services provided by multiple servers (TSO from multiple machines or a split CICS application), a dilemma exists on how to report an outage in part of the system. Service is still being provided, but all users may not be able to access the service. The outage can be averaged between the services or counted as a full outage. Management has chosen to average these outages.

In order to reflect the view of availability seen by the end users, network data is included in the reports. This is indicated by reducing the percentage reported for each service location(see report, figure 2). Network outages can pose some problems. If a location is serviced by more than one line but is reported as a single service location, the percentage of availability is calculated by dividing the total available hours for all nodes into the total scheduled hours for all the nodes. This method accounts for outages to only a portion of the service location.

AVAILABILITY DATA COLLECTION

Prior to this year, the availability data was manually collected by the computer operators, summarized by the operations shift supervisor, and reported only to the data center management. For upper management, the data was summarized and reported with other management summaries. A computer-assisted method for collecting availability data was developed. Commercially available systems to collect and report information about system availability required some manual adjustments, a decision was made to develop a system rather than use one of the existing products since it could be developed rather quickly. The existing data collection products can only report when the service begins and ends on the computer system, and may not reflect when the service is actually available. As an example, if CICS abends at 10:27 and is restarted at 10:28, traditional data collections methods will report a 1 minute outage. In fact, CICS may have taken 2 minutes to dump after the abend message was received and 5 minutes to restart to the point of restoration of service for a total outage of .1 hours or .15 percent for a service scheduled 68 hours per week. While being a trivial amount, for an unstable system experiencing many of these outages, this could be of note to management.

The availability data entry system uses SAS® to build a daily schedule for the online services to be tracked. Each service is then displayed with blank fields for the computer operators to enter the actual start and stop times and JES job number(see figure 1). Additional fields are available to enter outage reasons should an unscheduled outage occur. This is used to provide statistics about the types of outages that occur. Five sets of these fields exist for the possibility of 4 unscheduled outages on a single day. For systems with scheduled outages, multiple records are required for each set of service times. After the data is entered the hours and percentage available are calculated and the availability data base is updated with the current day's entries.

The network availability data has not been as easy to collect and maintain as the host availability. Automated methods were tried for collecting outage data. The use of NPDA alerts was attempted. There were problems in determining outage start and end times from the available data. All outages are recorded by the system, but depending on when and how service is restored it was not always possible to match the two records. The outage data is collected outside of the mainframe using a PC, uploaded and summarized. Because some network outages may recover themselves quickly, sometimes without the users being aware other than slow response, it was decided to report only outages that are longer than 3 minutes. Outages are applied to the standard service hours using the methodology previously described. The data is then merged with the host availability data to produce a consolidated number for each node reported.

SERVICE DATA

The consolidated report of service and availability includes data on response time. Response time data has always been misunderstood. There is host response and network response, and depending on how the measurements are taken and the software products used, a consistent response picture may not be accurately reported. This is not a problem as long as everyone reading the report is aware of the measurement. CICS host response begins when the transaction is started within CICS. Network time or queueing within CICS prior to transaction start is not counted. With definite response turned off, CICS response time ends after the last message is sent and the transaction terminates. If definite response is turned on, the CICS transaction waits for the terminal / controller to acknowledge the receipt of the screen. This may add a significant volume of data transmitted across the lines, thereby increasing response time. In one instance when definite response was accidentally turned on, response increased by a half second. Some measurement products require that definite response be used to record host response.

RTM, a hardware feature that collects response data, is available on IBM 3274 controllers. Using the NLDM or NETVIEW software, RTM collects statistics for defined services. The records are written to SMF as type 39's. The data is summarized by the service locations defined for reporting. One of the problems using the RTM data is that any devices not connected to a controller with the RTM feature (Tandem, Wang, LANs, etc) will not have any response time data. If this is a significant portion of the network, other alternative methods of collecting the data may be necessary.

THE REPORTS

The consolidated report (figure 2) shows the breakdown by service and service location. This report has been sent to the end-users. The columns (A, B, C, and D) show the availability of the service, the average network response time, the percent of network transactions under 3 seconds, the percent of network transactions under 5 seconds response time. The report is produced on the mainframe. If any adjustments are required,they are made prior to uploading to the electronic mail system for distribution.

On a monthly basis the data is combined with other host and non-host service indicators to produce a set of graphs(figure 3) for upper management. These include the service indicators described above and others such as word processing and local area networks. Much of data collection has not been automated, thereby requiring considerable effort to collect and tabulate the data. These graphs have been extremely well received by management.

THE REPORT HISTORY

Much of the data in the report (figure 2) evolved from a number of internal reports. A consolidated report was needed for management.

One of the first reports developed detailed a profile of CICS internal(host) response time. The report was sorted and summarized in various ways. The report was not effective because it presented too much data for management and could be misleading. The report showed that host response time was good, even though there were numerous complaints about response. A summary report was developed to show a response breakdown for the different service locations. This report presented a more concise picture about internal response time. In the CICS response breakdown report, data was summarized for each CICS service by service location. The report detailed the average response, percent of transactions completing within 3 seconds, the number of transactions by response limit.

The first version of the network response summary report directly summarized the SMF type 39 (RTM) records. The volume of data that was required made producing the report quite time consuming on a weekly and monthly basis. Software was used to summarize the data on daily basis so that reporting could be on a more timely basis. The RTM data is reported in the same manner as in the CICS report described above.

SUMMARY

Online computer services are a primary business function. There needs to be tracking of the service given to different users of the services provided. This system may not provide the data needed by all installations, but those that are not compiling the information or producing reports for management on some of these indicators may not be able to present a picture of the service given to the users. Graphics is a preferred way of showing the impact of the numbers to management. With a little time and effort, a meaningful set of reports and graphs can be created.

QUALITY IMPROVEMENT IN CAPACITY MANAGEMENT

Brian P. Wessner
Amdahl Corporation

ABSTRACT

Only a few short years ago the practitioner of Capacity Management was considered more of an artist than a person performing a rigorous analysis of future data processing resource requirements. As computer hardware has increased in power, and the resulting workloads becoming orders of magnitude more complex, the "art" of Capacity Management has been transformed into much more of a science. As the complexity of the analysis increased, the quality of that analysis has become more critical than ever. What were accepted "rounding" inaccuracies can now become significant shortfalls in system capacity. With today's business so dependent on automated systems for their lifeblood, shortfalls in system capacity can have disastrous results. This paper describes an integrated four-stage approach to the science of capacity management. It then proposes a method to enhance the quality, and hence the effectiveness and usefulness, of the process.

HERE'S THE SYMPTOMS

Have you ever had to ask yourself any of these questions:

* What happened to response times when we put up the new application? I thought our capacity forecast said we could handle it OK!

* We have a DASD management program, but how did we run out of available space so soon?

* We estimated the size of the new system with an analytic model, but why didn't we even come close to what we needed?

* Why have our workload levels been all over the board?

These and dozens of other questions like them have been asked by and of those having established capacity management programs. Having these questions asked by you, the manager of the capacity management program, sheds some doubt on the effectiveness of the program you worked so hard to get started. When these questions are asked OF you, they can be extremely embarrassing or potentially career-limiting if posed by upper levels of management.

WHAT'S THE PROBLEM?

You've had a good capacity management program going for some time now. The useful life of processors and DASD have been extended more than once; scheduled upgrades have occurred when you predicted they would; effective workload management has improved user service levels. How could changes in resource requirements be so grossly underestimated that system performance "went down the tubes"? Not only were business systems affected, but also your department's hard earned reputation for providing quality service.

Let's look at a different aspect of the process not normally included in most capacity management programs: the QUALITY of the capacity management program itself.

A TYPICAL CAPACITY MANAGEMENT PROGRAM

Any capacity management program is designed to take the existing environment, introduce anticipated growth projections, and forecast the timing and the amount of capacity upgrades. Input to the process comes from a variety of sources. Each data element describes needs at different organizational levels. This data must then be integrated into a single resource forecast. The bulk of the data translation and resource forecasting comes from within the capacity management process.

Let's look at a typical capacity management program and consider the major steps in the method, the inputs, the major outputs, and the decision process for handling future capacity requirements. The four stages are summarized in Figure 1.

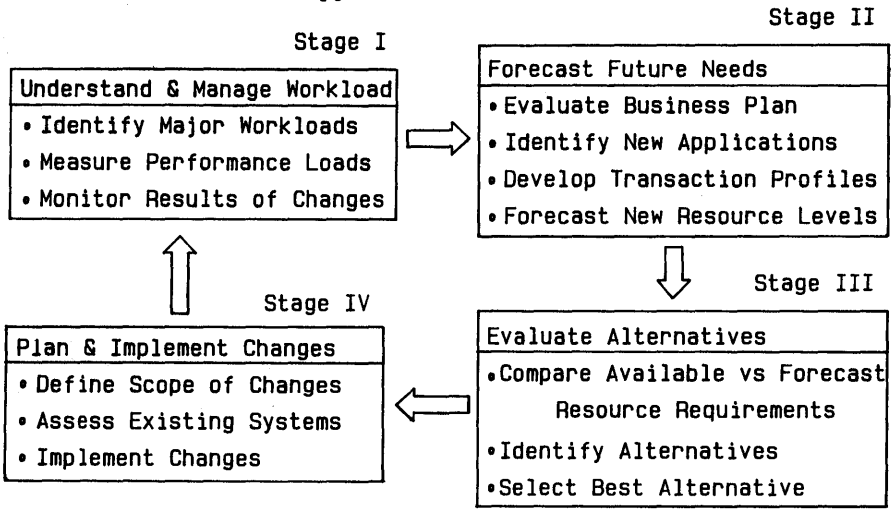

Figure 1. Four-Stage Capacity Management Process

The first stage in the capacity management process is to UNDERSTAND AND MANAGE THE EXISTING WORKLOAD. This objective can be achieved through:

(1) identifying major workloads to be evaluated. This should include on-line applications environments (CICS, IMS, etc.), typical on-line support systems (TSO, etc.), and batch or other background workloads that do not have real-time resource needs.

(2) measuring the performance provided by the overall system and the resource consumption levels required to provide that level of performance. These values can be developed using system-wide monitors such as RMF or VMMAP, job-oriented reporting systems such as JARS, and network monitors.

(3) Once the first two tasks are completed, monitoring and specific tuning actions can ensure continued satisfactory performance levels. Tasks (2) and (3) will then become the ONGOING FIRST STAGE after the capacity management program is in place.

The second stage of this capacity management process is directed at FORECASTING FUTURE NEEDS to be supported by the overall system. This stage includes:

(1) evaluating the current business plan to identify new or significantly changed business strategies.

(2) translating the business plan into requirements for new or enhanced applications systems.

(3) defining anticipated transactions, and their profiles for each of the new or existing applications.

(4) forecasting adequate resources to process the anticipated workload and still continue to meet service level requirements.

The third stage focuses on the EVALUATION OF ALTERNATIVES TO MEET THE FUTURE REQUIREMENTS. The forecasts developed in stage 2 are used as the primary input to this stage of the process. Based on those forecasts, the process then addresses:

(1) predicting future performance of the existing resource against the forecast from stage 2, and

(2) evaluating alternate configurations if existing capacity cannot handle forecasted workload levels.

The fourth and final stage of the capacity management program addresses PLANNING FOR AND IMPLEMENTING CHANGES TO EXISTING SYSTEM RESOURCES. Specific resources have been identified in stage 3. The next stage is to plan for the implementation of those resources. Potential changes are not limited to additions to the current system configuration; changes may include hardware reconfiguration, new or enhanced procedures, or tuning of available system components.

Once changes have been made to the current environment, return to the first stage of the process and continue to monitor overall system performance.

WHAT IS "QUALITY" ALL ABOUT?

Before we can point to those things that result in a "quality" capacity management program, let's look at some of the characteristics of any quality improvement program.

First we need to define "quality." We all know it when we see it, but "it" is typically a subjective impression or opinion: the new car that doesn't require continual trips to the dealer; the craftsman who takes deep pride and satisfaction in what he makes (many times by hand); or the capacity manager who is determined to develop accurate, timely forecasts of future computing resources. The bottom line definition of quality is "conformance to requirements." When someone is asked to "do it right the first time," the "it" is the requirement; in our case, the capacity management process.

Doing it right the first time defines an explicit standard of performance. DO IT RIGHT ALL THE TIME - not 99 percent or 90 percent, but all the time. Let's say that an airline mechanic attempts to repair nine out of ten planes correctly the first time. Would you want to be a passenger on that tenth plane?

How do you get things right the first time? Do you build a complex system of checks and balances to catch errors and then attempt to correct each one? With that approach the error has already occurred and you're adopting a "damage control" approach to correcting the problem; or you have to repeat the process again, adding a new control "on the fly" to prevent the error from happening a second time. Why not design the the system itself to PREVENT errors from happening? By specifying the system up front, before actually using it, you can define exactly what requirements are to be met. You can then identify where errors are most likely to occur and build in appropriate actions to prevent those errors from happening.

How do you measure quality? Should you devise one or more measures or yardsticks of quality performance? What about a "quality index" based on a mathematical formula? These approaches do not get to the bottom line: lack of quality costs your company MONEY. The money may be spent to modify the process, to buy and store excess inventories, to rework goods already manufactured, or worse yet to account for lost revenue from a dissatisfied customer.

How to Improve the Quality of Your Capacity Management Program

A capacity management program, like any other process-oriented activity, takes specific inputs, acts on those inputs through a series of processes, and produces outputs. The output, a product or service, is provided to someone. That someone can be called the "customer." To produce a satisfactory output you must understand the expectations, expressed in terms of requirements, that are in the mind of the customer. Viewing DP as a service-oriented organization that supports business goals and objectives, we must consider the ultimate customer to be the business manager that depends on those services.

What is the requirement, the "it" to be met? For most capacity management programs the requirement can be defined as:

> Ensure that sufficient computing resources, of the type necessary, are provided in a cost-effective manner to support successful business operations; the resources are to be available when they are needed and they must perform to agreed-upon standards.

Let's go back to the four-stage capacity management process and see how the quality of the process can be improved.

In the first stage we identify the major components of the overall workload. But how do we define "major"? Any application that assists a critical business function should be considered a major application. Manufacturing

companies rely heavily on order processing, materials management, inventory control, and order distribution systems. Technology-based organizations depend on design and engineering applications. Financial institutions conduct business through automated teller machine (ATM) networks. Other industries can also identify equally appropriate major systems that contribute to the success of the business.

Performance expectations are then used to determine how the current environment "measures up" against requirements for each major system. Service level agreements may be used to define user expectations. These requirements should be expressed in business terms understood by and agreed to by both the business unit and the DP organization. For example, an insurance company may measure business success by the number of new policies that are processed in a given time period. The performance of a policy processing system should therefore be measured in the same terms. DP then translates that need into specific resource consumption levels per unit of work, such as an online transaction.

The second stage of the capacity management process focuses on forecasting future needs. This stage combines inputs from a variety of sources into a single measure of anticipated requirements. It is important to include high-level forecasts, such as those found in the business plan, in the forecasting process.

Many times DP does not have access to the business plan to help in the forecasting process. Even if the plan is available, it may not describe projected sales growth, the timing of new products or service offerings, or the acquisition of additional business units. To reduce these uncertainties, DP should work with the major business units to define a set of possible business scenarios. Each scenario would be based on changes in key business growth assumptions. DP would then develop a range of alternatives based on each scenario. General management would assign a probability to each business scenario to guide the evaluation of potential capacity requirements.

Anticipated transaction volumes, as well as their profiles, should be tested for "reasonableness" against historical growth projections. If last year's business plan projected a 10 percent increase in orders, did the order entry system actually process 10 percent more transactions than the year before? What about the year before that? Compare the actual versus projected volumes to establish a trend in the projections published in the business plan. If projections are consistently higher or lower than the measured volumes, future forecasts should be adjusted accordingly. Processing done by today's system probably differs from when the system was originally implemented. Yesterday's queries may have become today's updates that consume significant computing resources. Only by tracking transaction profiles, and comparing those profiles to the planned business strategy, can consistent resource forecasts be made for the applications portfolio.

Resource forecasts are directly affected by the confidence placed in the business and application projections used to develop those forecasts. Forecasts developed in a uncertain planning cycle can be identified as "best case," requiring the lowest increase in resources; the "worst" case, associated with the highest growth scenario; and the "most likely" case with the highest probability of occuring. These scenarios then form a range of forecasts based on the business climate, not the computing environment. Business management can then direct the actions of DP based on the strategy it selects to run the business.

As we enter the third stage of the process the business environment has been defined and the resource requirements have been established. The next questions to consider are: "Can the current configuration handle the forecasted requirements? Will service levels continue to be met?" If the answers are yes to both questions then nothing more is necessary during this stage. If additional resources are required, what kinds of resources are they? For example, increased I/O resource usage can be accommodated through:

* adding new storage strings,
* caching frequently read program or data files,
* installing electronic data storage devices,
* reconfiguring of existing data storage resources,
* moving data to lesser used storage resources, or
* implementing a data archival program.

Each of these actions has its own advantages and disadvantages. Each action can address the I/O resource issue. The job of the capacity management process is to identify these potential actions and combine one or more of these actions into alternatives that can be evaluated by upper management.

What criteria does the general manager use to evaluate any set of alternatives? The manager considers the COSTS, the potential BENEFITS, and the RISKS associated with selecting each alternative. Recommendations (outputs) provided by the capacity management program should be presented in those terms; the process itself must then be structured to evaluate alternatives based on cost, benefits, and risk. Alternatives presented for management review may not be acted upon. The decision to bypass an alternative should be a conscious one made based on information that is presented in terms which can be understood by the business decision-maker.

Once the most desirable alternative has been identified the fourth stage, that of implementing the alternative, can begin. As with any change having a significant business impact, an action plan should be developed. The plan should identify resource additions, define organizational responsibilities for specific change activities, coordinate activities with the overall system change plan, and track progress against the plan. To plan effectively for and implement system configuration changes the process should address:

(1) identifying specific hardware and software components or procedures affected by the change;

(2) timing both the overall change as well as individual components of the change. For example, no change should be attempted during peak processing times such as year-end closings. A major change can be broken into smaller segments when possible;

(3) continuing satisfactory system performance while the change is being made. If performance may degrade while the change is being made, the duration and extent of performance degradation should be considered before going ahead with the change. If the impact of the change is too great, then other alternatives should be sought;

(4) minimizing the risks associated with the planned changes. Risks may relate to availability, performance, accuracy and timeliness of processing results, access to resources, or opportunity costs to the business if automated systems cannot be used while the change is in progress; and

(5) creating FALL-BACK PLANS to address each change. Each fall back plan should define the extent of the planned change, parameters measuring the success of the change, guidelines to decide if the change

should be "backed off," and the procedures to perform the fall back. The fall-back procedure should be tested and approved prior to actually implementing the change.

Resource modification attempts to eliminate resource shortfalls or reduce contention for available resources. Each change that is made carries with it specific expectations for improving resource capacity. Improvements following the actual change must then be compared to the expected change. But what criteria should be used to measure the success of the change, and how are these criteria applied by the capacity management process?

Before even starting this validation process, one important question must be answered: "What will happen if the change does not meet the stated requirement?" If no action will be taken then go no further. You are wasting your time with a validation process that will never improve the quality of your capacity management decisions. The answer to the question should be: "We will find the reason why the process (or data used within the process) did not provide an accurate forecast. We will update the process (or its data) to ensure that this error does not occur again."

How do you design this validation process? Start by identifying key factors that determine the success, or the conformance, to the requirement that you are attempting to meet. Then establish an acceptable measure of achieving that objective. For example, if an increase in processor capacity was expected to decrease response time by 15 percent and the actual improvement was only 5 percent, then the forecasting process or the input to the process was in error. Now locate the source of the error by reviewing the steps of the process that were used in this decision. How does this evaluation differ from previous successful evaluations? Was the data different? Was this the first evaluation since a major shift in business requirements or did the business shift occur AFTER we started the analysis? Did we recently install a new data collection or analysis tool?

Once the error has been found, identify corrective actions. These actions should include:

(1) describing the changes to be made,

(2) testing the proposed changes,

(3) deciding who will implement the changes,

(4) documenting the changes, and

(5) training those involved in the updated process.

Just as when making changes to computing resources, changes to the capacity management process require careful consideration and planning in order to meet the requirements of the process.

OTHER ELEMENTS IN QUALITY IMPROVEMENT

Up until now we have focused on improving the quality of the process itself. Let's shift our discussion to areas beyond the actual process that can contribute to an overall improvement in quality.

Quality of the process can be expected to improve as we remove obstacles that prevent people from doing the job right the first time. Typical obstacles can be removed by:

(1) providing adequate facilities, such as computer time for modeling exercises,

(2) installing tools needed to enhance or streamline the analysis process, such as financial evaluation spreadsheets,

(3) developing a training in sound capacity management techniques, project management, change control, and negotiation techniques,

(4) defining capacity management policies and procedures to ensure the consistency of the process, and

(5) enlisting management support and commitment to the success of the capacity management program

Each of these items can make the capacity management process more effective for the business it supports. Taken together, they can ensure the development of a QUALITY capacity management program.

SUMMARY

A quality capacity management program can result in tangible benefits to the bottom line of the business organization. In addition, DP's reputation can be strengthened immeasurably through timely, accurate, and business oriented management of future computing resources. The steps that were discussed in this paper form the framework for the development of a quality capacity management program that will benefit the business organization for years to come.

System/Software Engineering

ABSTRACT

There is a constant need for studies to identify, confirm and track long-term trends and problems, and various oscillatory behaviors such as over hours of day, days of week or month, etc. Such studies usually need to be done quickly. As such, the data for them must be conveniently stored. This paper describes a special performance and capacity data base created to maintain appropriate performance and resource usage data on-line for periods covering long time spans, such as up to one or two years at the MTA. It consists of hourly averages for each day in a collection of selected critical performance and resource usage parameters. Samples of quarterly reports generated from it are included.

1. INTRODUCTION

There is a constant need for ad-hoc studies and regular reporting over long time spans, such as months, quarters, or a year or more, that identify, confirm and track long term trends and problems and various oscillatory behaviors such as over hours of day, days of week or month, etc. For this purpose, it is desirable to maintain an on-line data base that contains a collection of critical data for time spans of at least a year, perhaps two years. The rationale for this type of database is developed in an earlier article by H. E. Jack [1]. The original raw SMF data, usually archived to tape, is too voluminous and cumbersome and too inconvenient to use for these purposes. Commercial performance data base systems such as Merrill Consultants' Merrill's Expanded Guide (MXG) or Morino Associates' MVS Integrated Control System (MICS) convert the SMF and RMF data into more convenient to use SAS[2] datasets. Additionally, they contain a collection of packaged reports that are good for general reporting and some troubleshooting, but they are still too voluminous and cumbersome for this use. But, their collection collection of extensive, detailed, conveniently detailed data is ideal for very rapid trouble shooting. These data, whether raw SMF or the more convenient SAS conversions, in their entirety would require 4 IBM 3380E volumes for a month of MTA data. Thus, it would be uneconomical to store all this data on-line. For the objective stated here, a collection of condensed data is required. This paper describes one effort at such a data base. Section 2 is an overview which briefly outlines what aspects of the computer system are of principle interest and the time granularity of the data to be collected and stored. Section 3 describes the method of building the data base along with the selection of items chosen and the rationale behind the choices. Section 4 shows and discusses the quarterly reports presently produced from these data. Section 5 assesses the present system and outlines future directions.

2. OVERVIEW

The first problem is to decide what aspects of the computer system are to be characterized. This determines the specific data base items to be collected. The next problem is to determine the level of time granularity for the data, i.e., instantaneously, hourly, by shift, daily, weekly, monthly, quarterly, etc. These two problems will now be briefly addressed. These issues are developed in more detail in Ref. [1].

2.1 THE FEATURES TO BE CHARACTERIZED

For the purposes of this data base, only the most critical aspects of the computer system should be characterized, at not too detailed a level. Most critical is data on the utilization of the CPUs, the memory, and the I/O subsystem. The next level of criticality is the workload responsible for these utilizations.

2.2 WHAT LEVEL OF TIME GRANULARITY

To represent the state of a system, observations of its key features can be recorded instantaneously (the level of the raw data, i.e., 5 minutes), hourly (averages over the hour), by shift (averages over the shift), daily (averages over the day), etc. Averages over a long period, such as shift or day, do not adequately capture the peak periods. For example, over a 10 hour shift the average CPU utilization could be 40%, while it was 95% for about two hours steady (20% of the shift) and only around 26% the remaining eight hours (80% of the shift). This misses a very serious situation. At the other extreme, data for every 5 to 15 minutes can be too detailed. For instance, a CPU utilization of 99% for a 5 minute interval, with adjacent intervals below 70% usually represents little pain. It can be seen from this that the interval chosen must be long enough for the averages to indicate overall conditions, yet short enough to preserve some temporal detail. An hour is chosen as the interval because it is long enough for averages to indicate overall conditions and short enough to retain temporal details. Additionally, it conforms to our cultural division of the day - lunch hour, happy hour, etc.

3. BUILDING THE DATA BASE

This section first describes the method of building the special data base. Then it discusses and describes the specific data retained and the sources from the performance data base and the SMF record types that are the source of the data base files.

3.1 THE METHOD OF BUILDING THE DATA BASE

For convenience and efficiency, the data base was built from the MICS system in use at the MTA. There is no requirement to use MICS; this can be accomplished with other performance data base systems or with raw SMF data and homegrown programs. Presently, this special data base is updated for use in generating quarterly capacity and performance status reports. A MICS Special data base was established to process the SMF tapes for the SMF and RMF components of MICS. It collects information for about 10 days per update. Available DASD limits this data base to five updates. After five of these updates, another job is run to extract information and update the performance and capacity data base, extracting the hourly sums of the selected data base items. The selections are made by way of SAS Keep statements. In the future, this data base update will be incorporated into the daily MICS update job. Figure 1 diagrams the present method of building and updating this data base.

3.2 THE DATA AND ITS SOURCES

Table 1 shows the collection of the SET and KEEP statements used to build the data base. All of the files are similar in construction to the MICS daily files using MICS type file names; this allows for common reporting procedures and is not a requirement. They contain data averaged or summed over each hour.
HARCPU is the CPU activity file derived from SMF Type 70 records. This file contains data on various user types (TSO, Batch, Started Tasks) in the system as measures of the extent of use (multiprogramming level); the number of users in various wait and ready states as a measure of prospective shortage of CPU resources; the busy, wait and up times, the configuration indicator, and on-line/off-line status for each CPU engine as measures of CPU activity and availability, and the number of various I/O interrupt as measures of the interrupt activity of the CPU.

HARCUA is the control unit activity file derived from SMF Type 73 records. This file contains controller activity and utilization data for measures of usage and request queue levels as a measure of performance problems and capacity shortage. The specific data items differ between MVS/370 and MVS/XA.

HARPCA is the physical channel activity file derived from the SMF Type 73 records. This file contains physical channel activity, utilization and service time data for measures of usage, and queue counts as a measure of performance and capacity problems.

SCPLCA and SCPLCU are logical channel (for MVS/370) and logical control unit (for MVS/XA) activity files derived from the SMF Type 73 records. This file contains data on requests deferred, channel/control unit busy and various queueing statistics as a measure of performance and capacity planning.

HARTCA is the total channel activity file derived from the SMF Type 73 records. The file contains data derived from the combination of physical and logical channel/control unit activity.

HARDEV is the device activity file derived from the SMF Type 74 and, from Type 78 records for MVS/XA only. The file contains data on DASD device activity, utilization and service time data as measures of usage; on number of requests pending, and various queueing data as measures of performance and capacity problems.
SCPPAG is the paging and swapping activity file derived from the SMF Type 71 records. The file contains data on paging, swapping, and virtual memory activity.

SCPPGA is the performance group workload file derived from the SMF type 72 records. This file contains data on the usage of CPU and main memory, as well as I/O and swapping activity for each performance group. In order for this file to be effective, it is important to assign each major software component (CICS, database system, etc.) and application group to an individual control performance group for tracking, even though it may not be necessary for performance or service level control of the group involved.

SCPPSD is the page/swap data set activity file derived from SMF Type 75 records. This file contains data on the usage of each page and swap data set including percent of use and I/O activity.

BATJOB is the job information file derived from the SMF Type 30, subtype 5 and Types 6 and 26 records. The file contains data on input queue time, input job classes and spooling and printing data.

BATPGM, BAT_ST, and BAT_TS are step oriented data for batch jobs and started task and TSO user data files derived from the SMF Type 30 subtype 4 records. The file contains data on TCB and SRB CPU times, I/O counts for DASD, Tape and Unit Record devices, virtual and real memory usage, and paging and swapping data.

4. THE QUARTERLY REPORTS

Figures 2 through 10 show examples of the quarterly reports. The first five, Figures 2 to 6, make up the performance section. The next three, Figures 7 to 9, are the capacity section. Figure 10 makes up the workload section. All graphs except Figure 2 are for Prime Time hours (Monday to Friday, 0800 to 1800, excluding holidays) because this is the most active and most critical period; Figure 2 is for all 24 hours over the whole reporting period. There is heavy use of on-line applications using CICS and IDMS database system, heavy interactive (TSO) activity, and moderately heavy demand batch activity, all running in competition with each other on each of three systems. The figures include a brief written summary of the graphs, describing the graphs and their significance.

These graphs are part of the quarterly report that is distributed to all Information Service management, from Assistant Directors and up, throughout the MTA and the agencies it serves.

4.1 THE PERFORMANCE GRAPHS

The first set of graphs, Figure 2, shows the processor utilization for each system by hour of day. The source data is the HARCPU file. The graphed values are the average over all days of the quarter as well as the maximum and minimum average values observed for each hour during the quarter. They are labeled "AVERAGE", "MAXIMUM" and "MINIMUM", respectively. This profile identifies the daily peaks and valleys of the day, including the usual mid-morning and mid-afternoon peaks and the lunch time valley in between.

Figure 3 shows the processor utilization for each system for each day in the reporting period. The source data is from the HARCPU file. This allows the identification of

heavy days and the worst case hours of each day with the characteristic behavior of these factors.

Figure 4 shows the demand paging for each system for each day in the reporting period. The source data is extracted from the SCPPAG file. This allows for tracking the paging subsystem and, indirectly, the real memory utilization.

Figure 5 shows the aggregate channel utilization for channels with DASD attached. It shows the data, extracted from the HARPCA file, for each system for each day of the quarter.

Figure 6 shows the aggregate DASD volume utilization of the volumes that account for the top 30% of total utilization for each system for each day of the reporting period. The source data is that extracted from the HARDVA file.

4.3 THE CAPACITY GRAPHS

Figure 7 shows two graphs. One is the aggregate processor usage averaged over the Prime Time hours over the quarter for all systems combined. The other is the peak hour average over the quarter for each system. The peak hour usage is what must be supported, while the shift average acts as an indicator of overall usage. It uses data obtained from the HARCPU file.

Figure 8 is the real memory usage during the peak hour of processor usage. To date, this data has come from OMEGAMON/MVS[3] snapshots taken at the peak hour for several days and then averaged.

Figure 9 has two graphs. One shows DASD storage usage compared to installed capacity. the other shows DASD access, the number of actuators available compared to the number needed to provide acceptable performance. The storage data is from the MICS VCC (VTOC/Catalog) component. The access data is estimated using the methodology of J. B. Majors [2].

4.3 THE WORKLOAD GRAPHS

Figure 10 shows the number of batch jobs ending during each day of the reporting period. This is a measure of system throughput.

5. FUTURE DEVELOPMENTS

Presented here is the first cut at this special Performance/Capacity data base and its present limited use of it. In the future, the data in this data base will be used for more extensive reporting. In particular, more detailed workload reporting, such as by agency and application, to track the fine grained temporal usage by agency, as compared to the usual gross monthly usage tracking, often done for accounting purposes. Additional data sources for tracking the on-line and data base facilities and the VTAM network remain to be added to the MICS system and extended to this data base. The capacity parts must be fully automated. Finally, the specific data items stored need to be reviewed and more finely tuned from this initial form.

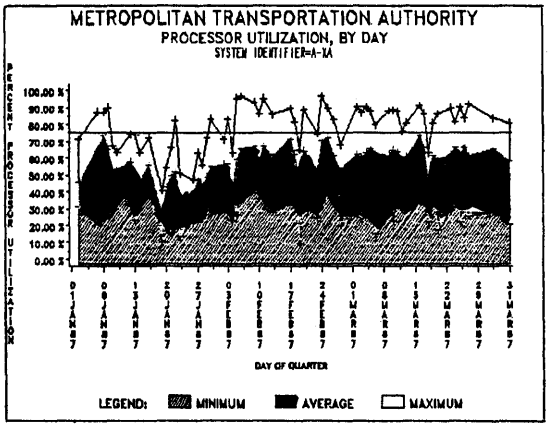
PROCESSOR UTILIZATION, BY HOUR

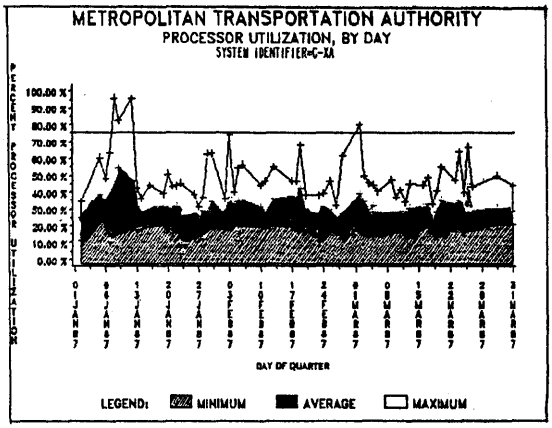
THE GRAPHS SHOW THE MINIMUM, AVERAGE, AND MAXIMUM CPU UTILIZATION BY SYSTEM OVER THE QUARTER. THE AVERAGE FOR EACH HOUR IS THE CPU UTILIZATION FOR THAT HOUR AVERAGED OVER ALL WORKING DAYS OF THE QUARTER. THE MINIMUM AND MAXIMUM VALUES ARE THE LOWEST AND HIGHEST VALUES, RESPECTIVELY, OBSERVED FOR THAT HOUR OVER ALL WORKING DAYS IN THE QUARTER.
RECOMMENDED THRESHOLD: 75% UTILIZATION

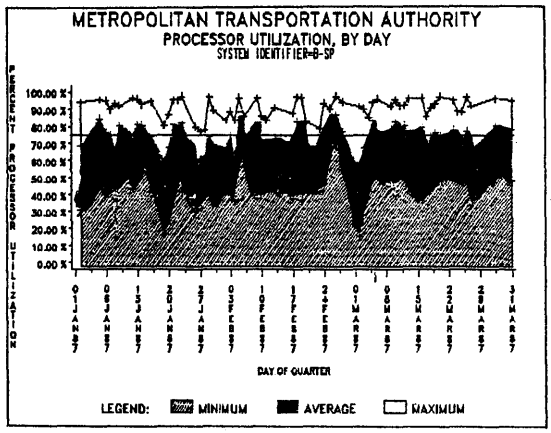
HIGHLIGHTS

THE PEAK HOUR HAS STAYED AT 10-11 A.M., EXCEPT THE C-SYSTEM HAS ITS PEAK BETWEEN 8-9 A.M. IT IS THIS HOUR WHICH IS USED TO PROJECT PEAK CAPACITIES AND LOADING.

FIGURE 2







PROCESSOR UTILIZATION, BY DAY

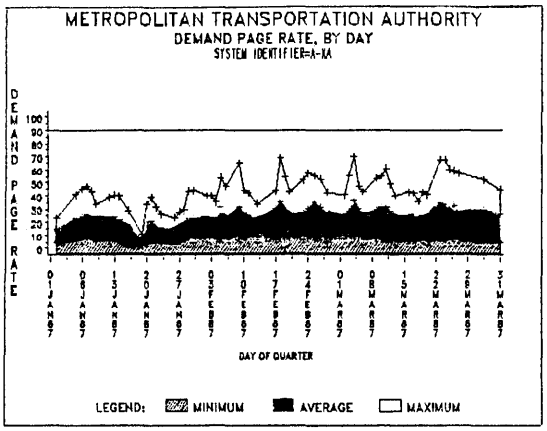
THE GRAPHS SHOW THE MINIMUM, AVERAGE, AND MAXIMUM CPU UTILIZATION BY SYSTEM FOR THE PRIME TIME SHIFT OF THE DAYS OVER THE QUARTER. THE PRIME TIME SHIFT IS 8 A.M.-6 P.M. FROM MONDAY TO FRIDAY. THE AVERAGE IS THE CPU UTILIZATION AVERAGED OVER VALUES OF THE PRIME TIME SHIFT FOR EACH WORKING DAY IN THE QUARTER. THE MINIMUM AND MAXIMUM VALUES ARE THE LOWEST AND HIGHEST HOURLY VALUES, RESPECTIVELY, OBSERVED DURING THAT DAY'S PRIME TIME. FOR PLANNING PURPOSES, THE AVERAGE CPU UTILIZATION IS TRACKED IN ORDER TO ENSURE THAT IT DOES NOT EXCEED THE INSTALLATION THRESHOLD.
RECOMMENDED THRESHOLD: 75% UTILIZATION

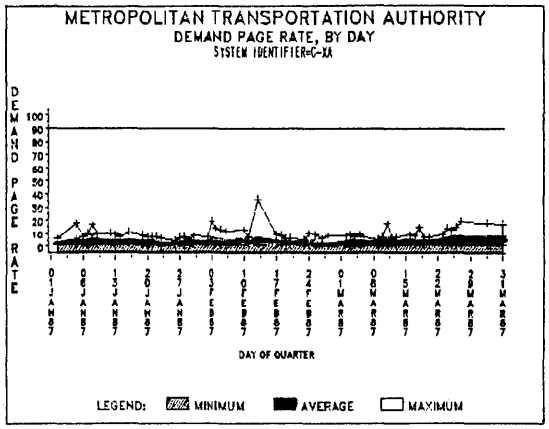
HIGHLIGHTS

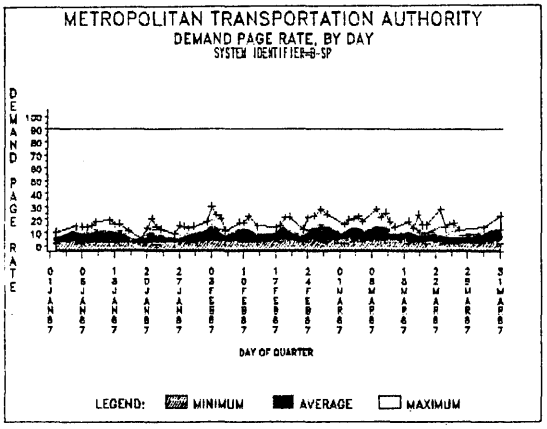
- THE INCREASED UTILIZATION ON THE SYSTEM B HAS CAUSED BY THE ADDITION OF THE NYCTA HUMAN RESOURCES SYSTEM IDMS DATABASE REGIONS, INCREASED TSO AND, IDMS USAGE FOR OTHER NYCTA AND LIRR WORK. THIS HAS CAUSED AN IMBALANCE IN UTILIZATIONS BETWEEN THE A AND B MACHINES: THE SHIFT IS TO THE B . CORRECTIVE LOAD BALANCING WILL BE DONE AFTER THE INSTALLATION OF THE NEW 3090-200 PROCESSOR IN THE EARLY PART OF THE SECOND QUARTER.

- CPU UTILIZATION ON SYSTEM C HAS REMAINED RELATIVELY STABLE IN THE 30% TO 40% RANGE . THIS VALUE WILL INCREASE AS MORE ONLINE WORK IS OFFLOADED FROM THE A AND B SYSTEMS ONTO THE C SYSTEM.

FIGURE 3







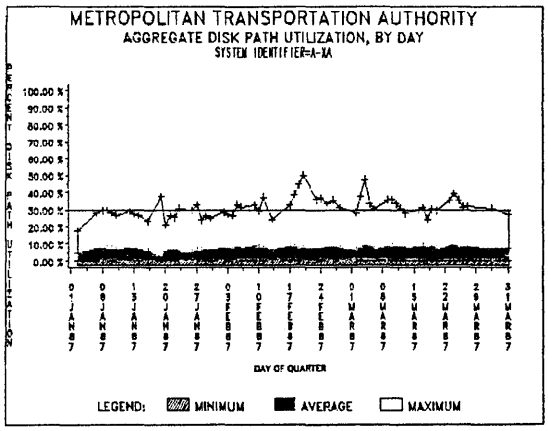
DEMAND PAGING RATE, BY DAY

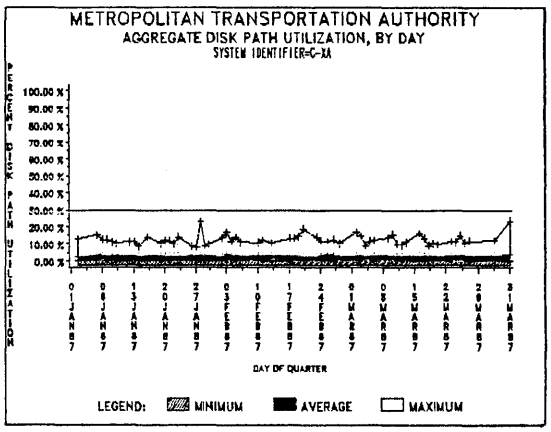
THE GRAPHS DEPICT THE MINIMUM, AVERAGE, AND MAXIMUM DEMAND PAGING RATES (PAGES/SEC) BY SYSTEM FOR THE PRIME TIME SHIFT OF THE DAYS OVER THE QUARTER. THE PRIME TIME SHIFT IS 8 A.M.-6 P.M. FROM MONDAY TO FRIDAY. THE AVERAGE IS THE DEMAND PAGING RATE AVERAGED OVER VALUES OF THE PRIME TIME SHIFT FOR EACH WORKING DAY IN THE QUARTER. THE MINIMUM AND MAXIMUM VALUES ARE THE LOWEST AND HIGHEST HOURLY VALUES, RESPECTIVELY, OBSERVED DURING THAT DAY'S PRIME TIME. THE SYSTEM SUPPORTS USERS WHOSE MEMORY REQUIREMENTS FAR EXCEED THE AMOUNT OF REAL MEMORY CAPACITY OF THE SYSTEM. THIS IS ACCOMPLISHED BY RETAINING IN REAL MEMORY ONLY THAT AMOUNT OF THE USERS' PROGRAM CODE AND DATA THAT WILL SIMULTANEOUSLY ALLOW THEM ALL TO GET INTO THE SYSTEM AND TO RUN EFFICIENTLY. THIS PORTION OF A USER'S REAL MEMORY USAGE IS CALLED THE WORKING SET. WHEN PROGRAM CODE OR DATA IS NEEDED THAT IS NOT IN MEMORY, THE SYSTEM TRANSFERS THEM FROM AUXILLIARY STORAGE (DISK) TO REAL STORAGE IN CHUNKS OF 4K PAGES. THIS IS CALLED DEMAND PAGING. DEMAND PAGING IS GOOD INDICATOR OF CONTENTION FOR MEMORY.
RECOMMENDED THRESHOLD: 90 PAGES/SEC

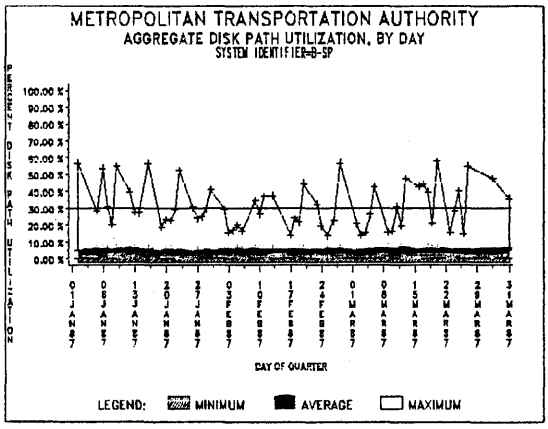
HIGHLIGHTS

- ON ALL THREE SYSTEMS, DEMAND PAGES RATES ARE WELL BELOW THE THRESHOLD OF 90 PAGES/SEC. THESE LOW RATES ARE DUE PRIMARILY TO THE ADDITION OF REAL MEMORY TO THE A AND B SYSTEMS IN THE SECOND QUARTER OF 1986, AND HAVE REMAINED STABLE SINCE THIS UPGRADE.

FIGURE 4







AGGREGATE DISK PATH UTILIZATION, BY DAY

THE GRAPHS PRESENT THE MINIMUM, AVERAGE, AND MAXIMUM DISK PATH UTILIZATION BY SYSTEM FOR THE PRIME TIME SHIFT OF THE DAYS OVER THE QUARTER. THE PRIME TIME SHIFT IS 8 A.M.-6 P.M. FROM MONDAY TO FRIDAY. MINIMUM AND AVERAGE VALUES WERE DERIVED FROM THE AVERAGED UTILIZATIONS OF ALL DISK PATHS ON A GIVEN SYSTEM; THE MAXIMUM VALUE REPRESENTS THE HEAVIEST-UTILIZED DISK PATH FOUND DURING THAT DAY.

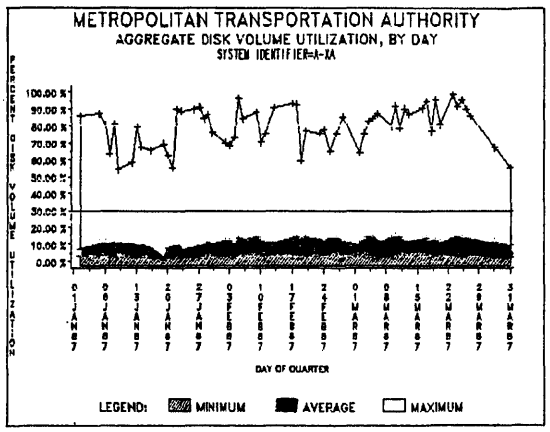
A DISK PATH CONSISTS OF A CHANNEL PATH/DISK CONTROL UNIT COMBINATION WHICH CONNECTS EACH BANK OF DISK DEVICES TO THE CPU. THE PATH IS BUSY WHENEVER DATA IS TRANSFERRED TO OR FROM DISK. PATH UTILIZATION IS THUS A MEASURE OF THE I/O INTENSITY OF THE WORKLOADS RUNNING ON A GIVEN SYSTEM.
RECOMMENDED THRESHOLD: 30% UTILIZATION

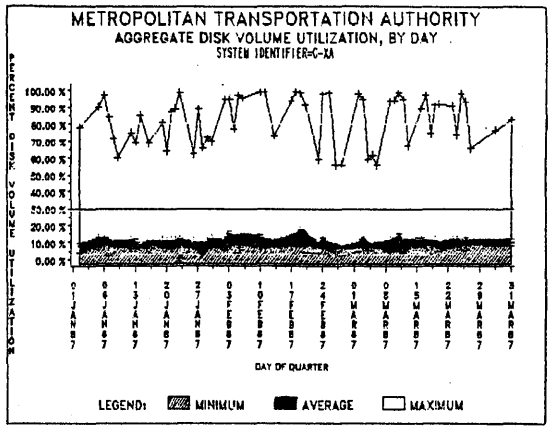
HIGHLIGHTS

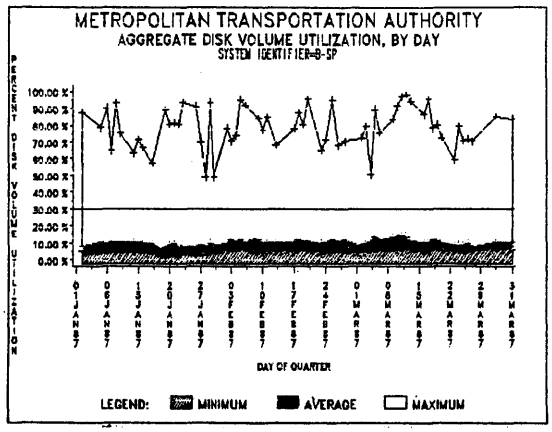
- AVERAGE PATH UTILIZATION IS WELL BELOW THE 30% UTILIZATION THRESHOLD.
- THE MAXIMUM PATH UTILIZATION IS CAUSED MOSTLY BY PAGING AND SWAPPING ACTIVITY. ALTHOUGH UTILIZATIONS ABOVE 30% ARE NOT RECOMMENDED FOR PATHS SERVICING USER REQUESTS, PATHS SERVING SWAP REQUESTS USUALLY EXHIBIT HIGH UTILIZATIONS WITHOUT ADVERSELY IMPACTING OVERALL SYSTEM PERFORMANCE. THUS, HIGH SWAP PATH UTILIZATION IS NOT A PROBLEM IN AND OF ITSELF. HOWEVER, TWO FACTORS SHOULD BE NOTED:
  - SOME OF THE PLOTTED MAXIMA CONSIST OF PATHS SERVICING USER REQUESTS;
  - SWAP DATASETS ARE SHARING PATHS WITH USER I/O.

CONCLUSION: DASD I/O IS GRADUALLY BECOMING A BOTTLENECK TO SYSTEM PERFORMANCE AND REQUIRES TUNING.

FIGURE 5







AGGREGATE DISK VOLUME UTILIZATION, BY DAY

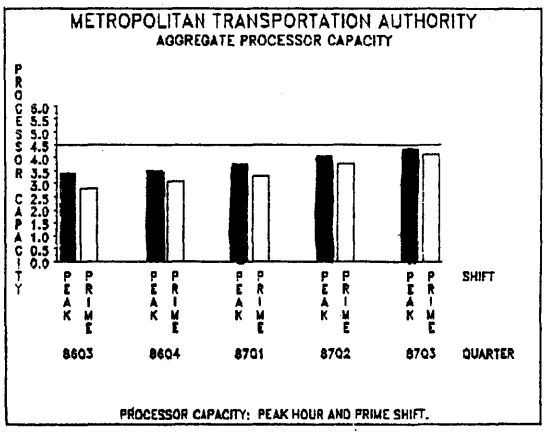
THE GRAPHS DISPLAY THE MINIMUM, AVERAGE, AND MAXIMUM DISK VOLUME UTILIZATION BY SYSTEM FOR THE PRIME TIME SHIFT OF THE DAYS OVER THE QUARTER. THE PRIME TIME SHIFT IS 8 A.M.-6 P.M. FROM MONDAY TO FRIDAY. THE DATA FOR THESE ANALYSES ARE DASD VOLUMES WHICH ACCCOUNT FOR 80% OF THE ACTIVITY. THE MINIMUM AND MAXIMUM VALUES REPRESENT THE LOWEST AND HIGHEST HOUR DETECTED FOR THAT DAY. MINIMUM AND AVERAGE VALUES WERE DERIVED FROM THE AVERAGED UTILIZATIONS OF THE TOP 30% OF VOLUMES ON A GIVEN SYSTEM; THE MAXIMUM VALUE REPRESENTS THE HEAVIEST-UTILIZED DISK VOLUME FOUND DURING THAT DAY.
RECOMMENDED THRESHOLD: 30% UTILIZATION

HIGHLIGHTS

- AVERAGE VOLUME UTILIZATION IS WELL BELOW THE 30% UTILIZATION THRESHOLD
- A FEW DISK VOLUMES ARE EXHIBITING HEAVY I/O ACTIVITY. THE BULK OF THESE VOLUMES ARE SYSTEM PACKS CONTAINING SYSTEM LIBRARIES, CATALOGS, AND PAGING/SWAPPING FILES. IN ADDITION, SEVERAL TSO VOLUMES ARE BEING HEAVILY UTILIZED. SYSTEM VOLUMES WILL BE EXCLUDED IN LATER REPORTS IN ORDER TO CONCENTRATE MORE READILY ON I/O GENERATED BY USER TASKS. ALTHOUGH THE PLOTTED MAXIMA APPEAR SOMEWHAT FRIGHTENING, IT SHOULD BE NOTED THAT THESE POINTS REPRESENT A FEW, HEAVILY-UTILIZED VOLUMES - MOSTLY SYSTEM AND WORK PACKS, AND SOME USER VOLUMES (E.G., TSO).

CONCLUSION: DASD I/O IS GRADUALLY BECOMING A BOTTLENECK TO SYSTEM PERFORMANCE. REDISTRIBUTION OF DATASETS OVER THE PACKS IS NEEDED. SUCH ACTION REQUIRES THE USE OF ADEQUATE MEASURING TOOLS.

FIGURE 6



METROPOLITAN TRANSPORTATION AUTHORITY
AGGREGATE PROCESSOR CAPACITY
PROCESSOR CAPACITY
PEAK PRIME SHIFT

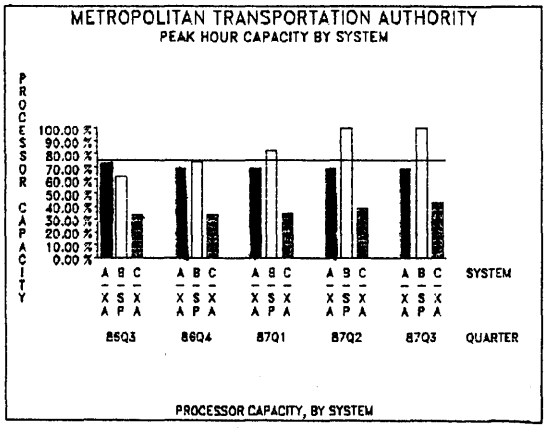
PROCESSOR CAPACITY: PEAK HOUR AND PRIME SHIFT.



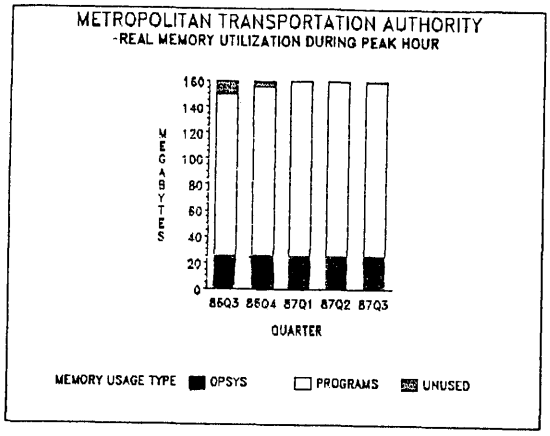
AGGREGATE CPU CAPACITY

THIS GRAPH DEPICTS THE INSTALLED, USED, AND AVAILABLE CPU CAPACITY OF THE MTA DATA CENTER OVER FIVE QUARTERS - THE PREVIOUS TWO, THE PRESENT, NEXT TWO. THE NEXT 2 QUARTERS WERE DERIVED BY EXTRAPOLATING THE GROWTH SHOWN OVER THE FIRST THREE QUARTERS. THE EFFECTIVE CAPACITY IS 75% OF INSTALLED CAPACITY, OR 4.5 CPU HOURS OUT OF THE TOTAL CPU CAPACITY OF 6 CPU PER ELAPSED (WALLCLOCK) HOUR.
CPU UTILIZATION IS GROWING SLIGHTLY SLOWER THAN PREVIOUSLY PROJECTED. THIS IS THE THIRD QUARTER 1986 LOAD DUE TO NYCTA BUDGET DATA ENTRY (BDES) BATCH WORK. THIS LOAD WILL, HOWEVER, RETURN IN THE THIRD AND FOURTH QUARTERS OF 1987. THE UPGRADE DUE IN THE SECOND QUARTER OF 1987 OF REPLACING THE IBM 3081KX PROCESSOR WITH AN IBM 3090-200 PROCESSOR INCREASES THE AGGREGATE PROCESSOR POWER BY ABOUT 33%. THIS SHOULD PRECLUDE CONCERNS FOR CPU HORSEPOWER FOR AT LEAST THE NEXT TWO OR THREE QUARTERS.

PEAK HOUR CPU CAPACITY BY SYSTEM

THIS GRAPH SHOWS THE CPU UTILIZATION OF EACH SYSTEM OVER FIVE QUARTERS - THE PREVIOUS TWO, THE PRESENT, AND THE NEXT TWO. THE VALUES FOR THE NEXT TWO QUARTERS ARE DERIVED BY EXTRAPOLATING THE GROWTH SHOWN IN THE FIRST THREE QUARTERS.
DURING THE SECOND AND THIRD QUARTERS OF 1986, A LARGE AMOUNT OF WORK WAS MOVED FROM SYSTEM "A" TO SYSTEM "B". THIS ACTION RESULTED IN A MORE BALANCED UTILIZATION BETWEEN THESE TWO MACHINES. INCREASED DEVELOPMENT ACTIVITIES ON THE "B" SYSTEM HAVE DESTROYED THIS BALANCE. THE OVERUTILIZATION OF THE "B" SYSTEM WILL CONTINUE THROUGH THE SECOND QUARTER OF 1987. AS THE NEW IBM 3090-200 PROCESSOR IS INSTALLED AND "BURNS IN" DURING THE SECOND QUARTER, THE WORKLOAD WILL BE APPROPRIATELY REDISTRIBUTED OVER THE THREE SYSTEMS TO ACHIEVE BALANCE.
BECAUSE OF THE EXPECTED UPGRADE OF THE IBM 3090-200 REPLACING THE IBM 3081KX, AND THE A-SYSTEM WORKLOAD MOVING FROM THE ONE-HALF IBM 3084QX TO THE NEW PROCESSOR, THE PROJECTIONS FOR THE A-SYSTEM UTILIZATION SHOULD BE REDUCED TO HALF OF THEIR PRESENTLY SHOWN HEIGHTS. THIS IS BECAUSE THE TWO CPU ENGINES ON THE IBM 3090-200 HAVE ABOUT TWICE THE COMPUTING POWER AS THAT OF THE TWO CPU ENGINES ON ONE-HALF OF AN IBM 3084QX.

FIGURE 7



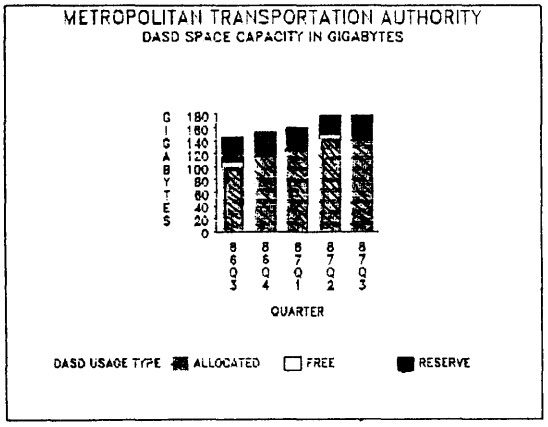
REAL MEMORY UTILIZATION DURING PEAK HOUR

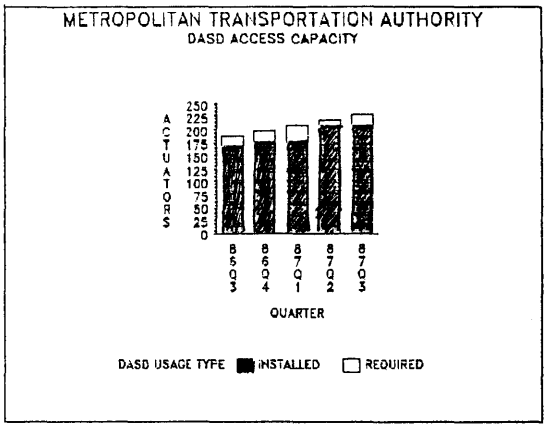
THIS GRAPH DEPICTS A MODEL SNAPSHOT OF REAL MEMORY UTILIZATION DURING THE PEAK HOUR (10-11 A.M.). THE BULK OF MEMORY IS USED BY APPLICATIONS, ESPECIALLY ONLINE IDMS AND CICS REGIONS; REMAINING MEMORY IS SPLIT BETWEEN OPERATING SYSTEM (MVS NUCLEUS, ACCESS METHODS, ETC.) AND UNUSED FRAMES.

MEMORY UTILIZATION IS GREATER THAN ANTICIPATED BECAUSE PREVIOUS SCENARIOS ASSUMED THE USE OF THE 3084 IN SINGLE-IMAGE MODE (ONE COPY OF THE OPERATING SYSTEM RUNNING BOTH SIDES OF THE 3084) INSTEAD OF THE CURRENT PARTITIONED MODE (EACH SIDE UNDER CONTROL OF SEPARATE COPIES OF THE OPERATING SYSTEM). THE IMPLEMENTATION OF SINGLE-IMAGE MODE, DELAYED DUE TO SOFTWARE PROBLEMS, WILL ELIMINATE ONE COPY OF THE OPERATING SYSTEM AND FREE APPROXIMATELY SIX TO SEVEN MEGABYTES.

THE FULL MEMORY IS NOW BEING TOTALLY USED. FROM THIS POINT ON PAGING CAN BE EXPECTED TO INCREASE AS ONLINE SYSTEMS WITH THEIR INCREASED MEMORY DEMANDS CONTINUE TO GROW. THIS EXPECTATION OF INCREASED PAGING MAY NOT BE FULLFILLED DUE TO THE DIFFERENT ARCHITECTURE OF THE IBM 3090-200 DUE

FIGURE 8





DASD SPACE CAPACITY IN GIGABYTES

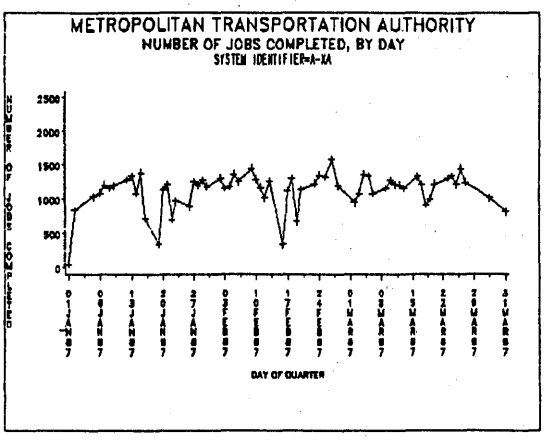
CURRENT PLANNING CALLS FOR A MAXIMUM EFFECTIVE DASD SPACE UTILIZATION OF 75% OF INSTALLED CAPACITY (I.E., 25% OF INSTALLED CAPACITY FOR RESERVE, FILE GROWTH, ETC.). THE FREE SPACE REPORTED HERE IS THE TOTAL INSTALLED MINUS THE AMOUNT ALLOCATED MINUS THE 25% OF INSTALLED CAPACITY FOR RESERVE. IF THIS NUMBER FALLS BELOW ZERO, IT IS REPORTED AS ZERO AND THE RESERVE IS REDEFINED AS THE TOTAL INSTALLED MINUS THE AMOUNT ALLOCATED. THE CURRENT INSTALLED DASD CAPACITY IS ABOUT 161 GIGABYTES (A GIGABYTE IS ONE BILLION BYTES); EFFECTIVE CAPACITY IS THEREFORE 120 GIGABYTES.

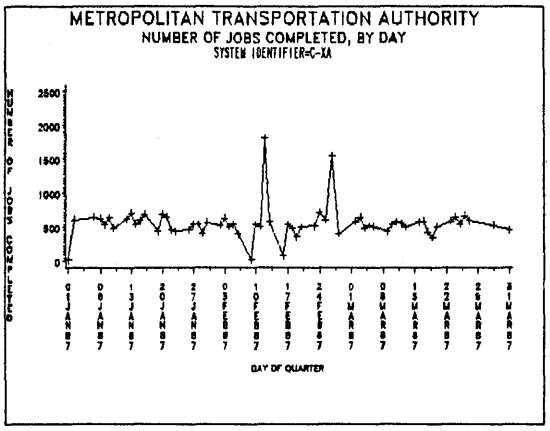
THE EFFECTIVE CAPACITY IS EXHAUSTED. BUT RELIEF IS IMMINENT BECAUSE 8 IBM 3380 DASD DEVICES (32 ACTUATORS AND 40 GIGABYTES) ARE DUE TO BE DELIVERED ABOUT JUNE 1, 1987 UPON COMPLETION OF THE NEW DASD ROOM. THIS SHOULD MEET OUR STORAGE SPACE NEEDS FOR THE THIRD AND FOURTH QUARTERS OF 1987. THE SECOND QUARTER 1987 STORAGE WILL, HOWEVER, BE TIGHT.

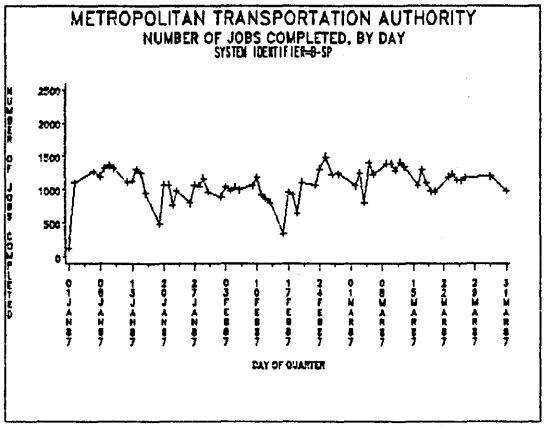
DASD ACCESS CAPACITY

"ACCESS CAPACITY" IS A TERM WHICH REFERS TO THE NUMBER OF ACTUATORS - DISK ARMS - REQUIRED TO SERVICE THE I/O RATES GENERATED BY THE GROWING WORKLOAD. AS SHOWN, THE MTA HAS APPARENTLY EXCEEDED INSTALLED ACCESS CAPACITY SINCE THE THIRD QUARTER OF 1986. I/O SUBSYSTEM TUNING WOULD BUY BACK ABOUT 15% TO 20% OF THE ACCESS CAPACITY. SOME DEVICES AND PATHS ARE PRESENTLY UNDERUTILIZED WHILE OTHER ARE OVERUTILIZED. OTHERWISE ABOUT 32 ADDITIONAL ACTUATORS ARE NEEDED TO GUARANTEE GOOD PERFORMANCE. 32 MORE ACTUATORS ARE DUE TO BE INSTALLED ABOUT JUNE 1, 1987 AFTER COMPLETION OF THE NEW DASD ROOM. THAT CAPACITY WILL BE EXCEEDED AS QUICKLY AS IT IS INSTALLED. TUNING BY REDISTRIBUTING DATA SETS OVER THE VOLUMES WOULD BUY BACK AT LEAST ABOUT 20% OF THE ACCESS CAPACITY. DASD ACCESS CAPACITY, ALONG WITH THE GIGABYTE PROJECTIONS, DEFINE THE AMOUNTS OF DASD WHICH ARE TO BE REQUIRED TO SUPPORT THE WORKLOAD.

FIGURE 9







WORKLOAD GRAPHS

NUMBER OF JOBS COMPLETED, BY DAY

THE GRAPH SHOWS THE NUMBER OF BATCH JOBS COMPLETED DURING EACH 24 HOUR DAY OF THE QUARTER FOR EACH OF THE THREE SYSTEMS.
RECOMMENDED THRESHOLD: N/A

FIGURE 10

FINANCIAL CONSIDERATIONS IN CAPACITY PLANNING

Jerry L. Rosenberg
SRM Associates, Ltd.

ABSTRACT

The corporate decision to acquire additional data processing equipment is usually based on multiple considerations. The most critical of these is often the financial aspects of the available configuration options. While capacity planners have become more sophisticated in the methods of selecting the best technical configuration, we have been slow to address the budgetary aspects of our recommendations.

This paper will point out the topics that should be considered and presented to develop more complete hardware recommendations. The author will discuss the key areas of financial concern and how they affect purchase decisions. The hidden costs of new equipment will be covered. These will include site preparation, software licenses, personnel costs, conversion efforts, peripheral equipment, and cost of money.

A case study will illustrate the use of a standard PC based spreadsheet package for analyzing costs and determining present costs of equipment. The author will use this technique to develop a total cost of a configuration by year and show how to represent the real yearly dollar cost of each alternative.

Before we enter into a discussion of the content and nature of the financial analysis that capacity planners should perform, we should first consider what might be a common question - Why should capacity planners worry about monetary issues at all?. To best address this question, a definition of the goals of capacity planning must be established.

The goal of capacity planning, as I see it, is to insure that the proper configuration is in place to address the data processing requirements of the enterprise in sufficient time to maintain satisfactory levels of service to the user community in a cost-effective manner.

This goal is not accomplished when the right technical solution is determined. It requires that the proper configuration be justified, acquired and implemented in a time-sensitive manner. Figure 1 represents this view of capacity planning. It must be an interface function that incorporates and addresses the technical aspects of the data processing environment and staff with the service needs and expectations of the user communities. In addition, it must be understood that these two often diverse groups are further influenced by the overall demands and goals of the corporation. These high level goals are usually related to and expressed in the desire to increase profitability. It is vital for the capacity planner to accept and understand that most bottom-line decisions in the corporation will be made based on profitability and return on investment. The logical approach is to not fight the tide but rather to go with the flow and utilize the financial aspects of configuration analysis to our own advantage.

As an added incentive, I would ask capacity planners to consider whether they have ever submitted a plan to management that was well developed, artfully presented and technically correct but which was not followed for budgetary or other financial reasons. The most common complaint I hear from capacity planners is - They ask me to do the study, then they don't listen to me anyway. This counter-productive frustration is avoidable. You really cannot expect anyone to respond to you if you do not speak to them in the language that they understand. Let's face it, businessmen talk money, and ultimately it's businessmen who make the final decision concerning data processing acquisitions.

If you have agreed with the discussion so far (or, at least, not discounted it totally), let's continue with a very high-level overview of the contents of a capacity study. My suggestions for contents of a capacity presentation would include:

- o Statement of the objective of the study
- o Methodology used
- o Hardware and software alternatives
- o Benefits/exposures of each alternative
- o Lifespan of each alternative
- o Impact of not adopting each approach
- o Cost (current and future) of each alternative
- o A recommended approach

The remainder of this paper will deal with the presentation of cost factors. As a first step, let's do some mental stretching exercises to prepare us for this activity. As can be seen, many of the other sections of the presentation are technical in nature, while the cost issue has to be more business or management in scope. To begin to make the transition, we can view the concepts and terminology that are inherent to each group:

Technical Concepts	Management Concepts
Monitors	Planning
CPU	Budgeting
I/O	Chargeback
Memory	User Service
Benchmarks	Cost of Service
Modelling	Return on Investment
Statistical Analysis	Useful Life

It should be no surprise that corporate management expects to see an analysis and recommendation that addresses and that is couched in the issues that are listed in column two. Their goals are optimizing profits and minimizing costs. If we, as capacity planners, want to get their attention, we have to deal in these issues.

Many of us in the technical arena have a difficult time even beginning this process of financial analysis. For those who require a checklist to help them through the transition period, I offer the following steps that can be taken to help one become more sensitive to the financial aspects of data processing.

- o Understand the primary business of the firm
- o Understand how computing supports the primary business
- o Start thinking and talking about profitability
- o Discuss both costs and return on investment
- o Don't be afraid of financial terms and concepts

As you get more comfortable in dealing with the financial issues, you can incorporate the following guidelines:

- o Wherever possible, equate costs to potential returns. What this really means is, always try to present the positive side of the picture. It is best to show data processing acquisitions as investments rather than costs.

- o Relate your analysis to the corporate bottom line and the budget. Always attempt to illustrate how the recommended approach will aid other departments in the fulfillment of their goals. Point out how this effort will lead to increased corporate profitability.

- o Discuss the costs of not meeting service level objectives. These will include:
  - Lost sales due to inadequate service
  - Lost revenue due to the inability to react or due to lack of knowledge
  - Employee Dissatisfaction
  - Inhibited Business Growth
  - Violation of Service Level Contracts
  - Legal Problems as a result of Non-performance

Figure 2 summarizes the point I am trying to make. Sooner or later all of us have to accept that the monetary issues must be addressed to insure a satisfactory outcome to the capacity planning process. Hopefully, the reader agrees with this proposal and we can continue on to the discussion of those factors which make up configuration cost that should be analyzed and presented.

Cost Factors in Configuration Analysis

How does one go about including financial analysis in a capacity study ? First, we should begin by understanding all of the cost factors that apply to configurations. Just as we accept that sizing a CPU does not constitute a complete evaluation, we must understand that there are more financial considerations than just the lease vs. buy concern. In the technical analysis we are astute enough to include the necessary ancillary equipment required to create a total configuration. In the financial analysis we must discuss all of the potential monetary exposures. At a macro level they include:

- o Hardware
- o Software
- o People
- o Facility
- o Supplies
- o Overhead
  - Indirect Costs
  - General Business Expenses

The paper will discuss each of these topics and itemize some of the concerns that should be addressed. In addition, as a second level topic set, the following concepts will also be covered:

- o Direct Costs
- o Cost of Early Disposition
- o Conversion Costs
- o Life Expectancy
- o Supportive Equipment
- o Licenses

In most cases, these issues can result in savings rather than costs. If this is the case, be very sure to bring this to light. Let's discuss each of the major areas in some detail.

Hardware

This issue is the most readily understood component of financial analysis, but it does have some pitfalls. To put the exercise in the right perspective, we should postulate rule #1. The capacity planner is not the corporate financial analyst. He is going to include cost and benefit figures in his proposal but he is not the one who is going to perform lease/buy analysis, estimate the value of money or find the most advantageous third party arrangement.

The capacity planner is only responsible for enumerating all of the costs associated with a given technical solution and making reasonable comparisons between alternate solutions. The key here is to make sure that you are comparing apples to apples. Don't try to estimate the best lease arrangement, just use the same one for all comparisons. What this means is, if you use a purchase price for one configuration, don't compare it to a third party three year lease for another. We are simply trying to establish a relative cost/benefit ratio. It is important that all factors are adjusted to the same base. In essence, we are not attempting to develop an absolute cost of each configuration. That will depend on negotiations and leasing terms. We are trying to establish the relative financial impacts of various configuration alternatives.

When dealing with hardware costs, it is also important to relate to several key components in the cost equation: Supportive Equipment, Early Disposition, and Life Expectancy.

Supportive Equipment

This is an often neglected hidden cost in configuration selection. The CPU alone does not constitute the configuration. Most likely changes to all the peripheral pools will will be required. Each of these must be delineated to produce a complete picture of the requirements of the recommendation. The costs of all components of the suggested configuration must be addressed.

Early Disposition

The capacity planner must be aware that most configurations are financed over a fixed time period. Even if there is no penalty for early lease buy-out, there is still the need to account for the book value of the equipment in the asset columns of the company books. We must either consider this to be an extra cost that is included in the equation or we must find an equitable solution to the disposition problem.

Fortunately, in current times, with the advent of multiple data center corporations, the question is often easily addressed by relocating a piece of equipment from one site to another. The ability to suggest this course of action requires that the capacity planner keep aware of two key pieces of information: the current lease/amortization status of in-house equipment and the capacity requirements of the entire corporation. The effort will be well rewarded. It is always expeditious to have a means of defraying any costs that you might be incurring.

Life Expectancy

This topic is a double edged sword. The tendency might be to over estimate the potential cost of a configuration in order to lower the projected annual cost. Resist the temptation. If you succumb, at the end of the real useful life of the equipment, you will be faced with the early disposition question mentioned above. Except that the equipment that you are disposing of will have a highly inflated book value that you cannot recoup. Spend the time and effort and develop a reasonable life expectancy for the configuration that you propose.

There have been several papers over the past few years that have addressed hardware related financial issues. I

refer the reader to those for future discussions of lease/buy analysis, third party options, etc. These are important issues to consider, but are more complex than the novice financial analyst should attempt. For starters, we are trying to just identify and itemize as many of the costs associate with a given proposed configuration as possible. In addition, we will be concerned with quantifying the benefits (financial) of each component of our recommendation.

Software

The need to convert software or alter existing licensing agreements is often overlooked in developing configuration costs. The licensing issue alone can radically affect monthly charges.

There are some obvious reasons for a software change resulting from a hardware acquisition. Recently, many data centers coordinated conversions to XA to coincide with (or predate) the implementation of new hardware. I suspect that many of them did not represent the software conversion as a necessary cost of the new equipment. It really was. In addition, to make full use of the new environment, new releases of sub-system software (CICS, IMS, etc.) will be installed over time. These should also be addressed. The planner should not avoid these items since it is often easy to offset the costs of conversion with long range benefits. Including all of the cost factors gives management the impression that a thorough job has been done and makes them more confident with the overall recommendation.

The question of software licenses can often work to your advantage. The critical question to ask yourself in reviewing licenses is are they CPU or site based. For those products that are site based (one license permits you to use the product on any CPU at a site) there is probably little change in the costs associated with the product. However, for those components that are priced per CPU (the license allows the use of the product on only one CPU), there is a potential for either cost or savings. If you are making a one for one replacement, It is probable that the costs of software will stay constant (except where new releases have higher costs). If you are replacing CPU's with an increased number of CPU's, then the costs will increase.

The good news is that very often the acquisition of a large CPU is the result of incorporating workloads from several smaller complexes. If this is the case, the company stands a chance of recouping sizable software rental costs for CPU based products. When making comparisons, be sure to investigate how each proposed configuration and workload mix will affect the software license question and include it in your analysis.

People

Whatever the activity, there will be some costs incurred for the expenditure of time and effort. Don't forget them. They can add up. Even if you do not feel comfortable equating the time required to actual dollars for hardware and software efforts, at least mention that these issues exist so that management can consider them.

The proposal should include the efforts of hardware and software implementation, conversion needs, re-education and the possibility of an increase or decrease in real head count. (It is hard to operate two machines with the same staff as you operated one machine.) It is advisable to bring these issues out in the open under your control rather than to allow another department (i.e.. operations management) to use them in countering your recommendation later on.

Facility Requirements

This is another often overlooked area of cost. There is a significant amount of site costs that occur in direct support of the computing environment. These costs vary greatly from configuration to configuration. At a minimum, the following expenditures must be investigated:

- o Floor Space
- o Power
- o Cooling (AC, Chilled Water, etc.)
- o Site Preparation

The increase or decrease in the the cost of each of these can greatly effect the overall cost of the target configuration. In addition, if there is any discussion of possible geographic changes regarding the data center, there can be enormous differences in these costs from one locale to another. The costs of these support components of the data center and the time involved to implement them must be evaluated.

Supplies

On occasion, there will be the requirement to convert some inventory items as a result of a change in the configuration. For example, the decision to acquire cartridge tape units to replace standard reel models will necessitate the purchase of an inventory of new tapes. In addition, it may require a considerable conversion effort in modifying JCL or transferring tape data sets. These costs must be itemized when proposing the new tape units. In all likelihood, the increase in speed and reduction in errors will more than compensate for the expenditure. But we should make that case before someone else puts us on the defensive.

Overhead

All other items that I may have missed can be incorporated into the overhead category. (This is a very useful technique I acquired while performing analytic modeling efforts. Just as in the modeling case, where overhead (or other) represents real CPU or I/O activity, the overhead cost category equates to real dollars. Each corporation will have varying overhead costs that the analyst has not addressed in one of the other areas.

If the indirect costs of personnel (vacation, education, space, insurance) have not been included in the people category, include it now. In addition, general business expenses must be addressed, such as increased insurance costs for plant and equipment, additional phone lines and carrying charges to support added TP activity, new costs due to the delivery of output as a result of a data center move, etc. There can be many costs which will be unique to the particular situation. Simply ask yourself honestly whether you have covered all of the costs and financial impacts of the recommendation that you have made.

As a good frame of reference, remember the analysis that you conducted when you bought your house or your last car. The real issue was the bottom line cost per month. Think in those terms and you will be okay. But don't forget the add on alarm system, undercoating, paint finishing, extended warranty, added cost of insurance, etc. All of those can greatly affect the cost of the automobile you choose (assuming that you have already negotiated the trail of options that brought you from the sticker price to the real price).

Don't make management feel that they are uncovering the real monthly cost one expensive layer at a time. Try to honestly identify all the relevant issues, quantify the dollars associated and justify the expenditures. You will stand a much better chance of getting your recommendations accepted. You will also stand a much

better chance of impressing management with the thoroughness and integrity of your work.

Why?

Why do I, a data processing person, want to go through this exercise ? Data processing does not exist as a unique scientific endeavor but rather as a critical support structure in the corporate enterprise. It is therefore incumbent that data processors relate to the goals of the corporation. Those goals are most often translated and expressed in monetary terms. If we want to live in the corporate realm and personally progress within it, we must learn the language.

Perhaps we should start to retitle our job descriptions to be more in keeping with corporate goals. What we really want to do for the company is resource management not simply capacity management. Capacity management implies that we can measure how much service a particular grouping of hardware and software can deliver and how much bigger that grouping has to be in the future. Resource management also includes an understanding and analysis of the ancillary requirements of the delivery of service, the costs of supplying that service and the net value to the corporation.

Remember, always relate to the net bottom line. Not only what it costs, but what it's worth. If you can illustrate that the the configuration you are proposing is a profitable choice for the company, not only will that proposal be more successful; **so will you.**

Analysis Example

The four year analysis in Figure 3 illustrates a methodology for presenting a financial evaluation of a configuration. This breakdown, with accompanying text, permits an understanding of both yearly and total costs. Supplying this analysis for each configuration that is proposed will allow a quick comparison of the financial implications of each decision.

The dollar values in figure 3 are for illustrative purposes only and are not the real prices of of any particular configuration. In fact, the technique that has been employed makes use of delta values rather than absolute values. The absolute value method would use, as prices, the full market price of each component. What the author has done in the example, is to reflect the change (delta) in cost for each item as compared with the current configuration. Either approach is acceptable and the choice will depend on the financial data available to the analyst and the desired presentation format.

The spreadsheet was generated using LOTUS, a PC based spreadsheet package. The analyst had to supply the assumptions for the useful life of the configuration and the inflation rate (cost of money) per year. In addition, the price delta and one-time costs were supplied. All remaining values were automatically derived through spreadsheet formulas and macros. For those interested in the underlying spreadsheet formulas, please contact me and I will send you a copy.

As mentioned above, the first pieces of data to be supplied are the estimated useful life of the configuration and the anticipated yearly inflation rate that applies to costs. The strength of the spreadsheet package is that the analyst can easily change either or both of these variables and recompute all the values for yearly and total costs. Likewise, any of the pricing estimates can be easily adjusted as required. This gives the analyst the capability of answering some financial what-if's with sensitivity analysis.

The next step would be the establishment of prices for each catagory. In the example, the delta approach was used so the numbers inserted represent the net change (plus or minus) from the current sistuation. I have not considered the issue of residual cost in this example. Conceptually, we either deduct the estimated salvage value of each configuration before computing the delta price. The analyst is invited to consider adding a column to the spreadsheet to enumerate this value if desired. In the example, we are anticipating changes to the CPU, DASD and tape sub-systems, and other equipment (i.e. printers). The increased cost (net) of each of these is entered.

In the area of software, we foresee an increase in the licensing fee of the SCP component, but there is an expected decrease in the fees associated with other program products. In the example, this is due to the consoldation of two smaller systems into a significantly larger complex. As a result, there will be a sizable decrease in per CPU license costs.

With regard to personnel expenditures, we anticipate that some additional costs will be incurred. This value is the result of netting the required manhour costs to accomplish the hardware and software conversions with the reduction in staff that is anticipated due to the merging of two complexes into one and with educating our in-house staff on the new environment (operator training, systems programming internals courses, etc.).

Both on-going and one-time expenses are expected for the physical site. Some up-front preperation work must be completed and additional chilled water capacity is required to support the new equipment. Both of these are reflected in the one-time cost column. For on-going costs, the analyst should obtain the square foot cost used in the standard cost allocation schemes in the company. The required floor space per complex can be obtained from hardware specification manuals or from the vendor. Remember to allow for door clearances and other required extra footage. (The operator has to sit somewhere). Kwh (kilowatt hour power) costs and cooling costs sholud also be obtained from the corporate cost accountants. If these numbers are not available just leave them out and place a footnote in your presentation that denotes the expected percentage difference in costs based on relative space and kwh requirements.

The supplies listed are a one-time purchase of cartridge tapes to be used on the new tape drives.

The overhead values include estimates of normal business expenses (added insurance, personnel benifits, etc.) that are associated with the above items. This value was derived from an overhead formula that was supplied by the corporate accounting staff.

With these values in place, the spreadsheet will automatically fill itself in and yield yearly and total costs. Also, for those who are interested, the net present value of the costs (current year cost column) is supplied. It is interesting to note that the CPU delta of 2 million dollars can grow rapidly (more than twice) when the sundry costs are added and amortized.

The analyst can produce these spreadsheets for several configuration or financial scenarios. It becomes an easy task to point out the relative costs of each alternative. To complete the picture, he needs only discuss the offsetting benefits of the anticipated change. (How to address that topic is another paper).

I believe that if capacity planners consider the financial issues and include them in recommendations the generated proposals will have greater credibility with management and as a result the plan will be more readily accepted and implemented.

CAPACITY BUDGETS AND FINANCIAL BUDGETS: RELATING THEM TO EACH OTHER THROUGH RESOURCE ACCOUNTING

Joseph W. Richardson
J. P. Morgan, Inc.

- Abstract -

Cost acounting can help capacity planners communicate more effectively with corporate management. Although data center chargeout has often been justified, an understanding of both capacity and financial plannng is needed to develop the right system. Deciding what to charge for requires an understanding of computer measurement, so that metrics will be selected that are suited to the reasons why management want a chargeback system. Transforming those metrics into terms that both non-technical and technical management can understand requires an understanding of internal financial analysis - that is, cost accounting.

Resource accounting systems are particularly appropriate vehicles for expressing both computer and financial measurements simultaneously. In additon, they offer the means to charge for reserve capacity (also called "excess capacity") in a way that is perceived as fair by everyone.

This paper presents measurement issues from the perspective of corporate management, and describes the application of both financial and capacity planning techniques. Whenever possible, both techniques are applied to the same issue. Standard rates are described as a means for combining both measurement techniques. Examples are presented which incorporate these ideas. Finally, a combination of financial and capacity planning techniques is recommended as the way to provide corporate management with information needed for control, while providing technical management with accurate, yet meaningful, input to corporate decision making.

INTRODUCTION

Accounting for the use of data centers is not a new subject. Commercial service bureaus have been doing it for years, in order to remain profitable. Many other organizations have also used chargeback techniques for years. Some have simply wanted data center users to be aware that the service is not free, while encouraging them to use the facilities. Others have wanted to allocate the expenses of operating a data center to the company's lines of business (such as the cash dispensing machines provided by many banks). Still other companies want to encourage their end users to choose off-peak hours, or at least to schedule their work so that resource-intensive work will not be submitted at the busiest times. (Development data centers would often like to do this.)

Cost accounting, also called "management accounting," has been used for years by many different kinds of organizations to help management accomplish precisely these goals. Therefore, when problems arise while applying chargeback techniques to data center operations, the cause is usually a lack of common understanding between specialists in financial measurement and computer measurement. If the problem is lack of familiarity with project management techniques, these have been discusssed by Yourdon and others. If the problem is lack of understanding of chargeback issues, these are discussed elsewhere (see "References").

This paper presents measurement issues from the perspective of corporate management, and describes the application of both financial and capacity planning techniques. Whenever possible, both techniques are applied to the same issue. Standard rates are described as a means for combining both measurement ideas. Finally, a combination of financial and capacity planning techniques is recommended as the way to provide corporate management with information necessary for control, while providing technical management with accurate, yet meaningful, input to corporate decision making.

ISSUES FOR DATA CENTER PLANNING

Both capacity planning and financial planning are techniques for corporate planning. Both are used by organizational units to communicate goals and resource requirements to upper corporate management. Among the issues shared by both methodologies when preparing data center plans for the coming year are:

1. How much processing capacity do we need?
2. How much online storage capacity do we need?
3. How much transmission capacity do we need?
4. How much local output capacity (i.e., print or punch) do we need?
5. How far into the future should we plan?
6. Which resources can be shared, and which ones must be dedicated to individual data center users or workloads?

Although the issues are similar, one methodology (capacity planning) usually focuses upon manufacturing capacity (1), while the other (financial planning) usually focuses upon the cost to the corporation. Manufacturing companies are accustomed to combining the two processes. Several other industries are not yet accustomed to this.

The six issues are listed again, but this time typical measurements used by each discipline are also included.

1. How much processing capacity do we have? do we need?
   - Capacity measures include percentage used of total CPU hours available (90th percentile, mean, and average), time available for application programs after determining and applying the capture ratio for the entire system, etc.

(1) if data centers are viewed as factories

Both historical data and input from corporate business plans are required if these or other measures are to be accurate.

- Financial measures include the annual or monthly cost of processors, the cost for work actually done on the processors (assuming that rates do not change during the year), the difference between the monthly cost of providing processors and the monthly charges for work performed by the processors, etc.

  Simple graphs showing resource requirements or expenses (using constant unit charges) over a period of time may be prepared from each set of measurements. Such graphs are frequently helpful when describing how demand has changed over time.

2. How much online storage capacity do we have ? do we need?

   - Capacity measures include cylinders and gigabytes. Analysis may focus on permanent storage plus two uses of temporary storage: temporary datasets (the "passed" datasets of IBM's OS asnd its successors), and permanent datasets which are routinely created and deleted during a normal day's processing (for instance, to enable a steam of jobs to be restarted somewhere in the middle).

     Analysis of VTOCs, VSAM catalogs, and RMF/SMF data provides the material for such studies. Input from people familiar with future business volumes is also required. Abends due to the unavailability of DASD space may provide a means for monitoring the accuracy of the forecasts, although such abends often signal a need to change the scheduling of batch jobs or make other performance adjustments.

   - Financial measures include the cost of the online storage capacity, the cost of that portion which is not allocated to datasets, and the cost of that portion which is allocated to datasets. Financial measures also include the cost of rerunning jobs which abend, because there is not enough space for temporary datasets or for those permanent datasets which are routinely created and deleted each day.

     Both financial measures and hardware measures are especially informative if they are summarized by a definition of "workload" which is meaningful to non-data processing management. If separate chargeback invoices are prepared for each major application or low level end user group, then the invoices may offer a helpful definition of "workload" for planning purposes.

3. How much transmission capacity do we have? do we need?

   - Capacity measures include how often lines or line groups are at least fifty percent occupied during a specified interval, actual network response time (measured in various ways but excluding host response time) compared to desired response time, the frequency with which a receiving node halts transmission to itself, buffer shortages in either an INN or a BNN, etc.

   - Financial measures include the cost of supplying transmission facilities, and late charges caused by busy transmission facilities. Financial measures may also include costs allocated to specific users, if this is technically feasible and can be done economically.

4. How much local output capacity do we have? do we need?

   - Capacity measures include defining local print (or punch) workloads, analyzing the quantity of printed lines or pages per workload, noting the total quantity of printed lines or pages at times of the day/week/month, identifying delays in the availability of printed output which are caused by "printer busy," etc.

   - Financial measures include cost per standard quantity of lines, cost per standard quantity of printed pages, late charges due to the print pool's being overloaded, invoiced costs charged to each workload (if workloads are used for chargeback purposes), etc.

   - Both capacity and financial measures may demonstrate inherent cycles in the workloads when plotted over time.

5. How much additional capacity of each kind do we need as a reserve for the future? How far into the future?

   - Capacity planning techniques include models, as well as trend analyses of cpu / DASD / communication / local print usage, adjusted to reflect next year's business plans. Demand may be forecast in terms of units of total resource consumption, numbers of transactions during peak periods, frequency of peak periods, etc. for the entire data center, major workloads, or both. Recommendations to obtain additional capacity assume that existing capacity is already being properly used by application of performance tuning techniques. These recommendations also assume that, as a result of purchasing or leasing additional equipment, reserve capacity for the data center to grow into will become available in diminishing quantities until additional capacity is obtained.

   - Financial planning measures include similar measurements expressed in dollars, rather than in units of resource consumption or percentage of "busyness". Financial budgeting is the principal technique used to express these forecasts in financial terms. Note that in data center planning, the determination of unit rates as part of a resource accounting cost allocation system is a good example of combining capacity planning results with financial planning results. (This is discussed more fully below.)

6. How will these different kinds of capacity be made available? Will workloads be rescheduled to fit within existing capacity? Will sufficient capacity be purchased to accommodate peak demand without having to reschedule work? If a compromise is necessary, how will it be decided?

   - Capacity measures include availability of resources during peak periods, frequency of peak periods, temporary or permanent use of resources by one or another workload (where a "workload" may be characterized by resource consumption characteristics or operational characteristics), etc.

   - Financial measures include the dollars budgeted for the coming time period (usually one year) by workload, the total expected expenditures which wil be recovered by a chargeback process, the percentage of total expected expenditures which will be deferred for future recovery, etc.

COMBINING CAPACITY PLANNING AND FINANCIAL PLANNING

Effective communication with non-technical management requires that the results of these two planning techniques be combined. Capacity planning presents recommendations in quantitative, but non-financial, terms. Financial planning presents recommendations in financial terms with which corporate management is familiar. However, financial planning alone will not tell management what it really costs to support each workload in the data center. To do that, measurements created by capacity planning must be included.

Resource accounting offers a method for combining the results of both kinds of planning. It gives detailed information about the cost of providing data center resources for all work in which management is interested. Unit rates, if properly constructed, combine the results of both planning methods. When the unit rate for a resource (cpu time, for instance) is computed by dividing estimated total annual consumption into estimated annual cost of the resource, the rate will be a function of both planning techniques. If these unit rates are then used to estimate the yearly cost of each workload in the data center, capacity planning recommendations will have been translated into the cost of supporting each workload in which corporate management is interested.

If resource accounting is the basis for data center chargeback, unit rates can include the cost of reserve capacity (also called "excess capacity") or not, as management desires. Charging for the reserve capacity, which is really a reservior, has been one of the thornier issues. Often, the real problem is telling management how much reserve capacity there is, without requiring corporate management to become engineers. Capacity planning can state how much of each available resource will actually be used (e.g., sixty percent). Management can then decide whether to prorate the real cost to the company between "used" and "reserve," and include only what is "used" in the rates. Naturally, if management decides to do this, the next question is, "When will the deferred charges be included in the rates?" Guidelines for timing the recovery of deferred charges are beyond the scope of this paper. However, resource accounting clarifies the issues, and can improve communication between data center management and corporate management.

Examples of how this method has been used successfully follow. At the end, recommendations for using this method are summarized.

EXAMPLES OF RESOURCE ACCOUNTING FOR DATA CENTERS

1. A cost allocation system for a traditional production environment

   Management wants this chargeback system to allocate the expenses of operating the data center to services marketed by this financial services company. The services could not exist without the data center. Management needs to know what it costs to produce these services, in order to measure their profitability. Management also wants to compare actual and budgeted expenses, to make financial planning as accurate as possible.

   Each fall, during the corporate budget process, resource consumption estimates are prepared. Earlier, questionnaires were sent to the end user areas, and meetings were arranged to collect their business forecasts for the coming year. These forecasts are analyzed together with trends derived from data stored in performance data bases. Discrepancies are reviewed with end user areas. The forecasts are eventually expressed as quantities of various resources that will be consumed during the coming year. Recommendations are made concerning the quantity of each resource that should be available, to ensure sufficient capcity. Both chargeable and non-chargeable resources are included. Chargeable resources are those which appear on invoices (such as DASD). Non-chargeable resources are those which are not charged out separately (such as channels), but which are clearly required for the data center to provide the expected level of service. This stage of the planning process provides information for performance/capacity management, as well as for financial management.

   All expenses associated with the data center (salaries, equipment leases, depreciation, etc.) are identified and assembled. Management decides what portion of these expenses will not be factored into the rates. For example, if a new data center were built which won't be fully occupied for five years, or if a two-year supply of DASD were purchased at discount, some of the actual expenses would be deferred for future recovery. In both of these examples, reserve or "excess" capacity has been acquired. Excluding the cost of reserve capacity is a straightforward way to avoid charging end users for capacity which they cannot use. As that reserve capacity is used, its costs may be included in the rates.

   Finally, unit rates are computed. The expenses which will be factored into the rates are allocated to "resource pools." Each chargeable resource is a resource pool. Allocation is accomplished by the usual cost accounting technique of first allocating direct expenses (such as operators' salaries), then prorating indirect expenses (such as supervisors' salaries) according to direct expenses already allocated.

   Note that the costs of non-chargeable resources, whose identity is important only to performance/capacity management, are allocated to chargeable resources. The intent is to use unit rates to

recover the entire data center budget, except for that part which is deferred. The rate for each chargeable resource is computed by dividing estimated annual consumption into the dollars allocated to that resource. The resulting rate is a "standard cost" which combines the results of capacity planning with financial planning.

These rates are then used to prepare budgets for various workloads. During the year, actual charges are computed using these same unit rates. Actual charges are compared to budgets to provide management information.

2. A cost allocation system used with a pricing system for an information center

Management has a different philosophy for the information center than it has for the traditional production data center. The production center supports applications which constitute part of the company's product line. They are too critical for management to permit them to be run anywhere else but in the corporation's own data center. Management is concerned about the expenses of operating the production data center, but not about whether the production center's applications should be run there at all.

The information center provides data center services which are necessary to the corporation, but which don't necessarily have to be provided by the company's own data centers. Most of the applications on the information center require a few weeks to develop, rather than several months. They tend to require less DASD and other resources. They are usually programmed in FOCUS or a similar language, rather than in a lower-level language. They are almost always oriented towards answering inquiries, instead of towards updating large files with great quantities of data.

These applications could be developed and run using commercial service bureaus. However, the information center is more readily available than outside service bureaus. Since its end users can use either the informaton center or an external resource, information center management keeps its rates competitive with external rates. If the information center's charges are higher than an outside service bureau's charges would be, then end users can decide whether the information center's service is sufficiently better to be worth the higher price.

This information center is not a profit center. Ths is, the information center is not required to show a profit. Its managment is required to demonstrate that it is providing a cost-effective service. To do that, information center management has selected a combination of a pricing system and a cost allocation system. The pricing system is quite detailed, so that end users pay only for those services which they actually use. Whereas the production data center allocates the costs of using five basic resources (CPU time, printers, dedicated DASD space, archive tapes, and specialized communication equipment), the information center charges for ten: CPU time, primary dedicated DASD space, additional dedicated DASD space, printers, special forms, archive tapes, tape mounts, instruction in one or another of the programming languages, programming for an end user, and general consulting. Note that the information center does not charge extra for using the center during prime time. That is because the information center tries to be more affordable than an outside service bureau would be.

Management needs to know how much it costs to support each end user, as well as how much each end user should be charged. For this purpose, five cost pools have been selected: CPU time, dedicated DASD space, tape storage, printers, and staff assistance. These are considered to be the critical resources whose availability controls the quality of service which the information center can provide.

For each end user, both pricing and costing records are maintained. Two sets of rates are used simultaneously: unit pricing and unit costing. The unit pricing rates are determined largely by surveying the competition's rates and from constant discussions with end users about their applications, needs, and budgets. (End users' budgets must be approved in advance by corporate management.) The information center can change its pricing rates during the year, but must be prepared to justify the changes. Unit cost rates are determined the same way that the production center's cost rates are determined (see above) as part of the annual budget process. Unit cost rates can only be changed once each year, so that comparisons of variances between actual and budgeted charges will be meaningful.

Since the unit cost rates ("standard costs") are set the same way as they are for the production data center, they also express a combination of financial planning and hardware capacity planning. Creating and using unit rates as part of a resource accounting system allows management to concentrate on managing the service provided by the information center, without wondering what it is costing to provide that service.

3. A cost allocation system with surcharges and discounts added for use with a development testing environment

The chargeback system for the development testing facility reflects a third philosophy, different from either of the two systems described above. Most of the applications being developed in this facility will eventually be operated in the production data center. They are part of this corporation's product line. Management does not want the details of these applications residing outside the company, where they might be inspected by competitors. However, management still wants the development testing facility to be operated efficiently.

To accomplish these goals, the development facility's chargeback system uses unit costs, and does not use prices. However, due to the kind of demand placed on its resources, surcharges and discounts have also been introduced. Six chargeable resources have been selected: CPU time, dedicated DASD space, shared DASD space, tape storage, tape mounts, and printer. To facilitate the use of surcharges and discounts, job and sysout classes have been created corresponding to low, medium, and high resource contention with other jobs.

The critical variables where "contention" is concerned are CPU time, tape mounts, and printed output. Job classes enable control over the use of CPU time and tape mounts via surcharges and discounts. Sysout classes facilitate control over printed output in the same way. SMF and JES exit routines are used to ensure that published rules about the use of job and sysout classes are enforced by the operating system.

A surcharge is applied to excessively large print outputs during prime time. This surcharge can be avoided by directing such output to a sysout class whose writer is not activated until after prime time. Similarly, surcharges are applied whenever a job is submitted during prime time which uses the high priority job class and calls for any tapes. A job submitted during prime time with any job class except the low priority class, which exceeds its alloted CPU time, is likewise surcharged. The surcharge for excessive CPU time or tape mounts can be avoided by submitting such jobs after prime time, or by specifying job classes whose initiators are not activated during prime time. During third shift, and all day on weekends, discounts are in effect. While discounts are in effect, there is no distinction among job or sysout classes.

Although management has decided on different chargeback philosophies for the production center, information center, and development center, unit cost rates are computed the same way for all three chargeback systems. However, additional steps are required in the development center chargeback system to calculate the surcharges and discounts.

1. Surcharges are computed by estimating what it would cost to provide additional processing capacity, or to provide enough operators to mount tapes or load printers, to ensure that 95 percent of all test jobs submitted during prime time would be turned around according to the service agreements, no matter what their resource requirements. The estimated additional expense is then divided by 260 (the standard number of work days in a year), then divided again by 100 (the estimated number of excessive jobs which would be submitted each day if there were no surcharge - see footnote 2). The result is a surcharge per job, whether the surcharge is due to tape mounts, excessive CPU requirements, or excessively large printouts.

2. The discounts are simply negative surcharges. That is, each job which is submitted during the times that discounts are in effect receives a discount equal to what the surcharge would be.

The system of surcharges and discounts was instituted to allow for the unexpected. The development managers' best estimates are factored into normal cost recovery during prime time. However, product development always includes some surprises. The surcharges and discounts make it easier for management to express how much an immediate solution is worth to the company in dollars and cents.

(2) The number of jobs changes annually based on experience.

CONCLUSION

Resource accounting offers a useful way to describe the results of capacity planning in terms which corporate management can understand. The technique, also called "cost accounting," has been used in manufacturing for years. By viewing the data center as containing resources which are consumed by the work being done there, these techniques can readily be applied to data center accounting. Cost accounting, after all, was developed to give management better control over the expenses incurred while producing the goods and services which each company offers for sale.

There have been many discusions about charging for "excess," or reserve capacity. End users resist accounting systems which charge them for resources they do not use. If resource accounting is the basis for data center chargeback, management has the opportunity to defer charging for resources until they are used. By developing and using "standard rates" to compute end users' charges, the problem of charging for "excess capacity" can be resolved.

EXPERIENCE IN COST ALLOCATION

Joseph Stancavish
Manufacturers Hanover

ABSTRACT

Cost allocation is often referred to as an art and not a science. Those responsible for allocating costs would like cost allocation to be as exact as possible in order to defend any costs that users of data center services receive. Where measurements are not exact, a judicious combination of data center performance experience along with fimiliarity with data center operations is needed to satisfactorily resolve unclear issues. This paper addresses the author's experience in cost allocation at a large money center bank.

DESCRIPTION OF THE CURRENT ENVIRONMENT

Manufacturers Hanover Corporation is a large New York based money center bank providing a multitude of banking services for wholesale and retail customers. Many data centers support these services. The data center that is the object of this paper is called Wholesale Computing Facility (WCF). As its name implies, WCF supports service to wholesale customers of Manufacturers Hanover. An example of a wholesale customer is another bank or corporation. The range of services provided include electronic banking, check reconcilement, real estate and mortgage, letter of credit, domestic and international payments, commericial loans, demand deposits and investigations. Each of these applications has corresponding products for which costs must be calculated.

The WCF has a 3084 QX processor along with a 3090-200 processor. MVS/XA with JES3, VTAM/TCAM, CICS and IMS are the major software products in use. The 3084 is normally the production system with test on the 3090. There are approximately 250 gigabytes of DASD.

ACCOUNTING STRUCTURE

A product is defined as a result of data processing work. An example of a bank product is a check reconcilement. Each product that uses WCF resources is charged by measuring resource usage in a number of areas. These areas include CPU usage, DASD storage, print usage, tape storage and mounts, contingency data center service emergency maintainance and others. These areas are called activities. Costs are then assigned to each activity in the data center. These costs are a combination of equipment, salary, occupancy, etc. From the assignment of costs to activities, a unit cost per item of activity can be calculated. When each product's resource usage is measured a total charge can be calculated.

An analogous situation is an automobile assembly line. The product is a car. In order to produce a car, what are the cost involved? First, activities must be defined. The activities could be: assembling the body, inserting the engine, installing the interior, painting the car, testing it, etc. Second, what are the costs associated with assembling the body? For each activity one would need to know the costs of materials, labor, occupancy, power, etc. If 50 car bodies were assembled in one day with an associated cost per day, one could calculate the cost per assembly. This would have to be done for each activity. The result would be a total cost per car. One could then price a car accordingly on the market to recover the costs and perhaps make a profit.

Is it that easy to charge for data processing services? Of course not!

PRACTICAL CONSIDERATIONS

The steps to an accurate and equitable cost allocation system are:

1. Develop accurate and complete inventories of all resources being charged.
2. Have a database of costs for each resource being charged.
3. Relate resources to products on a one to one basis where possible.

Developing accurate and complete inventories for all resources (e.g. CPUs, DASD, staff) is necessary to obtain the costs of data center services. The costs are obtained by looking at invoices associated with the items on the inventories. Relating resources to products one a one to one basis if difficult because of the sharing of respurces in the data center. Wherever possible the one to one relating of products to resources should be done because it simplifies the job considerably. More importantly, it reduces any overhead allocation issues that arise.

CURRENT IMPLEMENTATION

The major components of the cost allocation system are: a data collection program to gather resource usage on the desired activity and assign the usage to an appropriateproduct and a program to calculate the charges for distribution to the appropriate area.

The current implementation of the cost allocation system has various sources of input: SMF 30 records, SMF 6 records, the tape master catalog, a DASD database and manual input. The SMF type 30 subtype 5 record is used to record data on the CPU and tape mounts. The SMF type 6 record is used to record estimated data on print pages. The tape master catalog (TMC) is the source of tape storage information. The DASD database supplies data on storage used by applications. The manual input is for activities like contingency and emergency maintenance. LANDMARK monitor data is used for CICS regions.

The data collector portion is written in SAS. A combination of tables and code are used to assign resources to particular products. Job name or TSO userid is the indentifier for CPU, print, tape storage and tape mount activity. Dataset names and corresponding levels are used for the assignment of DASD to products. For example, in the dataset A.B.C: A is level one, B is level two and C is level three. In the case of CICS regions, the transactions ID is the identifiers are used for other activities. An example of this is a table of port assignments for telecommunications ports.

An example of the data collector output is shown in Table 1. Across the page lie a subset of the total activities measured by the data center. Along the left side are the line items. These can be products, product groups, CICS regions, overheads and test departments. The ideal situation is to have the data collector show only product usage with no ambiguilty due to shared resources. This ideal is only partially acheived. Product groups are shown where there is some ambiguilty as to particular product assignment but where the general area of assignment is known.

Overheads are shown when there are resources used for the benefir of the data center as a whole and not any particular product or product group. CICS regions are shown as the whole region. Another program must analyze the CICS data to assign it to the appropriate product. Test departments have a table of TSO users assigned to them. Any charges produced by the test departments are then charged to the product areas by the test department themselves.

1. Distribute unused capacity according to actual usuage.
2. Distribute unused capacity equally to all products.

The first method is the one used in the current implementation. The second method is unfair to products which have small actual usage. The product may have more unused capacity charges than actual use charges.

TABLE 1. OUTPUT OF DATA COLLECTOR.

	CPU		PRINT		TAPES STORED		PRIVATE MOUNTS		SCRATCH MOUNTS		DASD SPACE	
DESCRIPTION	PCTSUM	SUM	PCTSUM	SUM	PCTSUM	SUM	PCTSUM	SUM	PCTSUM	SUM	PCTSUM	SUM
CHECK-RECONCILEMENT	14.22	32	3.36	110	23.43	97	6.51	37	36.20	311	3.96	200.00
CHIPS-GROUP	9.33	21	1.19	39	4.83	20	69.01	392	27.59	237	5.58	282.00
CICS-REGION-CLS	22.22	50	2.90	95	11.35	47	6.34	36	11.41	98	0.16	8.00
DEPARTMENT-5746	6.22	14	0.06	2	1.93	8	1.23	7	0.58	5	1.76	89.00
GLOBAL-EXPOSURE-SYSTEM	7.56	17	85.94	2812	7.00	29	3.35	19	0.00	0	57.17	2888.00
INTERNATIONAL-INVESTIGATIONS	14.67	33	1.74	57	5.31	22	3.87	22	11.53	99	20.78	1050.00
ONLINE-OVERHEAD	6.67	15	2.84	93	19.32	80	3.52	20	7.45	64	0.55	28.00
SYSTEM-OVERHEAD	9.78	22	0.37	12	12.08	50	3.35	19	0.00	0	9.74	492.00
SYSTEM-SUPPORT	9.33	21	1.59	52	14.73	61	2.82	16	5.24	45	0.30	15.00
ALL	100.00	225	100.00	3272	100.00	414	100.00	568	100.00	859	100.00	5052.00

All this data was then organized into a spreadsheet. Rules to assign overhead distributions were developed with the help of the controllers department. The resulting activity usage was then input to another system to distribute expenses.

CAPACITY CONSIDERATIONS

An interesting problem arises in this system. This methos of cost allocation is called a full absorption system in the literture. Full absorption means that all costs must be recovered. However, full cost recovery means that resources are being paid for even though they may be unused. This leads to the interesting question: who pays for unused resources?

The CPU activity is particularly interesting. Where production online systems are involved, the CPU must be sized sufficiently large to handle any peaks. The resulting configuration handles online peaks well but leaves non-prime time with an excess of capacity. Add a backup processor, and an already large cost has doubled. What is evident here is that the online region peaks are driving the size of the processor up. The online regions, should therefore, pay the portion of the CPU which was needed to handle their requirements, In the current implementation this translates into a surcharge for use of an online region. The surcharge can be handled in a number of ways: a flat charge for using a region, an increased unit cost for online CPU usuage, increased activity volume for use of an online region with the same unit cost as batch. The current implementation utilizes increased activity in addition to the actual usage of each region to calculate the surcharge for users of online regions.

For other activities there are two basic methods to distribute unused capacity:

COST DEVELOPMENT

Activity volume was estimated for the coming year based on the activity volume of the previous year. Table 2 shows an assignment of costs to the various pools. Note that activiry volume should include explicitly some allowance for unused capacity for each activity pool. The result of dividing the total dollars in each pool by the total activity volume for that pool is the unit cost for a unit of activity in each pool. If there is a mapping between product transactions and the various units of activity a cost per transaction can calculated. User estimates of the product volumes could then be used to charge each user area.

Table 2. Allocation of costs to various activities.

	CPU	PRINT	TAPE MOUNTS	DASD	CONTINGENCY
SALARIES	$1,000,000	$200,000	$100,000	$500,000	$300,000
BENEFITS	$200,000	$50,000	$25,000	$30,000	$35,000
EQUIPMENT	$3,000,000	$100,000	$30,000	$900,000	$500,000
DEPRECIATION	$1,000,000	$50,000	$10,000	$300,000	$200,000
OCCUPANCY	$500,000	$20,000	$10,000	$200,000	$100,000
TOTAL	$5,700,000	$420,000	$175,000	$1,930,000	$1,135,000

DATA CENTER PERSPECTIVE

Because many users have difficulty defining what their products are and as a result have difficulty estimating product volume, there is a viewpoint which tries to remove some of the complexity of the cost allocation process. That idea does not require the end user to estimate his product volume but only to look at his old "bills" and see what he has used previously. He can state his expected actual usuage for the coming year. He doesn't have to know the relationshio between data processing resources and his products. Product volume estimates are not reliable.

FURTHER DEVELOPMENTS

The author is currently involved in the development of a PC based cost allocation system. The basic idea is to have the mainframe do the heavy processing for download to a PC. A PC database package can then be used to produce bills, simulate the effects of cost changes and debit or credit departments as necessary. The power of the PC based system is that changes to charges can be made quickly and easily.

CHARGEBACK VS. COST ACCOUNTING
THE APPROPRIATE EMPHASIS

George J. Gillen, Jr. and Billy F. Henry
Coopers & Lybrand

ABSTRACT

During the past five years, we have worked with several clients throughout the country helping with the implementation of Information Services Cost Accounting or "Chargeback" systems. This paper addresses the issues that have surfaced from company executives regarding financial management of Information Services.

More and more, implementation of a system for charging Information Services users is taking a back seat to a more comprehensive and important issue: implementation of a system that encourages effective utilization and management of information system resources.

Our purpose is to provide the reader with insight into the value that an effective Cost Accounting System can provide to both Corporate and Information Services management.

I. THE STATE OF INFORMATION MANAGEMENT

OUR EVOLUTION

From the age of the Abacus, through the era of the Slide Rule and up to the introduction of the Personal System/2*, one issue has pervaded the calculating device arena: "How can I do more, in less time, at a cheaper cost?" As a computer literate society, we will continue to strive for a better mouse trap to enable our organizations to gain a competitive edge while reducing overall costs.

However, one dilemma continues to plague management both within and outside of the Information Services (I/S) organization. The area of concern commanding management's attention more and more is cost. "I need to know what it costs to provide services so I can make intelligent financial decisions".

WHERE ARE WE

We in the I/S profession have done a pretty fair job of providing information technology to our corporate users. Engineers have given us faster processors and storage devices, card reader/sorters are cornerstones in the Smithsonian, and every manager with the desire, can run a Lotus spread sheet and access this mornings sales statistics from the comfort of his/her office or even home.

Technologically, we have progressed further and faster than any other area of the business. From a management standpoint, however, far too many of us rate a C or worse. Much to our chagrin, technology has not managed itself and we have not taken the steps necessary to manage it. It is our belief that those who will survive over the course of the next decade will be those who actively alter this course and aggressively manage the I/S business unit.

THE CORPORATE MANAGEMENT PERSPECTIVE

Given this as the State of Information Services today throughout much of corporate America, what does company management think of us? Below are some of the feelings expressed to us by company executives we have worked with over the past five years:

.. DP is still a black hole where corporate funds go in and very little comes out

.. Nobody in that group can tell me what it costs to run our application portfolio

.. If new technology is cheaper, why does the DP budget keep going up

.. The answer from that group is always more hardware, new software, more people; in short, more money

.. I would really like to find a way to measure my ROI for DP.

Two themes are consistent in these viewpoints. First, they keep referring to the "DP" department. Obviously we have not demonstrated to company management that our job is to manage information for the corporation. We are, or at least should be, more than just processors of data. Machines do a better job of that anyway.

Secondly, management seems overly concerned with money. In point of fact, they had better be or their successors surely will be. Today's environment demands that we be as cost conscious as possible. We need to ensure that every department is making the most out of every dollar spent and that the organization is functioning as efficiently as possible.

The I/S team is no different. We have the capability to financially manage and report on our activities just as any other department does. In fact, we can probably do a better job than most because of the tools available to us, and in most cases our vast experience.

II. COST ACCOUNTING VS. CHARGEBACK

Perhaps the best management tool available to us is a Cost Accounting system for I/S. We are talking here about a system that goes far beyond the traditional chargeback system many of us are familiar with.

WHAT'S THE DIFFERENCE

Most pure chargeback systems have one major objective: to identify aggregate costs and allocate those costs back to the user community such that, by month end or year end, the I/S budget has been accounted for.

The major problem we have seen with most of these systems is that they provide little or nothing in the way of management information. Charges are often not reflective of resources consumed. Changes in user behavior have little or no effect on their bills. Many services are deemed free by the user community resulting in costly and inefficient use (thereby driving I/S budgets up). Budget increases can only be justified in terms of nebulous increasing user demand. And many users end up paying for someone else. The result is mistrust and skepticism on the part of the users and management.

Enter the I/S Cost Accounting system. While using much of the raw data and statistics used for chargeback, the goals and objectives are very different. Fundamentally, we are proposing a management information system. And

by the way, we can charge users for services provided as well.

The basic difference in the two approaches is that a chargeback system strives to spread the I/S budget among the user community in some manner. If we also get some management reporting, so much the better. With an I/S cost accounting system, however, the primary goal is to identify costs. It allows you to monitor and manage such things as:

.. Budgeted vs. Actual Recovery
.. Budgeted vs. Actual Resource Consumption
.. Rate Performance
.. Budgeted vs. Actual Expenses
.. Year to Date Performance
.. Year End Forecasts/Reforecasts

The bottom line is that we now have a tool to help us manage costs. Costs which can very easily be allocated back to the user community fairly, accurately, and consistently.

SYSTEM OBJECTIVES

As we mentioned above, our objective in implementing a cost accounting system is to help us better manage the I/S function. The key objectives of the system should be:

.. The identification and accumulation of costs by natural cost category (i.e., Cost Pool)

.. The integration of cost accounting functions and other appropriate I/S management systems such as project and time management, capacity planning and telecommunications management

.. An I/S modeling capability for analyzing cost relationships, forecasting the cost of alternative service levels, and projecting standard service rates for budget and chargeback purposes

.. The billing of user organizations based on actual utilization of resources and standard rates.

Our goal is to run the I/S function as an integral part of the overall business organization regardless of whether your charter is service bureau, cost center, or profit center oriented. The cost accounting system is the tool that can help us.

CRITICAL SUCCESS FACTORS

Successful implementation of a sound I/S Cost Accounting system is not as easy as selecting and installing a software package, populating some tables and running the package against SMF tapes. There are several factors critical to the success of the project.

First, is Management Commitment. The projects we have seen enjoy the biggest success are those with the support of senior management throughout the company. More is required than just lip service.

Secondly, management must be involved. During the course of the implementation, several wide ranging decisions will have to be made, some requiring senior management approval. Keep senior management aware of the project. If they are kept apprized of the issues, they are more likely to be willing to make the tough decisions and support your efforts.

Third, no project of this size and complexity can be successful without sound project planning. Time spent up front laying out the detailed course of action to be followed may well be the key to a successful implementation. Several technical and functional areas will be involved throughout the project and their participation must be planned for. An effort of several weeks up front can save several headaches down the road.

The fourth critical success factor is Investment. This project will take time, effort, and money.

The amount of time you spend could range from 4 or 5 months to almost two years. This is dependent on how large the environment is (multiple large data centers or a one CPU site) and the makeup of the project team (the more experience on the team the shorter the time frame). Also, the use of external consulting assistance with directly applicable experience can significantly reduce the overall time needed.

To be successful in a reasonable amount of time, a great deal of effort must be expended. It is likely that a team of 3 to 5 full time people will be needed, supplemented throughout the project by specific areas of expertise such as Capacity Planning, Network Management, Applications Programming, and so on.

As we all know, there are no free lunches. This project will cost you money. The cost elements involved are; software package(s), outside assistance, and the cost of your own people. On the average, the total project cost should be around 2% to 3% of the I/S budget. When you think about it, that is a small price to pay to be able to have the system in place to help you manage that large (and ever growing) I/S budget. You might also consider that this is a one time charge that, with on-going care and feeding, provides a long term management solution.

TO CHARGE OR NOT TO CHARGE

The decision to actually invoice users for the cost of service provided can only be made within the business and political framework of your own organization. One of the largest impediments to charging is the issue of whether users can, in fact, have some control over the costs associated with I/S. Skepticism regarding the chargeback system and process is rampant in the industry and often with good reason. If the issue is approached through implementation of a true cost accounting system coupled with user involvement and education, the results can be surprising. Few people object to paying a fair price for good service and I/S services are no different. If a user feels comfortable with his charges (i.e., he understands what they are) and sees that different behavior on his part will affect his costs, the battle has been won. A true cost accounting system is your best weapon in this fight.

THE NEED FOR MANAGEMENT REPORTING

Central to the issue of more effective management of the I/S organization is the right information, not just "neat technical data". While EXCP counts may impact performance, they don't help us manage user relations any better. Neither will graphs of increasing CICS transactions help us sell management on the need for additional memory. We need to present the user community and corporate management with meaningful information from which intelligent decisions can be made. By demonstrating what resources are being consumed by whom (or by which applications) and presenting real cost figures, we appear to be much more business oriented. And we are. Too often in the past, the cost part of "Cost/Benefit" analysis has been merely a guess, and a poor one at that.

By using information provided by the cost accounting system we can effectively assist our management to understand:

.. What maintenance really costs
.. What development really costs

.. What systems are resource "hogs" and require modification, rewrite or replacement
.. What it costs to support a remote terminal.

In short, good management reporting from a sound cost accounting system can tell management where the I/S budget is going.

WHAT DO I GET?

After all of the blood, sweat, and tears of getting the system implemented, what have I really accomplished?

Hopefully, life will become easier (if that's ever possible in the I/S environment). From the standpoint of managing your own organization, you've developed a management control system that will help you run your organization more efficiently. You'll feel much more comfortable that you understand what's really happening in your department.

Next, you have the ability to give senior management something they've wanted for years: management information; financial data; cost analyses. They can now look at I/S the way they view other organizations and they'll feel more comfortable that you, too, can think as a business manager.

And let us not forget the people who really pay your salary; the users. In every client situation we've experienced, communication between I/S and the user community has opened up. To be successful, the implementation requires user involvement, and this opens the avenues of communication. The common mistrust and skepticism we spoke of earlier begins to fade and is replaced by understanding.

And finally, there is something that the I/S organization, Senior Management and the user community all share in; Defined Expectations. Each group now has an understanding of what is expected from the other.

PERFORMANCE ENGINEERING: SOME LESSONS FROM THE TRENCHES

Dr. T. E. Bell, Rivendel Consultants Inc.
A. M. Falk, TRW Defense Systems Group

ABSTRACT

Performance opportunities and problems exist in any application system. Performance Engineering exploits the opportunities while avoiding the most critical problems. It consists of performance prediction early in development, of tracking design and implementation, and of correcting performance problems throughout system life. Unfortunately, development managers are sometimes unsympathetic, vendor claims are often overly optimistic, and performance drifts away if not continually monitored. We suggest using simple models that are integrated and cover the whole system, making early estimates of resource consumption, taking measurements as early as possible, and tracking performance continually.

The implication from reading much academic and industry literature is that good, properly-motivated developers pursuing a structured development approach do everything right the first time. The authors of that literature live in a much simpler world than we do. Out here in the trenches we live with hard problems, with limited resources, with difficult performance requirements, and with our own mistakes. In this paper we present an overview of Performance Engineering as we have experienced it, a series of specific topics we have found to be important, and a set of implications and conclusions. The two objectives of this paper are 1) to indicate some of the practical lessons we have learned about doing Performance Engineering, and 2) to provide confirmation that Performance Engineering can yield great pay-offs to software development projects.

In addressing these objectives, we use examples from several systems whose characteristics are disguised. We must disguise the situations because of possible embarrassment to the dedicated developers involved.

PERFORMANCE ENGINEERING

Performance Engineering should be an integral part of developing any large system [1, 2, 3] -- as well as most small ones. But is the effort really the dry exercise in analytic modeling that is implied in much of the literature [4]? Our practical experience indicates that a good deal more is necessary for success. We have needed to work closely with developers so they feel that we're their personal risk-reduction technique rather than their adversary. (When we're really successful, we're confronted by the problem of developers complaining about the inadequate time we can devote to their specific problems.)

If Performance Engineering only encompassed a series of models, primarily based on simulation and queuing theory, it would not be particularly useful. We view Performance Engineering as being a far more fruitful effort -- composed of the projection, tracking, and improvement of application systems. This activity occurs during development, deployment, and operation. It uses a variety of techniques, but complexity of technique is a disadvantage rather than a desirable attribute.

Our approach to Performance Engineering involves making early **projections** and then measuring early performance in order to **track** against those projections. (Simply generating the projections is itself useful because it forces us to concentrate on the issues of particular importance to performance, and to identify the topics that must be worked to ensure that we have a solid baseline.) Usually, we have been shocked by the difference between the projection and the attained performance in early versions of the system. We must then work with developers to **correct** the problems so that the newly-projected performance can be brought to the level of requirements. This is an iterative procedure, but we have found that "corrected" approaches (when created with the active aid of developers) frequently come quite close to the required performance.

We also work with the suppliers of the hardware resources and system software to ensure that the architecture for a dedicated system is appropriate for the application. This turns out to be considerably more difficult than might be anticipated; the range of alternatives is very large, and the reliability of advertising data from vendors is frequently very low. Costs are usually considerable, so our projections must be reasonably accurate -- even though the applications are not yet implemented, and development efforts often go in unanticipated directions.

Performance Engineering is really difficult, and the number of wrong answers is truly impressive. It is also personally interesting, professionally rewarding, and an area of extremely high payoff for organizations developing large software systems. However, success in Performance Engineering requires a good deal more than just building a large simulation model or analytical model. Our experience is that the Performance Engineer needs to cope with a variety of unpleasant realities and to pursue ambiguous situations with simple models. The observations and suggestions listed below arise from our experiences in a number of projects.

UNPLEASANT REALITIES

We have observed several unpleasant realities in software development. Performance Engineers in some organizations may be immune to some of these, but we have observed them in different organizations undertaking a variety of different types of developments. Below, we present some of our observations along with some explanations.

MANY DEVELOPMENT MANAGERS BELIEVE THAT THEIR ROLE IS TO BUILD FUNCTIONALITY -- WITH PERFORMANCE SOMEONE ELSE'S RESPONSIBILITY

First-level development managers frequently believe that performance is the responsibility of someone else. This attitude is probably reinforced by the tendency of users and project managers to define functionality first, obtain an estimate of development costs, and then add performance requirements. However, we have observed instances in which this easy explanation is demonstrably untrue; performance requirements were articulated early, were agreed to by developers, were

recommitted to during the project, and then were viewed as someone else's problem. This situation seems to arise from several sources.

First, developers often find it easier to devote their efforts to finding that next functional software bug than to tackling tougher performance issues. Performance problems are often difficult to solve, require technological knowledge about the system (both hardware and software), and involve sophisticated approaches and tools. A first-level development manager was probably promoted to that level by being able to implement functionality, and he may find the new topics neither an interesting learning experience nor relevant to the world in which he has succeeded. Performance issues are both an intrusion and a threat to his position.

Second, a severe performance problem can mean a substantial redesign effort. Just getting the required functionality is difficult, and satisfying all these "other" requirements may result in a major redevelopment effort. The criticism implied by a demand for redesign (or just the probability of a review of his design) can be an affront to the individual. Many developers regard software development as an art, and their code as an expression of their own personal creativity. They can treat their code so possessively that any intrusion into their domain by a Performance Engineer is greeted with open hostility. One of our favorite comments by a developer is "If you're so smart, why don't you get in here and do some of the hard work?"

Third, developers don't have a natural understanding of Performance Engineering; unless they have seen successes from intensive analysis, they are skeptical. Many view the performance of a system as an uncontrollable result of the development process. In one case, a developer being reviewed argued that everything had been done to improve performance -- even including implementing the whole system in Assembler language. Therefore, examining the system or measuring it was simply an exercise in futility; his product was certainly the very best that could be obtained because of his dedication.

Fourth, redesign (or even minor revision) for the sake of performance can be disruptive and mean schedule slippage and adverse cost impacts. Such changes will be very unwelcome to the development staff who are already under pressure by management to produce the system on-time and on-budget. The easier path is to get something up and running -- and be able to report success. If necessary, those annoying Performance Engineers can be neutralized by simple hostility.

We have observed all the above situations, and have found some difficulty in remaining dispassionate when a developer's defense takes the form of personal attacks. In one case, the development manager's opening gambit was to ask how the Performance Engineering organization was going to fund any disruptions to his people's work. In another case the manager of a critical module wanted to turn over his work to the integration team to find out how the system would function as soon as possible. Then he'd go on to other work and leave the performance issues to someone else -- the Performance Engineering team. If your situation involves limited resources or constrained response time, you may find these tactics objectionable. If not, you're not involved in Performance Engineering.

Project managers can undertake several actions to limit the dysfunctional effects of developers distancing themselves from performance requirements. First, they can have performance requirements (eg, resource budgets) stated prior to the beginning of the project. Second, they can give appropriate weights to functionality and performance in early software deliveries; later deliveries will reflect the relative importance obvious from the manager's earlier actions. Third, in performance-critical situations managers can get personally involved in the issues on occasion. In one successful case, the project manager reviewed important performance memoranda (about two per year) and added his name as an author; the implication from his involvement was clear to the developers.

VENDOR PERFORMANCE STATEMENTS ARE OFTEN NOT USEFUL FOR MAKING PROJECTIONS

The computer marketplace is intensely competitive. Vendors make claims about their system hardware and software performance, and it is the Performance Engineer's responsibility to determine the validity of these claims and their applicability to the project. Aggressive vendors of "fourth-generation" software and alternative hardware products are particularly prone to optimistic generalization of performance figures achieved under narrow conditions. In hardware, for example, the familiar MIPS rating (Meaningless Indicator of Processor Speed) is a good example of the problem. These ratings are often based on running programs such as the Towers of Hanoi or the Whetstone Benchmark and bear little resemblance to any user application. They are typically small enough to be executed completely in the CPU's cache, so processing speed is far higher than can normally be attained. Only the user with the simplest of applications will come close to achieving the speeds implied by the vendor claims.

One of the most inappropriate techniques is to adopt a single indicator of performance (like MIPS) and blindly make projections for a complex environment. For example, one minicomputer vendor advertises a 10 MIPS rating for his machines, an impressive rate for his price -- if his machines were that fast. In fact, we have found that a rating of 3.2 is more appropriate for a variety of realistic applications. Many-faceted benchmarks (eg, the one described in [5]) are far more useful for a competent analysis. The Performance Engineer will be most successful if he provides his own benchmark and has all vendors (of CPUs, tape drives, disk drives, memory, communication front ends, etc) run that specific benchmark. The selection process can be simplified by discarding those vendors who refuse to run the benchmark; any selected system should be reevaluated if performance data are not available.

In the software realm, claims are similarly impressive, and doubtful. Such claims extend from microcomputers up through main-frames. For example, "vapor-ware" (software that has been announced but exists only as an idea -- vapor, and may never be any more firm) is a common problem. Its performance will be really fantastic "any day now". In the main-frame marketplace, performance claims have actually led to legal action on the basis that they are not legitimate. The Performance Engineer should refuse to accept the claims of vendors about performance unless they can be verified by meaningful benchmarking or (if necessary for forthcoming products) by doing an independent projection.

A large law firm purchased an accounting and word processing system from a small start-up firm specializing in software packages for the legal profession. Although the package had not been fully implemented, the selection committee was swayed by the vendor's claim that comparable features and performance would be provided at a much lower price than other packages offered by more-established vendors. The package not only failed to function as advertised, but it ran very slowly. Even though the firm had

competency to seek redress in court, this would hardly solve its needs for a system that performs well; the issue remains unresolved. Of course, the firm would advise a client against accepting a contract without legal review -- even if the other party assured the client that everything was perfectly fine. Yet it accepted the assurances of the software vendor of the appropriateness and speed of its product -- without a performance review.

PERFORMANCE SLIPS AWAY UNLESS IT IS CONTINUALLY MONITORED

Developers, for the most part, are dedicated and over-committed people, even though some of them would really prefer for performance issues to go away. They must make decisions about design and implementation every day, and they can hardly consider every possible issue each moment of the day. As they make their decisions, unexpected performance effects creep into the system, few of them beneficial. Many factors limiting performance are not recognized at the beginning of a development project, but the effects of these must be reflected in revised projections as soon as possible. Simply doing an initial analysis, making a projection, and then leaving things alone doesn't yield very good results.

After implementation has begun, performance of important subsystems must be reevaluated on nearly a continuous basis. With such reevaluation, unfortunate directions can be identified immediately, and corrective actions may be possible before extensive resources are devoted to the wrong option.

When unfortunate performance impacts are not avoidable, projections must be reassessed so that the project can determine whether compensating actions are possible. In one case, a DBMS for a real-time system was divided into several independent tasks to reduce memory impact. The overhead from message passing between tasks for each I/O was so high, however, that the CPU time per I/O doubled, and we projected an increase in system CPU consumption of over 10%. Early measurement identified the problem, and corrections were feasible before personnel were assigned to other activities.

In a second case, our early analysis of an important transaction indicated that it would be within its I/O and CPU budgets. However, as the design progressed, we realized that our analysis was incomplete; the sequence of activities would result in unacceptable response time. Therefore, we suggested that the application be divided into two parts that could be executed in parallel. By tracking performance (even before we could do any measurement), we were able to identify needed design revisions before implementation began.

In yet another case we tracked performance in several subsystems on a large project, and projected that performance would be adequate in one particularly challenging subsystem. Subsequently, we were preoccupied elsewhere and ignored that subsystem. Two months later we reexamined the subsystem (by doing some quick measurements) and found that a variety of problems had arisen. Considerable effort was required to bring performance back under control.

As systems are designed and evolve, performance problems invade and remain. As more effort is invested, the cost of removing the problems goes up.

EFFECTIVE TACTICS

Below, we suggest some tactics to make Performance Engineering more effective. These suggestions do not arise from any abstract theory or hopes for future software development practices. They come from our bitter experiences and sweet successes.

USE SIMPLE MODELS SO THAT FREQUENT CHANGES CAN BE ACCOMMODATED

With a really complete model of system performance, it seems that the Performance Engineer should be able to predict the system's throughput and response time. He should be able to compare predicted performance with achieved performance and identify deviations. He should be able to apply theory throughout the system. In fact, he will spend the bulk of his time detailing the model and trying to modify it to reflect the system's evolution. The effort required to build and maintain a complex model is effort diverted from addressing performance issues important to the system's success.

Instead, a simple model quantifying resource consumption and/or estimating throughput can guide efforts to the most important topics without requiring an excessive development effort just to implement the model. Probably, developing even a simple model will require the Performance Engineer to discuss the design of subsystems with developers and then to suggest the important performance aspects of the designs. Simply going through the process of defining these aspects of the design will provide opportunities for the Performance Engineer to work with developers and identify improvements -- as early as possible. In most cases it will surface unexpected areas of resource inadequacy and performance over-commitment, and it will provide a review of design from a new point of view. Problems can be jointly identified and jointly resolved. Of course improvements will require revisions in the model in order to reflect the new design, but modifying a simple model is straightforward.

In two cases organizations decided to develop extensive discrete-event simulation models, and assigned several people to undertake the effort. The models were developed, but lagged the development of the systems to such an extent that, in one case, a second model development was undertaken so that development trade-offs could be made in time to influence the design of the system. In the other case the complex model was replaced by a simple spread-sheet model because of difficulties in understanding the reasons for some results of the simulation model. Neither the developers nor the modelers could give an explanation for the interactions, so it was difficult to suggest alternatives for system improvement. The simpler model was easier to understand and therefore more useful.

(Models of existing systems are typically used to determine the effects of alternative hardware configurations, or to indicate the capacity limits of the current hardware with the existing software. These models have the advantage of being based on empirical data showing the results of system interactions, so far less speculation is required on the part of the performance analyst.)

MAINTAIN A GLOBAL MODEL REFLECTING SYSTEM-WIDE PERFORMANCE EFFECTS RATHER THAN A SET OF INDEPENDENT SUBSYSTEM MODELS

As design issues arise, quantitative analyses must be executed to support decision-making. As a project progresses, a variety of these analyses will have been done, and they can be used to project system throughput. Unfortunately, inconsistencies tend to creep into these analyses as they are updated on different schedules and with different objectives. The

result can easily be a deceptive set of answers for questions raised late in the project's life.

We strongly recommend maintaining a consistent model of resource consumption across the system. This model should be updated with each major modification of the system and each special performance analysis. The sources of values and relationships should be documented so that later revisions can be made without re-deriving the model.

In one large project we did a variety of performance analyses concentrating on assisting design personnel. The individual analyses sufficed until a major projection was required. At that time we found that, although we had diligently documented each individual analysis, we could not perform the required projection until we resolved a variety of inconsistencies. Resolving these was difficult because of undocumented and inconsistent assumptions implicit in various analyses. For example, a change in hardware resulted from an analysis of one subsystem that used that hardware extensively. The effects on another subsystem, however, had not been assessed because the hardware was not justified on the basis of its improvements to that subsystem. Subsequent analysis showed significant effects in the second system, and we needed to extend the analysis to reflect the effects on all subsystems.

MAKE ESTIMATES OF RESOURCE CONSUMPTION EARLY -- EVEN BEFORE INFORMATION IS AVAILABLE TO MAKE ACCURATE ESTIMATES

A Performance Engineer must focus attention on the most important performance issues as early as possible. Making early estimates of resource usage is difficult, and accurate estimation calls for experience both with the application and with making estimates. However, even imprecise estimates are very useful for identifying performance problems that will exist when the most optimistic estimate is used.

The difficulty with making estimates is usually a reflection of the difficulty of coming to grips with the important issues of performance design. If a Performance Engineer wants designers to address performance problems throughout the life of the project, he must undertake the effort to work with designers and decide on estimates for the use of each important system resource and for response times. We have repeatedly found that we need to suggest estimates to developers after discussing the design with them. System design is their skill, performance estimation and projection are ours.

TAKE MEASUREMENTS OF REAL SYSTEM PERFORMANCE AS SOON AS POSSIBLE

As implementation proceeds, measurement will eventually be possible, and should begin to replace estimates. If you've been working for months on estimates and models, you'll develop a style of working with system implementors. Switching from that style (involving estimates and models) to a style appropriate for measurement tends to require a force of will. In one case, the first measurement by a Performance Engineer came rather late, and indicated that the system's performance was drastically different from the models. Recovering performance at that late date was difficult and expensive. Earlier measurement was needed.

We have observed that some subsystems managers tend to resist early measurement. They believe that performance will improve after additional work is done and that they may be embarrassed by early results. Acquiescing to their requests for delay will invite problems to grow. Even if no problems were present initially (that must have happened sometime), performance will tend to degrade when no means is used to detect problems so that developers can correct those problems. Functional debugging is a fact of life, and so is performance debugging.

On the other hand, if the Performance Engineer takes the opportunity presented by early data to be arrogant and exclaim about the incompetence of designers, he will find that obtaining aid for making measurements will be increasingly difficult. The trick is to work with developers to aid them with the data before revealing adverse results to their superiors. At this stage of the project, the Performance Engineer's responsibility is to aid designers to improve their work. If radical changes appear to be needed, the situation should be discussed with developers before it is revealed to others.

We have found that early performance results are frequently frightening, and that upper managers can easily be panicked by the results. Although the Performance Engineer should not take the position of defending inadequate results, he should concentrate on ensuring that performance results are interpreted in the context of the development environment and the probable improvement resulting from further efforts.

CONCLUSION

Performance Engineering can pay off handsomely; it can ease the attainment of acceptable performance; it can significantly improve the probability of success in large software developments. However, it requires that problems in the real environment be recognized and addressed.

Practical measures must be taken to make Performance Engineering successful. Our experience is that working closely with developers is critical, that simple models must be employed, and that measurements should replace estimates as early as possible.

As the field continues to develop, we hope that others will document the lessons that they have learned. In addition to the academic literature, we need information from other Engineers that are facing the difficult problems in the field.

SERVICE LEVEL AGREEMENTS:
"Good Fences Make Good Neighbors"

George W. (Bill) Miller
American Airlines

ABSTRACT

A Service Level Agreement is a written contract between the user and the provider of a service. It identifies the parties to the agreement. It states the user's expectations regarding the volume, availability, and timeliness of the service, and the provider's obligations in supplying the service. It specifies the price of the service if appropriate, and the penalties to be assessed if volumes and/or services are outside of agreed limits. A centralized SLA control function provides a repository of SLA information and coordinates the administration of Service Level Agreements. This paper will define and discuss the key elements which make up a Service Level Agreement, as well as those related activities which must be present and functioning to allow the effective management of the installation's workload to include: Monitoring Procedures, Chargeback, Capacity Planning Procedures, and Organizational Structure. Also included is a proposed general format for Service Level Agreements and a checklist to assist in the inclusion of the proper elements for any given situation.

INTRODUCTION

The management of a large computer can be likened to the challenge of restoring order after a prolonged civil war. Everyone has chosen sides, old prejudices are cherished, and general suspicion is the order of the day. How does one replace this pervasive animosity with a sense of common purpose? The answer has something to do with mutual expectations.

Most of our working relationships can be seen in terms of a service to be provided, and the parties involved as the providers and users of that service. What a properly constructed Service Level Agreement (SLA) really does is to create a mutual understanding of the requirements and capabilities of both parties, and allows them to arrive at a realistic set of common expectations regarding the service to be provided.

In classic DP terms, computer service is usually seen as the processing of batch jobs or interactive transactions and it is this type of service that is most frequently the subject of a Service Level Agreement. Actually, in most working relationships, one can identify a service being provided to the user of that service. Certainly Computer Operations provides the service of controlling the daily utilization of the installation's computer resources by those who need the information provided by the various computer applications.

But just as surely, those with problems need the assistance of the help desk or the coverage group, various business elements need the services of the applications development people, and the operations people rely on the hardware planning people to assure the environment adequate to accommodate the installation's workload. Considered in this manner it is soon clear that most relationships can be described in terms of a service between a provider and a user or customer. We often tend to refer to internal "users" and outside "customers" although the two terms are basically interchangeable. The range of relationships for which SLA's should be constructed is a management decision. The point is not that all relationships should be covered by SLA's, but that most relationships could be.

It should be clearly understood that Service Level Agreements are one part of an overall installation management program which includes monitoring and historical analysis, capacity planning, and chargeback. The successful implementation of Service Level Agreements will require total organizational commitment.

Service Level Agreements:

We can define a Service Level Agreement (SLA) as a written agreement between the customer and the provider of a service which identifies the parties to the agreement, the customer's expectations regarding the nature of the service, the provider's obligations in supplying the service, and, when appropriate, the compensation for this exchange.

For purposes of discussion it is useful to structure the SLA into a number of specific elements even though these elements are largely interrelated.

1. Identify the parties to the agreement.
2. Describe the service to be provided.
3. Specify the volume of demand for service over time.
4. Define the timeliness requirements for the service.
5. Discuss the accuracy requirements.
6. Specify the availability of the service required.
7. Define the reliability of the service provided.
8. Identify the limitations to the service that are acceptable.
9. Quantify the compensation for providing the service.
10. Describe the measurement procedures to be used.
11. Set a date for renegotiation of the agreement

1. PARTIES TO THE AGREEMENT

Depending on the scope of the agreement, the parties to the SLA may be groups within the same department, between major departments, or with customers outside the organization. In any case, agreements are best set out between individuals, either by name or by title, along with their physical location. After all, somebody is going to have to sign the thing.

2. SERVICE TO BE PROVIDED

For purposes of discussion it seems useful to define some terms.

Computer Resource Units (CRUs) are the basic units representing computer hardware activity. Examples would be CPU time, various I/O counts, tape mounts,

DASD storage, etc. Service Units (SUs) are weighted composites of several CRUs and are used to describe the overall hardware resource associated with some activity.

Computer Workload Units (CWUs) are the basic workload elements within the computing environment. Examples are batch jobs and interactive transactions. The resource characteristics of CWUs are described in terms of CRUs, i.e., we may describe the activity of a batch job in terms of the volume of CPU time and I/O counts.

Business Work Units (BWUs) are the business related activities that are the purpose of all this computer activity. Examples are bank deposits, claims received, units manufactured, or passengers boarded. Until we look at the work done in terms of BWUs, we have difficulty in distinguishing the computer installation of a bank from that of an insurance company or a manufacturing company or an airline.

The user of DP service may wish to describe activity in terms of Business Work Units (BWUs) of passengers boarded, etc. The provider of the service sees the activity generated by the conduct of the user's business in terms of a number of the Computer Work Units (CWUs) of jobs, transactions, or messages required to accomplish a passenger boarding. These computer related work units can in turn be translated into Computer Resource Units (CRUs) of CPU time, peripheral usage, etc. The Computer Work Units provide the necessary bridge between work as seen by the customer and demand as seen by the provider. We will look at these relationships again when we discuss pricing.

3. VOLUME OF SERVICE

It is not reasonable to expect that the provider of a service be required to agree to a specific quality of service without knowing the quantity of service which is to be demanded.

Both the expected volume and the time distribution of that volume must be considered and specified. Requirements should specify the average and peak rates at which this work will enter the system and the times during which this demand is expected to occur. The user should be provided with the incentive of better service at a reduced cost by avoiding peak usage periods.

It should be clear that the volume of demand is as much a part of the binding SLA as any other element. The quality or timeliness of service is agreed to be provided for a certain volume of demand at a certain time of day. If the actual volume of demand exceeds these estimates, then it is very appropriate to describe a reduced requirement for quality.

In addition, the customer should be required to define the expectation for the volume of service to be required over some significant period of time into the future. It is not unreasonable to ask for an estimate of volume of demand by month for the next 24 months. The provider cannot be expected to provide a high level of quality service over an indefinite period of time without knowing what is coming next. One of the most tangible benefits to be derived from the development of comprehensive SLAs is the information on expected workload growth that results.

This is particularly important during a time of the rapid incremental growth which would result from aggressive marketing of data processing services. In this situation an accurate estimate of demand from the customer is essential. The accuracy of the estimate may be significantly improved if the customer is allowed to describe demand in terms of Business Work Units. The added constraints on service requirements imposed by the service level agreement provide additional means for providing quality service in a rapidly growing environment.

Reference the fine paper by John Propst. (see [1]).

4. TIMELINESS OF SERVICE

The timeliness metric defined in the SLA will depend on the nature of the work. Discussion with the customer and analysis by the provider will have determined the number and kinds of Computer Workload Units which will be required to support the customer's Business Work Units. These computer workload units may be batch jobs or on-line transactions or input messages. Timeliness will probably be defined in terms of the Computer Workload Units, that is in terms of batch turnaround time or transaction or message response time.

Batch turnaround time may be stated as job start to job stop. For TSO submitted jobs, particularly applications development and user submitted production, distributions of the form "90% within 2 hours" are appropriate. Specific times will vary by class. Additionally for production jobs some times outside the host may be needed, e.g., input available to job submit, or print complete to delivered to the user. Scheduled production jobs may define service in terms of whether the scheduled completion time has been met, e.g., if input is available by 8:00 p.m. then output will be delivered to the user by 8:00 a.m., etc.

Transaction or input message response time as perceived by the user is generally the time from when the enter key is pressed until the keyboard unlocks and a response is received. Measurement of times outside the host processor present measurement challenges although a variety of tools and techniques exist for measuring or estimating these times.

Transactions with consistent characteristics are adequately described by a "90% within 2 seconds" distribution. Some transactions while consistent in their characteristics may be highly data-dependent. In such cases it may be necessary to link response times to the amount of data being processed, and define response time limits which relate to ranges of volume.

A number of examples of timeliness for non DP specific relationships can be found in the SLA checklist found in appendix A.

5. ACCURACY OF SERVICE

A discussion of accuracy generally relates to some minimally acceptable level of defects in the service provided. For batch jobs, for example, this may involve errors in the input data or in some frequency of reruns. In general, computers are impressively accurate, people are not. A number of examples are provided in the SLA checklist.

6. AVAILABILITY OF SERVICE

As an element of a SLA, availability is that time window during which service is to be provided to the customer. A frequently complicating factor is that a system may be up and accessible, but operating in a degraded manner.

The customer's notion of availability is that if work is going in and coming out at the usual rate, the system is available; otherwise, it is not. In fact, availability is the product of a series of system

components, any one of which can affect end user availability. These components include:

- local terminal equipment
- network equipment
- front end processor
- network control software
- mainframe processor
- control units
- I/O devices
- operating system software
- operational support software
- applications programs
- individual databases.

For each of these there is the possibility that a failure will result in loss of availability to at least some users. Obviously the probability and impact of component failure will vary with component. A Component Failure Impact Analysis (CFIA) is a process of identifying each of the components having the potential for affecting end user availability. The probability of failure for each component should be assessed, as well as the expected recovery time. Part of this process would be to verify that appropriate backup and recovery procedures exist for each.

In the event that significant outages do occur, consideration must be given to the most appropriate use of the available service. The SLA should establish the Disaster Recovery Priority for a particular application or user. Depending on the resource available and the needs of the user, this priority might be part of a pricing discussion.

This discussion owes much to an excellent paper by Tony Clifford-Winters. (See [2]).

7. RELIABILITY OF SERVICE

There is often some confusion as to just what is meant by the terms accuracy, availability, and reliability. We have discussed accuracy as a measure of defects and availability as a time window during which service is planned or scheduled to be provided. Reliability has to do with the comparison of actual availability to planned availability. There needs to be an acceptable definition of the conditions that accurately indicate whether or not the system is or is not fully available. Then reliability might most simply be stated as the ratio of the time that the system was actually available to the time during which the system was planned to be available. We would probably state this as a percent, and set a standard for an acceptable degree of reliability.

8. LIMITATIONS OF SERVICE

Customers do not operate in an environment of unlimited resources, nor do they operate alone. There are limits to the level of service which can be provided by the host environment even under optimal conditions. If the user requires a higher level of service than is currently available, then some interim agreements will be required while the environment is evolved to one with greater capabilities.

To the extent that applications share resources, they have the potential for interfering with each other. While some of these problems may be resolved by appropriate costing, there may be constraints imposed on the use of certain resources to enable various applications to coexist peacefully.

9. COMPENSATION FOR SERVICE

If Service Level Agreements are expected to be taken seriously, they should have some teeth. Cost allocation activities that go to great lengths to determine a customer's share of the cost of the installation and then report that cost for the customer's information are relatively worthless. High level summaries reported to corporate management can get some temporary attention, but this is a crude way to manage costs.

The way to keep us all honest requires a real live chargeback system. by chargeback is meant a procedure for not just attributing but billing the cost of providing computer service to the user of that service.

Service may be internal to the corporation or may be sold to an outside customer. It can be said that these present different goals: the goal of internal usage being to minimize costs by limiting demand, the goal of selling service to outside users being to maximize profits by encouraging demand. However, if it is accepted that the intelligent use of data processing is an activity to be encouraged, then both cases involve providing high quality service at a minimal (competitive) cost. The factors to be determined are units and prices.

The development of effective pricing structures will be determined by the need to recoup costs and the desire to establish a profit margin. When the corporation is its own sole user of DP service, the level of profit built into charges is essentially an accounting consideration. When the data center is selling service to an outside customer, the goal is to maximize profit while providing an attractive quality at a competitive price.

While the specific price structure can only be determined by careful financial analysis, it is useful to review some general principles.

Breakeven pricing is based on the notion that the total cost of the data center resource should be borne by the users of that resource. Each user pays a proportionate share of the total. The result is that charges will vary from period to period. A user's cost for doing the same work will go up when total utilization goes down and would decline when utilization is high. This discourages the user from using the resources to best advantage and makes planning very difficult.

Standard costing plus a profit margin assigns a fixed cost to each Computer Resource Unit (CRU) which in turn will fix the cost of a standard Computer Work Unit (CWU) which in turn will fix the cost of a standard Business Work Unit (BWU). The point here is that we are agreeing to use averages which will allow us to fix rates. We estimate the average cost for a unit of CPU time, or for I/O activity, or for some unit of DASD storage, and use these rates regardless of the specific level of utilization for a given period. We can go through a similar process of determining the average number of CRUs required to run a particular class of job or transaction, and arrive at a standard cost for a CWU. Likewise, we can determine that the accomplishment of a particular business activity typically requires a certain number of batch jobs or transactions or whatever, and arrive at a standard cost of servicing a BWU. Since the cost is based on a fixed average, the actual charge for service at any given time is an estimate. The overall results should be reasonable, however, and the advantage to the user of having consistent understandable charges is very significant. Standard costs can be revised when the SLA is renegotiated.

While this discussion is in terms of hardware resources, there are obviously other costs. The related people and environmental costs are often associated to hardware resources in terms of cost pools. The specifics of such things are proper topics of a comprehensive discussion of chargeback, but are somewhat beyond the scope of this discussion. For example, suppose that a travel agency can estimate the volume of passenger bookings (BWU) that it expects to occur in a given period of time. The agency contracts with some high class airline to provide them with the required service. Say, just for sake of an example, with American Airlines. After some analysis of the kind of business this agency does, it is determined that they will require an average of 20 transactions to accomplish a booking. The appropriate cost to process this activity is developed based on standard costing plus some margin for growth and profit. Charges are billed to the user based on the number of bookings accomplished. The customers cost is directly tied to the volume of business. The provider's cost will be more or less than planned largely according to whether the average number of transactions required to do the booking is more or less than 20. As these relationships change over time, the price structure will need to be renegotiated. Price incentives can be used to encourage greater efficiency on the part of the customer. In this way the customer has some influence over the cost of his service, and may consider the option of choosing to trade off DP expense for employee skill level.

Standard costing has a number of advantages:

- the customer can project volume in Business Work Units
- the customer is billed based on the amount of Business Work Units generated
- the cost of a Business Work Unit is fixed for the life of a Service Level Agreement
- the customer can reduce costs by requiring fewer Computer Work Units
- the provider can increase profits by operating more efficiently.

The primary difference in internal users and outside customers is in the method of payment. Internally, all this can get real in a hurry if the cost for the service is part of the user's budget.

In a non price-specific arrangement, compensation can still take place in terms of nonmonetary incentives and/or penalties. Compensation may relate to wage and bonus incentives or to the basic MBO process.

OPTIONS: The relating of appropriate charges to both the volume and quality of that service gives the user an incentive to utilize service as effectively as possible, and gives the provider an incentive to improve quality. For this reason it is necessary to tie service level costing to both volume and service.

Rates should be highest for demands made during prime shift, perhaps higher still during the peak mid-morning and mid-afternoon hours.

Disaster recovery priority or priority during periods of limited resource availability should require some additional financial compensation.

Batch turnaround times or interactive response times which are near the ultimate limits of the host environment should warrant premium rates, while more modest levels of service will cost less.

The implication here is that a user who demands premium service will expect to pay premium rates, and the user whose demands are more modest can expect to save money. The corollary is that if the user is provided with a level of service that is less then that for which he contracted, he is entitled to pay a lower rate.

Some very good discussions of costing are referenced. (See [3] [4]).

10. MEASUREMENT OF SERVICE

Comprehensive monitoring procedures are central to the establishment and maintenance of SLAs and to the effective management of the data center as a whole.

Proper monitoring procedures begin with the means for routinely obtaining installation performance information. Sources of such information include SMF files, RMF data, IMS logs, hardware monitors, network monitors, and manual logs. This collective information forms the basis for everything known about what has happened in the data center.

The large volume of this very detailed information requires that it be summarized for historical purposes. this summarized history is one of the single most valuable resources possessed by the corporation. Analysis of this information makes possible:

- the intelligent establishment of achievable Service Level Agreements
- the accurate assessment of charges to the user
- the performance tuning information required to insure that the environment makes the maximum resource available
- the historical trending which allows reliable forecasting
- the detailed modeling information required to support hardware planning.

The importance of this historical information to the corporation implies that the primary tapping of the raw sources and their initial summarization should be a consolidated activity rather than a separate effort for each area of interest. There should be a Performance Data Base (PDB) to serve as the source for this information by those requiring it.

Consolidation of this activity eliminates considerable duplicate effort both in manpower and in the significant amount of computer resource required to process these very large accounting files. An even greater benefit is the sharing of a single, comprehensive, and consistent source of historical information. Common access to an expanded fund of knowledge will enable more intelligent decision making.

The consolidation of these various activities requires a high degree of coordination to insure that all required information is present in the master performance data base, and that maximum advantage is taken of new tools and technologies in the field of performance monitoring.

12. RENEGOTIATION OF SERVICE

Under normal circumstances, service level agreements should be renegotiated at least annually as a part of the budget cycle. As a practical matter, they may need to be reviewed more often.

Some deviation from standard can be expected as a part of the natural dynamics of a large system, but SLAs which are significantly out of bounds for several months in a row should be renegotiated immediately.

Significant changes in the host environment or in the needs of the user would require immediate renegotiation.

Organizational Responsibility:

Organizationally, a centralized SLA control function should be established to provide a repository of SLA information. This central control would have the responsibility for chairing the SLA negotiating team. Members would include representatives of both the user and the provider of the service, and others whose involvement requires their participation. The centralized control function should also provide the coordination required to incorporate the various SLAs into the data processing limitations of the installation as a whole, and to allow their coexistence.

Responsibility should be explicity assigned for the following critical activities:

- to coordinate and assure the routine collection and archival of essential performance information, i.e., "the keeper of the data"
- the determination and periodic review of standard costs
- to assess the service level capabilities of the host environment as they form limitations on individual Service Level Agreements
- coordinate the creation of new Service Level Agreements and their subsequent review and renegotiation
- maintain a centralized repository of Service Level Agreements
- coordinate the creation of a Component Failure Impact Analysis (CFIA) to support availability service levels
- coordinate the creation of intra-organizational SLAs to support the CFIA activity
- generally facilitate the SLA process in a controlled, consistent, and unbiased manner

Conclusion:

The establishment of internal Service Level Agreements as a routine way of doing business will cause a significant impact to all areas of the corporation. Requirements, expectations and procedures will have to be discussed and formally defined. The eventual result will be to permit a greater degree of control over the cost and growth of services.

As a practical matter, the parties to the exchange will eventually come to a set of mutual expectations with an SLA. What the formal Service Level Agreement will do is to allow this to happen initially as a result of negotiation, rather then wait until differences in expectations have deepened into bitter disputes that force decision making at inappropriately high levels in the organization. Pay now or pay later.

APPENDIX A.

SERVICE LEVEL AGREEMENTS - Issues and Options

A Service Level Agreement (SLA) is a written agreement between the customer and the provider of a service. It identifies the parties, the customer's expectations regarding the nature of the service, the provider's obligations in supplying the service, and, when appropriate, the compensation for this exchange.

There are five major issues to be resolved in the development of Service Level Agreements:

1. Services to be covered by the agreement
   - classic central site/DP customer services
   - applications development
   - technical assistance
   - administrative support
   - training

2. Parties to the agreement
   - outside customer
   - internal user
   - within Data Processing
     DP will require hierarchy of SLAs for support
     within department groups
     across department boundaries

3. Development of the agreement
   - negotiating team
     customer(s)/provider(s)
     SLA coordinator (responsibility)
   - complete and detailed service definitions
     nature/volume/timeliness/quality
     standards and means of measuring
     incentives/penalties

4. Enforcement of the agreement
   - pricing structure (if appropriate)
     cost unit should relate to service provided
     price relates to both volume and quality of service
   - effective chargeback system required
   - non-price incentives/penalties
     MBO review item
   - capabilities for measurement and reporting must exist

5. Review of the agreement
   - schedule of periodic review and renegotiation
   - adjustments to volume/service/incentives

A proposed general format for Service Level Agreements and a detailed checklist follows:

SERVICE LEVEL AGREEMENT	Reference Number

This document constitutes a formal contract between
_____ (Provider)
and
_____ (Customer)
The specific support objectives and limits to the services provided are described within this document and its attachments.

Implementation Date	Review Date
Provider's Location	Provider's Coordinator
Customer's Location	Customer's Coordinator
Description of Service	
Volume	
Timeliness	
Accuracy	
Availability	
Reliability	
Limitations	
Compensation	
Measurement	

Provider Approval	Date	Customer Approval	Date

SERVICE LEVEL AGREEMENT CHECKLIST

This checklist is intended to assist in the development of a Service Level Agreement. Since Service Level Agreements can be used to describe a variety of services and parties, the particular elements appropriate to a specific SLA will depend on the circumstances.

Implementation date
- Effective date for this agreement

Review date
- Date or period for planned review of this agreement

Define parties to agreement
- Provider of service
- Provider location(s)
- Provider coordinator
- customer for service
- customer location(s)
- customer coordinator

Describe service to be provided
- Purpose of service
- Location of service
- Type of service
  - Commercial DP services
    - Batch jobs
    - TSO development (SPF)
    - IMS
    - DB2
    - APL
  - Real time DP services
    - ACP/TPF
    - VM/CMS
    - Other
  - Communications services
    - Terminals
    - Concentrators
    - Front-End
    - Lines
    - Modems
    - Network control
  - Applications development services
    - Functional review
    - Design
    - Testing
    - Implementation
  - Technical assistance
    - Computer operations
    - Software support
    - Control program support
    - Management reporting
    - Workload forecasting
    - Hardware planning
    - Strategic planning
    - Contract administration
    - Hardware installation
  - Problem resolution
    - Coverage
    - Help desk
  - Maintenance
    - Hardware
    - Software
    - DP internal
    - Outside vendor
  - Training
    - For DP
    - For customer
    - By DP Training
    - By outside vendor
  - Administrative support
    - Personnel administration
    - Medical support
    - Social services
    - Insurance
    - Employment services
    - Financial services
    - Procurement
  - Environmental support
    - Facilities
    - Security

Volume Expectations
- Batch jobs
  - Weekly totals - min, max, and average
  - Daily peaks - min, max, and average
  - Distribution over prime, non-prime and weekend
  - Projected 2-year growth
- Interactive transactions/messages
  - Daily totals - min, max, and average
  - Hourly peaks - min, max and average
  - Hourly distribution over prime, non-prime, and weekends
  - Projected 2-year growth
  - Terminal Count
  - Terminal Growth
- Ceiling on maximum or peak volumes
- Communications network volumes
  - Daily totals - min, max, and average
  - Hourly peaks - min, max, and average
  - Hourly distribution over prime, non-prime, and weekends
  - Projected 2-year growth
  - Terminal Count
  - Terminal Growth
- Applications development
  - Functional specifications
  - Manning levels
  - Testing requirements
  - Documentation
  - Implementation schedules
- Technical assistance
  - Specify services to be provided
  - Reports
  - Forecasts
  - Planning documents
- Problem resolution
  - Support services to be provided
  - Volume of demand for service
  - Daily totals - min, max, and average
  - Hourly peaks - min, max, and average
  - Hourly distribution over prime, non-prime, and weekends
  - Projected 2-year growth
- Maintenance services
  - Maintenance services to be provided
  - Expected volume/frequency
  - Scheduled/unscheduled maintenance/modifications/releases
- Training
  - Type of training to be provided
  - Training schedule
  - Class size/frequency
  - Location

Administrative support
- Type of service to be provided
- Expected volume/frequency

Environmental Support
- Type of service to be provided
- Scope/volume/frequency

Timeliness Expectations

Environmental capability provides limits

Batch jobs
- Turnaround times
  - Elapsed job start to job stop
  - Input received to output delivered windows
  - Average times vs. percentile distribution
  - Volume related ranges
- Conformance to schedule

Interactive transactions/messages
- Response times
  - Host processor times
  - Customer terminal times
  - Average times vs. percentile ranges
  - Volume related ranges

Communications services
- Network delay times

Applications development
- Conformance to scheduled implementation dates

Technical assistance
- Conformance to scheduled implementation dates
- Established frequency/publication dates
- Response to crises demands

Problem resolution assistance
- Wait time for service initiation
- Time for problem resolution

Maintenance
- Conformance to maintenance schedule
- Response to crises demands

Training
- Adherence to schedule
- Training duration

Administrative support
- Wait time for service initiation
- Elapsed time for service completion

Environmental support
- Adherence to schedule
- Response to crises demands

Accuracy

Accuracy relates to defects in service performed

Generally input-related for batch processing
- Determination of responsibility
- Rerun policies

Applications development
- Defects per unit of time
- Mean time between defects at implementation
- Elapsed time between implementation and stabilization

Technical assistance
- Defects per unit of time
- Accuracy of information
- Actual vs. forecast variance
- Repeats/revisions required

Problem resolution
- Accuracy of information
- Retries required

Training
- Test scores vs. standard
- Retraining required

Administrative support
- Defects per unit of time
- Repeats/revisions required

Environmental support
- Defects/violations per unit of time
- Corrections required

Availability

Commercial/Real time primary DP services
- Time period during which service is to be provided

Application development
- Project length

Problem resolution/maintenance/ environmental support
- Time period during which service is to be provided

Technical assistance/administrative support
- Normal office hours

Training
- Course schedule

Reliability

Reliability = actual availability as a percent of scheduled availability

Conditions and exceptions
- Perception of customer and provider may vary
- Periods of limited capability
- Frequency of interruptions

Limitations

Interdependencies

Impact on other areas
- Resource constraints
- Conflict with shared resources

Priority
- With respect to provider's other work
- With respect to customer's other work

Backup requirements

Security requirements

Disaster recovery policy and procedures

Cost

Definition of pricing unit(s)
- Charge for service provided, not resource consumed
- Cost of service fixed by provider
  - Computer resources
  - Man-hours
  - Materials
  - Related services
  - Profit margin

Relation of price to service
- Premium price for premium (faster) service
- Price adjustment for substandard service
- Price discounts for off-peak times

Relation of price to volume
- Decreasing scale to encourage volume
- Price penalties for excessive peak or peak-time volumes

Nonmonetary incentives/penalties
- Wage and bonus incentives
- May tie to MBO

Measurement

Responsibility
- Provider
- Customer
- Shared

Appropriate metrics

CAPACITY PLANNING IN THE AGE OF COMPETITIVE ADVANTAGE COMPUTING

Dr. Robert P. Goldberg
Dr. Leonard D. Lipner
BGS Systems, Inc.
128 Technology Center
Waltham, MA, USA 02254-9111

ABSTRACT

As information becomes the driving force behind company operations, and as it affects the relation between the company and the outside world, the Information Systems (I.S.) function has come to be perceived as a competitive weapon. I.S. today is often viewed as a critical partner to strategic business units, and even to company survival.

In case after case, the new computing environment has made extraodinary demands on the Capacity Planner. While having to cope with all the traditional CP issues, he is faced at the same time with a whole new set of problems. Many of these call for new skills, and sometimes even an expanded definition of Capacity Planning.

This paper describes the new "competitive advantage" computing environment, and its implications for the Capacity Planner. Using examples drawn from experience, we illustrate the new kinds of technical and organizational problems he faces, and the new skills he needs in order to solve them.

The Age of Competitive Advantage Computing

In a free market, successful businesses have always had to pay attention to the realities of competition. Like it or not, those who evaluate and shape business practices have had to keep the competitive environment in mind, at all times.

New business practices are usually either attempts to gain a competitive edge, or responses to such thrusts. In fact, one can often read the history of an industry primarily in terms of the competitive thrusts by its innovators and the responses they generate. While specifics vary from one industry to another, competitive thrusts and responses share a relatively small set of objectives. For instance:

1. To lower the costs of production, or at least to keep them from rising, by:
   a. Reducing or controlling the cost of labor, raw materials, and equipment, or
   b. Improving the efficiency of company operations (in design, manufacturing, warehousing, marketing, sales, accounting, etc.).
2. To increase revenues, or at least to keep them from declining, by:
   a. Increasing market share, for example by differentiating one's products in terms of unique added value, by superior products, or by a superior substitute product,
   b. Increasing the size of the market by identifying and selling to new customer groups,
   c. Charging a premium for features the market perceives to have special value,
   d. Developing and bringing to market entirely new products, especially those which leverage one's current strengths,
   e. Reducing the ability of customers to switch to another product or vendor, by creating a situation in which the cost of switching is high,
   f. Reducing the desire of customers to switch, by offering better products and/or services at comparable cost, or
   g. Reducing the ability of other companies to compete, by creating high barriers.

In its early days, computing had little influence in any of these competitive areas. More often than not, the original purpose of computing was to automate accounting, and, later, other administrative (i.e, record-keeping) functions: orders, manufacturing, personnel, etc. All of these uses were aimed at reducing costs rather than increasing revenues. In most businesses, however, administration as such represented a relatively small percentage of a company's expenses, and still does. So, while computers and automation produced sufficient savings to justify their acquisition (even when computers were expensive), these savings had little impact on the company's overall marketplace success or failure.

Online systems, like those for airline reservations or customer inquiry systems, were the first computer applications to influence company strategy and success in a major way, because they were developed not only to cut administrative costs, but to offer differentiated customer service, and thereby to increase revenue substantially. As they grew in size and function, it gradually became apparent that they could (if planned correctly and delivered on time) produce virtually all of the revenue-increasing competitive advantages listed above. Of course, it takes time to uncover and develop the applications with the most competitive clout; it doesn't happen in a day. But with the first development of online systems, the age of competitive advantage computing had begun.

This evolution away from the older view of I.S., as "back office administrative support," occurred gradually. However, it has accelerated in the recent past for three main reasons:

- the dispersion of computing power which put access to data into the hands of end users,
- the relative ease with which users can try out new ways of processing and viewing data to support their business activities, and
- most important of all, the competitive environment: the perception that the competition may well be using I.S., or planning to use it, to gain some advantage in the marketplace.

Today, end user computing is widespread, and its value (real and potential) is almost universally acknowledged. Up-to-date, centrally maintained data is often readily

available directly to business units, along with extremely rich English-like facilities for retrieving, combining, processing, distributing and displaying it. While most large companies still retain large central DP staffs for development and operations, expertise and computing power are now well dispersed in the user community. Since in this case familiarity breeds comfort, the days of "computerphobia" are just about over, at least among middle management. So, it's only natural to expect a great deal of experimental thought, and actual experimentation, regarding new uses of existing information in business. Indeed, that's what is happening.

Examples of Competitive Advantage Computing

It's hardly possible to read the DP trade press these days without seeing at least one item about a company which benefitted by discovering a new way to use its information resources. Often the benefit is small, but sometimes it has a major impact on the company's competitive posture. In a few extreme cases, the competitive thrust is so effective that it actually changes the structure of the industry in which the company operates. More often than not the performance of such applications is critical to their success.

It is now established that for almost every aspect of a company's operations, and every aspect of its relations with the outside world (e.g., with suppliers, customers, rivals, regulators, and the public), some company somewhere has found a way to use information to improve that aspect, and as a result, improve its competitive position. Competitive advantage systems can help a company in a variety of ways:

- They can lower those costs which are major contributors to overall product cost, helping the company become (or remain) the lowest priced vendor.
- They can improve the company's ability to respond to customer orders more quickly and reliably than the competition, often a major differentiating factor in commodity businesses.
- They can materially improve the quality of customer service, before, during and after the sale. This improvement can constitute a critical difference between companies, especially in those industries where such service is a major evaluation criterion for buyers.
- They can lock in customers, drastically reducing their desire to switch to another vendor, in part because the price of switching is high, and for other reasons as well.
- They can add significant value to existing products, for example where the customer has a need for information related to his use of a product, and the company is in a position to supply part or even all of that information, along with the original product. This is especially important in industries where there are few differences among competing suppliers.
- They can establish dominance in a niche marketplace, thereby erecting extremely high barriers for competitors.
- Information or information systems can themselves be marketed and sold, constituting new product opportunities for companies which have developed them for other purposes anyway.

A few specific examples will illustrate the diversity of competitive advantage systems. At the same time, these examples are chosen to show the (often unreasonable) pressures such systems can have on the Capacity Planner, who must somehow ensure that they'll have the power they need, when they need it, to perform as expected.

* Example 1: Airline Merger

The deregulation of the airline industry was the starter's gun in an acquisitions race among carriers seeking to benefit dramatically from economies of scale. Merging two airlines' information systems (and more specifically their reservations systems) is almost always an integral part of making such acquisitions work. While not normally a hard problem, the merger of two large and almost equal airlines led to extraodinary Capacity Planning issues.

Both airlines' original reservations systems were based on IBM's TPF, a high-performance transaction processing SCP which currently lacks multiprocessor support. So, the first question for the Capacity Planner was simply whether the combined workloads, PLUS forecasted volume growth, PLUS anticipated enhancements made necessary by other aspects of the competitive environment, would all run on any available uniprocessor. The answer, apparently, was NO.

Senior management made it clear that merging the reservations systems was a MUST for the merger to succeed. As a result, the next series of capacity planing questions involved evaluating the options available to make the combined TPF systems work:

- Was there a way to "split" the TPF system to permit two copies to run on two CPU's and to share the transaction load? One copy would own the databases and provide service functions to the other copy as, for example, in CICS MRO or ISC. Given the anticipated transaction volumes, and enhancements to the TPF system, would the two copies be able to handle the work?
- Was it feasible to consider modifying TPF (drastically) to provide multiprocessor support? What were the implications of entering what was essentially the SCP software business? Would it be possible to find/keep the people necessary to maintain it? What were the true costs, (initial and ongoing) of this approach, and did the benefits outweigh them?
- If the new airline went into the SCP business, were there new technologies which could materially reduce development costs (CASE, application generators, 4GL's, relational databases, etc.)? If so, what were THEIR capacity implications?

An important aspect of this problem, which is typical for competitive advantage systems, is the way the capacity planner is necessarily drawn in to I.S. planning discussions far earlier than he may have been in the past. Several factors account for this:

- The critical dependence of company success on the information system in question.
- The unique nature of the information system.
- The magnitude of the information system.
- The high visibility and importance of the information system's performance.

We'll see many of these same characteristics in other examples.

* Example 2: Patchwork Quilt Financial System

Nowhere are competitive advantage systems more in evidence than in the financial services industry. Many deals today are aimed at pooling the specialties of several companies in order to bring to market a multi-function financial service, offering the customer the ability to manage a diverse set of (unlike) financial transactions in a single account.

For example, one group of companies combined their computing expertise and information resources to offer a single account for managing stock, bond, money market and mutual fund transactions, as well as insurance and loan processing. Furthermore, to offer unique value, they provided not merely monthly statements, but online access to account information from PC's in the office or at home. In the mad scramble to establish an edge for their offering, they took the next step as well by combining these features with online access to public financial and other databases, advisory services, etc.

The lure of being first and best in a highly competitive market obscured the difficulty of creating the information systems needed to support such an offering. The mistake was to envision that the in-place systems supporting each of those INDIVIDUAL functions could be "glued together" relatively easily, with consolidated statement processing handled as a kind of "shell" around them.

The architecture of their system was badly flawed. The problem was that they built in, almost by design, critical bottlenecks in the batch component. To state it simply, each component system was scheduled to run "as usual", the one difference being that results of each run were saved in order to feed a critical new "consolidation of results" component. The individual batch components could to some extent be multiprogrammed, though at a price of additional contention and therefore stretchout. As functions were added to each component over time, this contention only got worse.

However, by far the most serious bottleneck was the consolidation run, since (1) it had to wait for all the individual component systems to complete, and (2) no printing of final reports could begin until consolidation processing was itself complete. (Typically, the daily consolidation run accessed ALL accounts in which ANY activity took place.) This one characteristic caused the overnight window to be missed repeatedly, leading to availability problems, and initially, poor customer acceptance of the offering. In the final analysis, it was the impetus for a 6 month delay in bringing an offering with adequate performance to market, due to (a) a requirement for substantial application redesign, and (b) a significant, unexpected capacity upgrade. During that period, competitive offerings appeared, severely blunting the first group's advantage.

In fact, there may have been no other way to bring the offering to market more quickly. Doing the job right, i.e., building consolidated processing functions directly into the individual component systems, may simply have taken longer than the window of opportunity stayed open.

Sometimes, taking too long exposes the risk that a competitor's offering will dominate the market. Their system may be as good, or better, or even worse, as long as it's earlier. If the service it delivers results in even moderate customer loyalty, it will be extremely difficult to compete with later on unless one brings out a substantially better product. They will have effectively upped the ante to an unacceptable level.

* Example 3: Intercompany Networks Using Electronic Data Interchange

Whenever two companies are in a supplier/consumer relationship, and do a substantial amount of routine business with each other, EDI may offer both of them numerous benefits. For example:

- For the supplier:
  - Reduce the cost of sales, by allowing the consumer to enter orders directly rather than through a salesperson.
  - Improve cash flow.
  - Reduce the likelihood that the consumer will switch to another vendor.
  - Many others.
- For the consumer:
  - Speed the order entry process, and make it more reliable.
  - Track order status directly, online, in order to make more informed business decisions about the scheduling of his own work.
  - Lower operating costs, by reducing the need to carry excessive inventories,
  - Many others here too.

There is no question that when set up properly, intercompany networks can deliver significant competitive advantage to all participants.

EDI, however, changes all the ground rules for the capacity planner. Other companies on the EDI network are driven by marketplace forces which are entirely outside his awareness, familiarity and knowledge. Yet those forces can seriously affect the service his users will receive, for two reasons:

- The performance of his computer is, to some extent, dependent on the response time of another company's computers. Since workloads on that other computer are driven by external forces, response times from the EDI-partner's computer may may be erratic, or they may exhibit patterns which are hard to recognize and even harder to predict ("from a distance"). The erratic performance may be caused by forces affecting the EDI workload itself, but in fact it may also be caused by unusual behavior in ANY workload on that other computer.
- Conversely, many of the transactions processed on the capacity planner's own computer originate in other companies. For reasons unknown to him their arrival patterns, and changes in their resource demands may behave in ways he finds inscrutable. So, for the very same reasons mentioned above, a major part of the information he needs may be entirely beyond his grasp.

The problem is even more complex when multiple companies communicate via EDI. Specifically, because of the way overall network performance depends on the performance at each node, a "blip" in one company's business can cause ripples in the computer systems of all of its direct EDI partners, then in all of their EDI partners, and so on.

* Example 4: Marketing In-House Developed I.S. Technology or Data Bases

As Information Systems develop and mature, companies sometimes find that they possess applications or data, originally built to serve their own needs which (they perceive) other companies or individuals may

find valuable. It's only a small step from there to the belief that a profitable business opportunity exists. In many cases, before they know it they've diversified into the I.S. technology business. Almost overnight, the "customers" of I.S. are not only internal users, but real, live PAYING customers.

Examples of such diversification exist in virtually every industry. An insurance company may discover that other insurers are interested in its home-grown system for processing a very unique kind of policy (say, pet insurance). Similarly, a department store chain may develop a system for managing a vast array of deals with trucking and other distribution companies, only to find other chains interested in acquiring the system. Even now, with vertical applications available in many industries, there are still a wealth of niche applications developed by ordinary companies, which are too specialized for software vendors, but still of general interest in the industry. They represent possible businesses.

Another available I.S. resource in many instances is spare computing capacity. Sometimes, companies procure this power as a (sensible, in our opinion) hedge against erratic peaks in important workloads. Sometimes, spare capacity is the result of a terrific upgrade deal. To recoup their expenditures however, companies sometimes try to sell this spare capacity to outside users.

In such an environment, quality of service suddenly takes on a whole new meaning. The capacity planner needs to avoid at least three pitfalls:

- Performance itself may be an integral part of the sales message, and when it is, it has to be delivered no matter what. This can of course lead to distortions in the use of priorities, and other methods of guaranteeing service. Specifically, internal work may suffer dramatically during heavy periods, as the price of delivering agreed-upon service to outside users. It's clear that this question should be addressed up front, and ground rules set which everybody, internal and external users alike, can live with.

- As was the case for EDI arrangements, workloads generated outside the company are always the hardest ones to predict. Users may contract for a certain minimum amount of usage, but they don't know, and won't in general be willing to predict, when that usage will occur. They won't commit to a maximum usage either, preferring instead to view the system as a utility, ready to meet any demand.

- As every software company knows, and as others quickly find out, system maintenance can be a far larger effort even than system development. It can, if one is not careful, place an overwhelming test load on the computer system. Perhaps just as importantly, it can impact one's technical staff, limiting the manpower available for such other capacity-saving activities as system and application tuning.

MORE Unreasonable Pressures on the Capacity Planner

The examples above are only a sampling of the ways competitive advantage computing can change the rules for the capacity planner. To illustrate how diverse these changes are, we list below some additional competitive situations, and their consequences for capacity planning.

- Acquisitions and Divestitures

Unlike the airline example which involved a single large acquisition, some companies follow the strategy of growth by rapid acquisition of many smaller companies. They look especially for those companies which show true synergy with the parent over time, and divest those which don't.

In such a corporation, information systems come and go, and even when management determines that IS functions should be merged, the capacity planner has to be extremely fleet-of-foot, because what is merged today may well be gone tomorrow.

Computing economy of scale is sometimes an integral part of the decision to acquire in the first place, especially in information-intensive businesses. It's clearly important for the capacity planner to be part of the initial disussions about the proposed combined operations, since he has unique insight into the method for determining their true costs.

- World-Wide Systems

As companies extend their markets around the world, it can happen that online systems have to be up for more and more continuous hours each day. This can obviously squeeze any required batch update window during which the online system has to be down. The extreme case, of course, is round-the-clock operation, (i.e., the batch window is zero!) which can be both an applications and capacity planning headache.

- Executive Information Systems

In every case the authors know of, special steps are taken to recognize when the CEO or one of his staff logs on, and to ensure them unlimited highest priority service. The problem is, of course, that both their usage periods and the nature of their work can be erratic. Careless planning can be disastrous to the performance of any other concurrent work on the system. One can always provide spare capacity for just such occasions, but one still has to know how much, and probably has to consider what to do with it at OTHER times.

- Supersystems

These are massive information systems, developed by companies attempting to establish dominance of specialized niche markets, in which information itself is a principal part of the deliverable. Many examples of these systems exist in banking and other financial service areas, such as mutual fund trade processing.

Supersystems have a number of characteristics which make life uncomfortable for everyone connected with them, capacity planners included:

. The window of opportunity is short. Several competitors enter a mad race to get their offering to market first. This almost mandates design and implementation compromises which lead to suboptimal performance.

. It costs a lot to bring a system to market which, due to its breadth of function, erects substantial competitive barriers.

. The risks are therefore enormous. Many situations are "winner take all".

. Both performance and cost-per-transaction are

critical success factors. Among other things, the system has to work at a cost commensurate with revenue.

When they are successful, supersystems also have the characteristic that their growth rates can be overwhelming, as competitors go out of business and large numbers of new customers show up "almost overnight". Getting a handle on reasonable workload forecasts, in time to do something about them, can tax even the nimblest capacity planner.

Skills for The CPM Specialist

It should be apparent from all these examples that the capacity planner who survives and flourishes in the competitive advantage company will have a unique set of skills. Naturally, he will have complete command of all the "classical" planning techniques for:

- Workload measurement, characterization, reporting and forecasting
- Service level management
- Performance modeling and prediction
- Technology forecasting and analysis
- Budget calculations
- Plan preparation and management, plus
- The many details within and alongside these tasks.

To these the planner with a strong sense of career survival should add the following:

* Be quick on your feet

  The best plans are sometimes subverted by an ill-behaved reality that follows its own rules. Let reality come first, and be ready to make major mid-course corrections on a moment's notice. That's what navigating on a stormy sea is all about.

* Develop a working understanding of the processes your company employs for both I.S. and business planning.

  This should be done regardless of how formal or informal those processes are. Determine whether they are done at all, how often, by whom, and most importantly, how integrated or separate they are. In order to develop a sense of where the business is and where it is headed, seek opportunities to discuss user information needs with both business and I.S. planners. Stress the (inherent) interrelationships among business venture planning, planning the information systems which support them, and planning the computer systems which support I.S. Finally, express your willingness to work with them in order to begin to integrate all these planning areas, as they should be.

* Seek a clear statement identifying your company's critical business systems, and their performance requirements.

  There's more to this than meets the eye, since perceptions of what is critical to company survival and what isn't vary a lot among people in the organization.

* Determine if your company's management believes in the use and value of information systems for competitive advantage.

  There are many industries in which information as such is simply NOT a major factor in making a company successful. However, if it is a major factor in your industry, determine the people in your company who think so, and nurture good working relationships with them. It goes without saying that to do this, you have to know a fair amount about the business your company is in: how success is measured, and what makes the marketplace tick. Fortunately, there are usually a great many ways you can find this out.

* Find out your company's strategic vision, and who is charged with communicating and pursuing it.

  Awareness of this vision can completely change the emphasis in your presentation of capacity plans to management. It can show clearly how you're helping the company position itself for success, in terms senior management can understand.

* Determine, and seek concurrence on, a list of "reasonable" I.S contingencies.

  This list should be based first on the most likely competitive thrusts your company will undertake over the planning horizon, and second, on expected thrusts by your competitors and your responses to them. In most cases it will probably be quite difficult to do this, but take your best shot, and use the advice of professionals who spend most of their time watching the marketplace.

* Include analysis of business and I.S. contingencies as a standard part of your capacity plan.

  Based on the list of contingencies described above. Make liberal use of sensitivity analyses, especially to be able to identify "early warning indicators" - a small set of marketplace and I.S factors to watch as early signals of the need for mid-course corrections to the plan.

  Develop a plan for hardware order positions to maximize your ability to respond to sudden requirements for capacity increases (or decreases, in the cases of divestments).

* Develop a tolerance for, and an ability to process, "fuzzy" forecasts. For those forecasts, and for other reasons, appreciate the importance and uses of spare capacity.

Conclusion

This paper describes many (but not all) of the approaches companies are taking today to reap maximum competitive benefit from their information resources. We have seen that in most cases, the capacity planner must be aware of the business environment, and must develop his plan with that environment clearly in mind.

The "classical" techniques for capacity planning can and must still be used. To these the planner must add a whole new set of skills and awarenesses, built upon cooperative relationships with other kinds of planners. These new skills represent maturation and career growth for the capacity planner, and they parallel the integration of I.S. and business planning in the company as a whole.

STRUCTURED MIS PLANNING

Veli-Matti J. Salminen
National Advanced Systems

ABSTRACT

A capacity planning project can easily become an overwhelming effort due to the generally fuzzy definition of what the boundaries of that project should have been. At the same time, businesses are seeking ways to integrate their MIS plans with their business plans, thus further clouding the issue. As a result, MIS capacity planning is changing from a single-person effort to a team effort and from an one-off exercise to an ongoing series of activities across the organizational boundaries.

This paper presents a different look at MIS planning based on solid experience. Identification of required planning components and participants is followed by a framework of managing the planning process across the organizational boundaries.

1.0 INTRODUCTION

The capacity planning process used to be relatively simple in the days of batch-oriented environments and past generations of program development tools, not in terms of required skills in statistical methods, but rather because of predictability of probable changes.

Commercial computing applications, in general, concentrated on automating already well understood manual processes with an objective of reducing peak activities from a couple of weeks' process down to a few days. Program development in general was a slow process, measured sometimes in years, and there were fewer commercial packages available to meet the needs of the users. There were also fewer users who had relatively undemanding expectations, at least partly because of the limited availability of cost-justifiable technology. In other words, the expected rate of change was slower by several orders of magnitude.

Today's computing environment, even in a relatively small corporation, is bordering chaotic with hundreds of individual users with diverse demands for MIS services. Today's applications attempt to invent and facilitate new processes, rather than automate the old. It is also no longer uncommon to have MIS users from outside of the business organization--the real customers. MIS organizations are rapidly changing from the sole source of internal computing facilities into full-service organizations. In the process, they are finding themselves often competing with any number of outside sources to provide computing capabilities and services for their users.

From the business perspective, the emphasis is no longer in administrative systems, as much as it is in supporting the 'front-line' business. The fight for a competitive advantage has developed into a high-tech warfare. Business management is demanding timely and swift MIS support, ranging from consistently high levels of quality in existing services to a capability of handling sudden changes in demands for new services.

It appears to be easier, more justifiable, and desirable than ever to follow the leading edge of technology with a bewildering number of alternative solutions for any given MIS problem. Coupled with an increasing rate of change and the demands for a higher level of MIS participation in business, the volume of alternatives puts serious pressure on MIS planning skills and capabilities.

2.0 DEFINING THE PROBLEMS

A substantial number of alternative tools exist today in the area of MIS planning. They range from long-term, on-going strategic planning consultancy services to extremely sophisticated modeling tools specializing in particular software subsystems or applications and, in some cases, specializing in single device types.

There appears to be no shortage of tools for aspiring MIS Capacity Managers at technical levels. So what's the problem? Why is it then, that the MIS plans often fail to identify latent demand, major organizational and business changes, and even relatively slowly changing directions in technology? Most of the installations can relate to specific instances of deployment of new computing equipment, applications or services, which resulted in one of two verdicts: "Too little - too late!" or "Overkill!".

There are at least three major contributors that lead to planning difficulties which are often not addressed at all:

1. MIS attempts a corporate wide plan single- handedly.

It has been suggested by R. Nolan that the evolution of the planning function in an organization follows through cycles, comparable to the now classic 'Nolan's Curve'. The maturity level of an organization can be seen from the positioning of its planning function. In simplistic terms the first four phases can be characterized as follows:

At stage one, MIS planning is concentrated on an individual and is short-term in nature.

At stage two, a task force is set up on demand to formulate the MIS plan.

At stage three, a permanent IS Steering Committee plays a participatory role in MIS planning.

At stage four, a Chief Information Officer (CIO) function is filled and given the means and the authority to effect corporate-wide participation in MIS planning, potentially leading towards its full integration into business planning.

This type of model is useful for describing the current status of MIS planning in your organization and for defining the practical boundaries for a given planning exercise. It emphasizes rather than minimizes the planning problems which increase downwards and decrease upwards through the stages.

At lower stages, the inaccessibility to business planning information, the projected image of a task oriented MIS, and the prevailing communication gap between MIS and the business organization form major obstacles to effective MIS planning.

2. Planning is addressed only after a problem has surfaced.

To a large extent, this situation is more an indication of MIS planning taking place around the annual budgeting cycle, use of a too short planning horizon, or the remoteness of the MIS planning process from day-to- day operations, rather than an indication of merely insufficient planning.

Budget time rarely offers opportunities to gather the right people to participate in planning and even if it does happen, the plan tends to be put together in a hurry, without the full attention and concentration it requires.

3. The plan addresses a specific short-term problem in isolation.

In the absence of long-term plans, mapping MIS goals, strategies and their relationship to current business goals and priorities and attempts to justify any incremental upgrades to existing resources become major undertakings. Fighting for one short-term upgrade proposal after another also gives an often erroneous impression that business management is not receptive to MIS suggestions for change, and projects a less than professional image of MIS planning to business management.

As the symptoms described above suggest, not all of the capacity planning problems are technical in nature at all, but rather; they are management problems often caused and reinforced by limiting functional responsibilities and priority setting within the boundaries of organizational reporting lines.

Communication and interaction across the reporting lines flows much better in some organizations than it does in others. The former group also appears to be doing a better job in managing the gap and in encouraging cooperation between the MIS and business functions. Observed from a Capacity Manager's point of view, the latter group displays classical problems which require a strong matrix management approach, which generally speaking, tends to fall outside the MIS Capacity Manager's "comfort-zone" and area of expertise.

"Stage 1" companies with unrestricted flow of communication, manage to do an excellent job in MIS and capacity planning precisely for this reason. As a result, they may not have a pressing need to "mature" and appoint a CIO to bring the business and MIS closer, nor are they in any hurry to become a "Stage 4" organization. On the other hand, CIO's in some "Stage 4" companies are having a very rough time attempting to bring the right people to work together across the functional boundaries of their organizations and surmounting some of those historical barriers.

3.0 IDENTIFYING THE MIS PLANNING COMPONENTS

Figure 1 illustrates the first cut of the major components of MIS planning relative to the three levels of business plans: the strategic, tactical and operational plans. It shows that MIS needs to consider the three levels of planning for each of the business planning levels for each of the supported business function. The total number of planning components can get fairly large in a large and diversified company marketing numerous products or services.

The second cut is shown in **Figure 2** where one of the components from Figure 1 is expanded and further refined into following four components:

1. Business assumptions
2. Organizational assumptions
3. Technology assumptions
4. MIS support strategy assumptions.

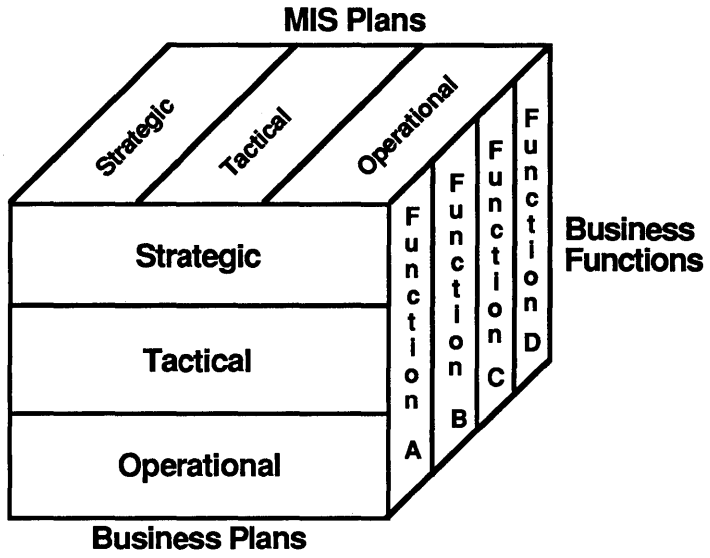

Figure 1: Matching Plans and Business Functions

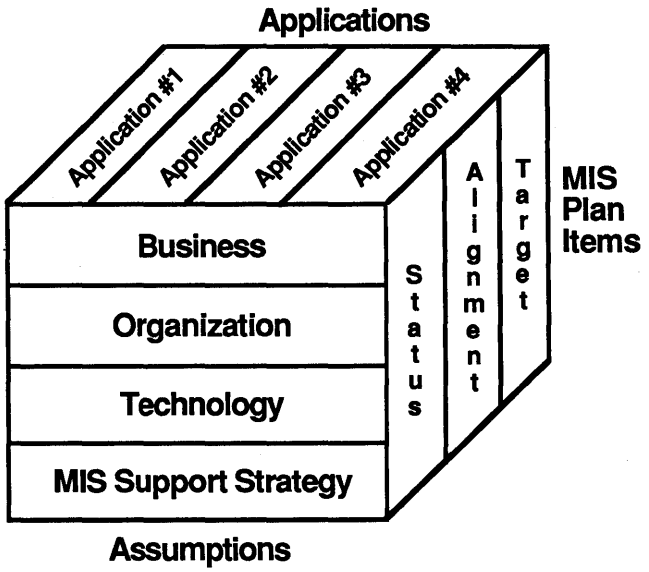

Figure 2: Exploded View

Each of the above then needs to be covered against the three position levels:

1. MIS position today in support of this business function
2. MIS alignment with the future position of this business function
3. Future potential of exploiting anticipated changes in technology in support of this business function.

In other words: Where do we stand today, where do we want to be tomorrow, and how are we going to get there?

Each of the four groups of assumptions may be refined in further detail, but that can be ignored for the moment. It is scary enough, as shown by the two illustrations above, that in order to produce a well thought-out MIS plan, over 300 areas need to be considered in some detail, and over 100 areas need to be considered even for a relatively short-term plan.

4.0 ALIGNING THE OBJECTIVES

The point is that the MIS plan is no longer an isolated document that defines the short-term needs for additional MIS resources. It is also almost impossible to successfully complete the plan without active participation from the business organization. The speedy acceptance of any MIS plan by business management is dictated by the degree it supports the overall business plans and activities.

A capacity plan is by definition a subset of an overall MIS plan. The other planning components also have to be completed to ensure that the capacity plan does not deviate from the stated direction and it gets accepted on merit, rather than on blind faith.

There is ample evidence, at almost every installation, that simply modeling the expected future growth of the existing workload is likely to result in a critical shortage of MIS resources to the short-term detriment of the company's primary business.

Planning in crisis mode to remove an already existing capacity problem is also highly undesirable. In crisis mode, the plan is typically prepared by one or two individuals, often resulting in a very limited one, which may be lacking long-term direction and synergy with any business plans.

A well-executed MIS plan requires the width of the company's business representation, a substantial amount of ongoing communication between the business and MIS organization, as well as the depth of MIS skills in capacity planning techniques.

Ideally, the Critical Success Factors of an organization should be structured in a fashion that they get addressed when the sub-organizations have addressed their CSFs, and so on, throughout the hierarchy, down to the personal levels.

Given that the consistent MIS service levels focus on achieving some of the critical goals outside MIS, it is necessary that the potentially affected business side of the organization participates in MIS planning. Firstly, in order to identify the shared objectives, and secondly, to gain maximum support and leverage to MIS plans.

Some MIS organizations are doing an excellent job of "selling" their services to their potential user groups. Some MIS organizations literally have a full-time sales person or a PR person on their payroll. While it may be an extreme approach and beyond the reach of an average MIS organization, this type of action does strongly promote joint ownership of problems, plans and justification for solutions.

MIS plan which used to have limited appeal to top management is transformed into a plan for the business organization to meet certain objectives. The chances of getting the MIS plan approved are greatly enhanced by a strong backing from the user community.

5.0 MANAGING THE PLANNING PROCESS

Each manager in any organization has at least a hidden objective to perform some planning. As a manager, one is expected to align the activities of his or her reports to support the "big picture", the business goals, and the goals of his or her immediate management. In addition to planning for future levels of compensation, managers are also responsible for planning for facilities.

How do these facilities differ from facilities and capabilities provided by MIS? How does planning for availability of office equipment or PCs differ from planning for different services and service levels provided by MIS?

There are some differences:

- Complexity of issues
- Uncertainty of future requirements
- Dollar amounts involved
- Cost allocation difficulties for new services to the first few users
- Traditional communications gap.

The biggest difference is that business management is rarely expected to plan for MIS related items, and the activities that would facilitate the planning done by MIS are not a formal part of their job description.

6.0 TAKING ACTION

Structured Planning refers to an "ideal" organization where a relatively small number of individual MIS-related planning items are constantly reviewed, updated and fed back to MIS as a part of ongoing responsibilities of several levels of operational business management across the organization. MIS' responsibility, beyond providing basic guidance and a mechanism to collect and analyse this information, should be to regularly review and summarize the information into a coherent MIS Plan which has the full support of the business organization.

"Stage 4" companies are addressing this need to cross the organizational boundaries from the top down, appointing a CIO function with a responsibility to make it happen. But, there are really very few reasons why the process could not be started from the bottom up, following the above guidelines. Maintaining informal networks of business associates is something each one of us does every day.

It is a relatively simple process to define the type of input that MIS management or the capacity manager needs from the business organization to do a good job. The difficult part is to define and implement the process throughout the company, which ensures that the assumptions and decisions made outside MIS filter back to MIS in a timely fashion. Doing it gradually on a personal level, rather than taking an ambitious wholesale approach right from the start, often has substantially better chances of bringing success on which to build later.

7.0 SUMMARY

MIS does have a lot to offer to the rest of the company in terms of the use of technology. And the business departments do add clout to the MIS plan as well as having the means to enhance MIS' understanding of the primary business of the company. What is needed is some basic 'marketing' action by MIS and some personal effort to promote a closer working relationship with business managers.

However contradictory it sounds, a successful implementation of structured planning demands flexibility in approach rather than a formalized process structure. Where "Stage 4" companies are tackling the cross-hierarchy communication problem by a top down management approach, the implementation of structured planning from the bottom up requires different a approach which relies on personal initiative and communication. The challenge is to gain the cooperation of key MIS users. Capacity plans which are clearly associated with the business demands, greater accuracy of the plans, easier risk management and cost justification provide the pay-off.

Who Goes There?
A Dialogue of Questions and Answers About Benign Hacking*

David F. Stevens
Lawrence Berkeley Laboratory

ABSTRACT

On August 23, 1986, it was noticed that the accounting files for one of LBL's computing systems failed to balance. On August 24, we received word that an unauthorized person was attempting entry into a Defense Department computer from LBL. Preliminary investigation indicated that LBL was the victim of a benign hacker, where "benign" is used in the medical sense. It was thought that the perpetrator was a graduate student from a neighboring university, and that it would provide a useful object lesson to other such folk if he were caught and admonished. LBL therefore embarked upon a journey of detection and containment instead of prevention. That journey continues today, having led first across the country, then across the Atlantic. In the course of the journey we have gathered a number of observations that should be of interest to anyone running a computer with any connection to the outside world.

Why the Computer Measurement Group?

The first and most obvious question is "Why should this material be of interest to CMG?" There are two reasons. The first is that one element of successful performance management is ensuring that enough capacity is available to satisfy the legitimate demands of all authorized users. Every cycle stolen or file hidden by an unauthorized user reduces the resources available for legitimate use. The elimination of unauthorized use thus extends the useful life of your present configuration.

The second reason for CMG to take an interest is that some of the tools developed for measurement and management purposes can also be used to detect unauthorized access. You are in the business of knowing where demand and usage originate; it is but a small extra step to distinguish between authorized and unauthorized usages.

What do you mean by "benign hacking"?

"Hacking" has gone through two metamorphoses of meaning. Its original meaning in the computing community was similar to its meaning in the golfing community. A hacker was one who butchered code. Then, some years ago, it was transformed from a term of opprobrium into one that indicated long hours willingly spent probing the dim recesses of system internals, searching for ways to accomplish Good Things. Finally, in the last decade or so, it has come to signify computing wizardry employed for personal purposes, frequently explicitly directed against governmental and large corporate installations.

In this dialogue I consider any activity resulting from (attempted or successful) unauthorized access to be hacking. (It is worth noting in passing that access by an authorized user at greater than authorized levels of privilege or for unauthorized purposes is unauthorized, and therefore a form of hacking.) Further, I define hacking that is limited to entry and consumption of resources, as distinct from intending to destroy or alter data, to be "benign". As noted in the abstract, *benign* is used in its medical sense: Not actively inimical, perhaps, but certainly intrusive and possibly painful. The presence of a benign hacker, like that of a benign tumor, is not to be considered a sign of good health.

Why limit the discussion to benign hackers?

Primarily because that's the kind I'm best qualified to discuss, but there are other good reasons:

- Benign hacking is more prevalent than the malignant sort (we think).
- It is more difficult to get people concerned about "harmless" hacking, even though in some respects the damage done to the institution can be as great for benign hacking as for hacking for gain. (Your image can suffer more from imaginative media accounts of recreational hacking than from serious accounts of hacker theft.)
- It is more difficult to detect benign hacking than vandalism.
- If you can detect and prevent benign hacking you have a good start at detecting and preventing vandalism and hacking for gain.

What do benign hackers do?

The total range of hacking activities runs from access only, just to prove it could be done (simply collecting scalps, as it were), through theft of resources (for the hacker's pleasure or do the hacker's personal work on someone else's computer), to grand larceny (altering bank balances or generating false invoices). We are concerned here only with benign hacking, which is essentially recreational in nature. In this context, most of the activity you are likely to encounter is generally related to snooping.

- Benign hackers look around; they browse through all directories they can gain access to, looking for interesting files.
- They document your commands (via trial and error; "HELP" facilities are a great help to them in this regard).
- They make lists of authorized users (the more valid ID's they know the more likely they are to get additional privilege).
- They read everybody's electronic mail (they are especially interested in messages about security breaches and countermeasures; they also look for passwords written in files).
- They look for programs that are looking for them.
- They look for (and try to crack) the password files.

* This work was supported by the U.S. Department of Energy under contract No. DE-AC03-76SF00098.

More active pursuits, but in the same general vein (that is, oriented towards allowing themselves undetected free use of your resources), are

- Attempting to disable accounting for their jobs;
- Stealing stale or unused accounts (usually by changing the password);
- Hiding files;
- Setting up bulletin boards;
- Attempting to disable security alarms;
- Playing games;
- Connecting to other systems from yours (and if you have a dial-out modem, they will try to use that, while you pay the phone bill).

How do they get in in the first place?

There are many avenues, ranging from the direct (someone gives them a valid password/ID combination) to the brute force (random dialing followed by random probes), but most of them take advantage of your cooperation through:

- Retention of default or generic logins with their original passwords;
- Use of common "temporary" ID's (such as *test* or *demo* or *guest*) with trivial passwords;
- Use of passwords identical to or derivable from ID's;
- Use of null passwords;
- Use of the same password/ID combination on multiple systems;
- Writing a password/ID combination for system A in a file on system B;
- Use of an unprotected remote login or file transfer from one system to another;
- The existence of commands (*who*, for instance) that can be executed without logging in.

They also run an extensive grapevine, and pass successful password/ID combinations around, both directly and through hacker-oriented nationwide bulletin boards.

How long does it take to break into a system?

That depends, of course, upon how much the hacker knows, how good your protection is, and how well your users follow good password practice. If you still use the default system operator or maintenance passwords that come with the system when it is is delivered, it takes about 10 seconds (for those are the first things tried). If you are well protected, and good practices are observed by all your users, it will generally take too long for casual hacking. Remember, however, that if another installation has network access to your system, you are only as secure as *that* installation and its user community. (This is a larger community than you might at first think. Widespead network access is now available to students at most of the institutions of higher learning in North America and Western Europe, plus many of the high schools, as well.)

Don't they have to know what kind of system it is before they start?

Most systems are very helpful to anyone who achieves a connection, and the login prompt often tells the caller the name of the company as well as the system and version number. Others are easily identified by the style of response to unsuccessful login attempts.

How many commercial sites are connected to networks?

Probably most of them of a size large enough to send someone to CMG. The telephone system, after all, is a worldwide network (and has been used to support transcontinental and transatlantic hacking). And any system with remote diagnostic capabilities has network access. Many service engineers have occasion to access many different systems, with differing password/ID combinations. It is fairly natural that they tend to record these nuggets of hackery on the fly leaves and back covers of their maintenance manuals, where they can be discovered through trashing. (In the '60's the term "trashing" referred to the intentional destruction of property. It now refers to a favorite "phreak"/hacker activity: the careful sifting of selected trash barrels looking for access-oriented jottings. It is successful often enough to encourage dedicated hackers and phreaks to fly across the country to raid a particularly fruitful site.) The point being, of course, that you are at risk not only from your own site, but from the engineer's trash bins in Boulder or White Plains or Dallas, as well.

But our dial-in numbers are unlisted....

Random dialers don't read directories, they just start dialing and hanging up if they don't get a modem tone. Many set their systems up to dial sequential numbers automatically for hours at a time while they are off doing more interesting things. And once they get a tone, as often as not, they announce the number (through a bulletin board or in the magazine *2600*) even if they haven't yet figured out what kind of a computer is on the other end. Some systems provide assistance, too: they have very helpful dialout programs that tell the user the previous number dialed.

Why should we care? (We don't have any secrets on our system.)

(This question tends to arise more often in the academic and research areas than in the commercial sector, but it has been heard there, as well.) You have data that is difficult or expensive to replace. You have data that contributes to strategic planning, to legal reporting requirements, to inventory management. Many of you have data that your employees and customers consider to be confidential. Some of you also have controllers who already think you're spending too much on computing, and who would not be happy to learn that some of it was going to unauthorized use.

But is this a real threat? Can anybody really get in this way?

Lawrence Berkeley Laboratory has observed a single hacker, over a four-month period, make more than 400 one-minute attempts to break into other systems from our site. Using a *very* limited repertoire of techniques (it's difficult to be truly creative in such a short time) he:

- reached about half the sites (i.e. was invited to try to login);
- succeeded in logging into 25 systems;
- became system manager at 9 sites!

That's better than a 2% success ratio at becoming system manager; more than three times that for simple access. That means that several of you here today are at risk. The odds today are, certainly, that if the hacker community wants access to your site badly enough, they *can* gain entry.

How did you find this guy? Why didn't you shut him out?

We found him through a combination of events, one of which was an imbalance in a double-entry bookkeeping system maintained for chargeback purposes. The discovery of the imbalance coincided with a report from another installation that an unauthorized remote entry had been attempted from Lawrence Berkeley Laboratory.

Our first thought was that the culprit was a student from a nearby college, so we set out to catch him in the act and create an example, rather than shut him out. In so doing we discovered much of the content of this paper. ("We", by the way, is primarily Dr. Clifford Stoll of our staff, assisted by folks from a number of affected institutions and law-enforcement bodies; chief among these outside folks was Steve White at Tymnet.) We *did* keep a rather close watch on our friend's activities -- for we had no assurance that they would continue to be relatively harmless -- and warned other sites whenever he succeeded in gaining entry.

One of the things we learned from having watched him for a while is that had we tried to shut him out when we first discovered him we would probably have failed, for he had already stolen several accounts. Thus, once we learned that it was not just a local student hack, we thought it worth pursuing to the end in the hopes of learning more.

How can one be sure one is safe?

If you are connected to a network or have a dial-in port you can be reasonably sure you're *not* safe. Collusion with your own staff aside, however, you can be as safe as you want to be. Safety consists in knowing all your users and in knowing the ownership of all files in the system. "Knowing your users" includes not only knowing who they are (a process of authorization and validation), but also of verifying that they are, indeed, who they say they are (authentication) every time they attempt to access the system. This is the fundamental purpose of a password scheme.

How much should we spend on protection?

This is a question of insurance, and as with all such questions you should weigh the cost against the expected value of the loss, and not overspend. Some of the costs on each side of the balance are relatively non-obvious. The cost of protection includes not only the cost of acquisition and implementation of protective measures, but also the costs inherent in the education of the users and in the irritation they experience at having to retrain their fingers to the new passwords. In estimating the expected value of a loss you must also include the cost of cleaning up after a breach. Even a "harmless" breach involves staff time and effort in detection, elimination of unauthorized files and acounts, tracing and prosecution (if warranted), and elimination of the system or procedural flaw that allowed the breach. These costs can be considerable. (In our case, they amounted to at least three months' full-time effort of a senior analyst, plus assorted bits and pieces of management time.)

What did you learn from your experience?

- When it starts, you never know how big it's going to get, or how far it's going to reach. We thought it would reach about a mile, and it turned out to extend from Berkeley to Europe. The level of interconnection of the world today makes it easy for a hacker to reach you in several hops, and he may choose to do so either to conceal his real origin, or because each step is limited for some technical or financial reason.
- The further it reaches, the more important it is to have a well-defined procedure to follow, and the more difficult it is to achieve coordination. The telephone company, for instance, prefers to deal with law-enforcement people in matters of call-tracing, rather than with technical people. So does the FBI. It has been difficult to get real cooperation from some agencies when contact is at the technical level, but technical contact is essential so that the sites being hacked can pool their knowledge of the hacker.
- Have clear communication paths. Know whom the telephone company will listen to, whom to call in any network to which you are connected, whom to call at the FBI or your local law enforcement agencies, etc.
- TYMNET has the tools and the willingness to help. Once alerted, they can complete a trace in minutes.
- The telephone company won't willingly trace beyond state boundaries without a federal warrant.
- Inform any other victims as soon as you can. Not only is this good citizenship, it will encourage them to notify you when the shoe is on the other foot.
- People use poor password practice -- even those who ought to know better. Among the poor practices exploited by our hacker are: continued use of default passwords; password identical to ID; trivial password (i.e., easily guessable, such as name when ID is initials, location, system name, same password on several systems); existence of non-password-protected ID's (e.g., *who* on some *unix** systems); listing of ID and associated password in the clear in files with suggestive names.
- Passwords decay with time. Other people get to know them through several mechanisms (accident, gift, guesswork, ...).

---

* *unix* is a registered trademark of AT&T Bell Laboratories.

- Whenever people are required to use system-generated passwords, they will write them down where a hacker may find them.
- Be careful when demonstrating systems to unknown people (at least one hacker claims to have gotten a password by looking over a salesman's shoulder during a demonstration).
- It's more difficult to discover unauthorized use *after* a valid account has been stolen than before.
- Don't use E-mail to discuss any aspect of a hack, unless you want the hacker to read it, too.
- An attached printer is an indispensable tool for serious tracing. Without one it is generally impossible to reconstruct the hacker's session. (If he has system privilege, he can destroy the log of his session before you can read it.) A printer linked in parallel with his output gives you a real-time track that he cannot erase.
- A network is weaker than its weakest link. (And all of the networks we belong to have some *extremely* weak links.)

What can we do to detect benign hacking and to protect against it?

The following lists are suggestive rather than exhaustive. No attempt is made to rank the items in order of effectiveness or cost; individual situations are too different to make such an attempt meaningful.

To detect:

- Look for hidden files. Many systems have legitimate ways to "hide" utility files so that they don't clutter up working directories. In *unix*, for instance, any file name beginning with a dot (such as *.login*) is hidden. It is also possible to place files into directories that are not usually searched.
- Look for files with "unauthorized" contents. (Since different organizations have different rules about off-hour use of computers, the definition of "unauthorized" can vary widely.) If you employ this procedure, it is important to ensure that the looker is ethical, and does not divulge the contents of any of the files looked at.
- Require that every network access carry trace-back information so that you (or the network operator) can determine the source of all traffic. Review the log from time to time and look for anomalies.
- Provide your users with enough accounting information so that they can discover if anyone else is using their accounts.
- Institute chargeback, so that they have a reason to read the accounting information and to inform you if it seems to be out of line.
- Employ double-entry bookkeeping. (One way is to keep a write-only record of all resource usage and then to compare that to all "charged" usage.)
- Tell users of unsuccessful entry attempts in their name.
- Tell users the date and time of their last successful login.
- Encourage the users to read those messages and notify you of any anomalies.

To protect:

- Authorize users individually and personally. Verify the user's identity (and employer) before granting access.
- Require the use of passwords for access, and adopt a sensible password policy. Some possibilities are:
  - -- Password cannot equal login name.
  - -- Changes of password cannot equal previous passwords.
  - -- Password must be at least 6 characters long, and contain at least one non-alphabetic character.
  - -- Password cannot be all the same character.
  - -- Password cannot contain a recognizable part of the login name.
  - -- Password must expire within 180 days of being issued.
  - -- Passwords belonging to terminated employees should be terminated.
- Require password changes. One practitioner has said "Treat your password like your toothbrush: Change it once in a while, and don't pass it around."
- Control access to particularly sensitive data by location (terminal or port of origin) as well as by name (password/ID).
- Let login ID's expire (to avoid proliferation of stale accounts).
  - -- Initial logins should be deactivated very quickly if they are not used.
  - -- "Active" logins should expire after some reasonable period of non-use.
  - -- A login should be terminated as soon as any employee who knows it leaves the company (for any reason).
- Fix any known loopholes that allow someone to increase his level of privilege.
- Protect network access.
  - -- Avoid network access procedures that require or encourage the writing of passwords in files.
  - -- Limit the privileges of any process that originates remotely.
  - -- Monitor the use of remote logins.
  - -- Install password protection on network access ports, including those used for remote maintenance.
  - -- Adopt a dial-back verification procedure for remote telephone access.

-- Restrict physical access to workstations possessing automatic login procedures for access to your mainframes.

- Protect log and journal files that give the history of interactive sessions. These can be read, and they can be as useful to a hacker as ordinary text files.
- Set file access protection defaults to something more restrictive than *world*.
- Require your system to remain anonymous until *after* you get a valid login. (Many systems provide a great deal of help by welcoming login attempts, or even when responding to a modem call. Don't provide anything other than bare ID and password prompts until you know who's at the other end.)

What do we do when we find someone?

That's up to you, of course. That depends upon what's at risk, what has been damaged, and how much effort you are willing to devote to the chase and possible prosecution of the offender.

Do you have any last words?

Only the following warning, adapted from Tolkien:

> It does not do to leave a live
> dragon out of your calculations
> if he has network access to your
> computer.

REAL WORLD PERFORMANCE MEASUREMENTS FOR UNIX-BASED SYSTEMS

Neal Nelson
Neal Nelson & Associates

ABSTRACT

During the past three years, benchmarks on multitasking Unix-based machines have decisively demonstrated that the processing capacity must be measured to determine comparisons between machines. Whether they are $5,000 micros or million dollar mainframes, the benchmarks underlined the unreliable nature of MIPS, Whetstones, milliseconds, megahertz or any other commonly quoted statistics. This paper reports on these benchmarks.

BACKGROUND

Before explaining my benchmarking activity and presenting some of my findings I would like to explain the sequence of events which prompted me to start working in the performance measurement area.

I started a software house in Chicago in 1973. For eight years my firm installed primarily small accounting systems, mostly on IBM System/32's, 34's and Series/1's. We also installed several non-IBM systems like Wang, General Automation, DEC, Hewlett Packard, Qantel, Nixdorf, and so forth.

We did primarily custom installations, and by 1982 we had written the entire range of business applications on twelve different brands of computers, in six languages, under sixteen operating systems. I had grown tired of "re-inventing the wheel", and so I looked for a market where I would not be subject to a new language and operating system every time a new product family was announced.

After studying the possibilities, I decided to move into the Unix marketplace and develop a package of general accounting programs in the "C" programming language. By 1984 we had substantially completed work on the accounting programs and had several successful installations.

Up until this time, the Unix machines we had been installing were the Onyx brand computers. We felt that we should seek another brand to recommend to our customers as the offerings from Onyx at that time were not competitive.

I knew nothing about benchmarking, and asked a business associate for information. I was provided with a set of public domain benchmarks, some sample numbers from previous tests, and instruction on how to run the benchmarks. I then went out and began to test every machine I could get my hands on.

Based on these tests results, I recommended a computer to one of my prospects. When my application software was installed on the recommended machine, it ran VERY slowly. At first I thought that the machine might be defective, since the benchmark had indicated that the machine would be quite fast. I ran the benchmark on the customer's machine, and the benchmark ran like lightning but my accounting programs just crawled.

At this point I knew I had a problem. I began to analyze the benchmark and realized that it was measuring shell scripts, compiles, calculation speed and so forth, but it was not measuring what most accounting programs do most of the time which is disk I/O (particularly random disk I/O).

I did an analysis of my accounting programs and broke the code structures down into fifteen broad categories of functionality (16 bit integer math, 32 bit integer math, sequential disk I/O, random disk I/O, etc.). I created my own benchmark from these function groups.

Running this benchmark on my old Onyxs and on the new machine I found that in several areas the new machine was faster, but in two or three it was slower, and sometimes a lot slower.

This information told me how I had to modify my applications to eliminate all unnecessary uses of the slow techniques. When that was completed, the programs ran at an acceptable speed, and solved my client relations problem as well.

At this point I vowed to never subject my clients to hardware problems of that nature again. So, using my own benchmark suite, I began a series of tests on all of the machines. The results differed from the first set of tests. This concerned me because often the results appeared very similar on machines which experience had shown to be very different in power and speed.

The first version of my benchmark was a single user benchmark. Soon I converted the benchmark into a multitasking benchmark. Again I retested all of the machines. This time the results agreed with my experiences as well as with user reports. By measuring degradation under increasing levels of load, I was able to make fairly accurate predictions about how a computer would perform in the "real world".

That multitasking benchmark has gone through several generations, and has since become a product at my firm. The product has evolved into eighteen test categories covering over 30 functions. Over the past three years we have run this benchmark on over 200 Unix-based computers. We maintain a database of test results which allows us to compare "anything to anything" very quickly. From our database we can print eighteen-page reports which compare two machines using a graph and a bar chart format for each of the eighteen categories.

My mental attitude on computer performance measurement has evolved into a series of "What happens if" questions such as, "What happens if we increase the memory size?", or "What happens if we install a new release of the operating system?"

The following illustrations will show some of our findings. I cannot include all 18 graphs for each comparison, so I have selected two or three (usually a calculation and a disk intensive test) that demonstrate the point.

EXAMPLE 1: NEW RELEASE OF OPERATING SYSTEM

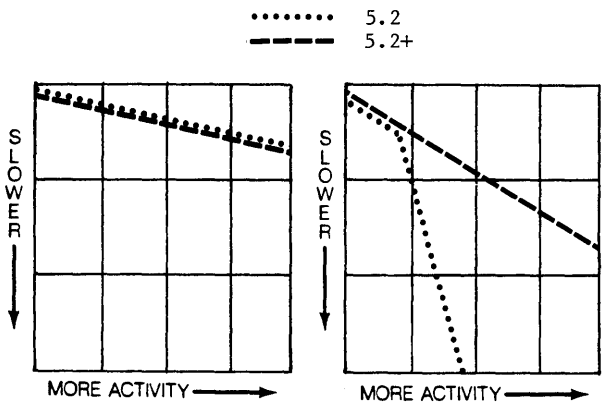
The first example deals with a new release of the operating system.

A manufacturer of a desk top Unix machine announced a new release of the operating system. The original release was 5.2 and the new release was sort of 5.2+.

The original release is represented by the dotted line and the new release by the dashed line.

The first graph of calculation type work shows little difference between the two versions.

Graph two, however, shows that for disk intensive tasks the original release experienced extreme degradation after four copies fo the test program were executed, whereas the new release seemed to correct the problem.



Graph 1 Graph 2

EXAMPLE 2: CLOCK SPEED COMPARISON

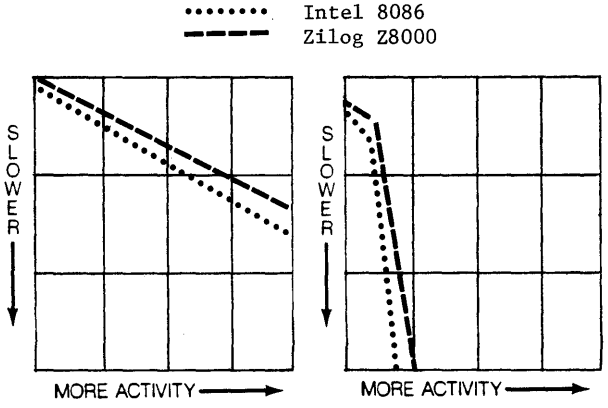
The next examples deal with different chip technology and clock speed.

Both of the next two examples were 16 bit computers. Both have the same memory size, and similar disks. The major difference is that one machine is based on a 4 megahertz Zilog Z8000 chip, while the other is based on a 10 megahertz Intel 8086 chip.

One would expect that the Intel based machine would be significantly faster than the Zilog based machine, however, graph three shows that the Zilog is actually running 20% faster that the Intel. This test consists of integer math, function calls, string manipulation, looping, branching, and so forth (Graph 3). There is no activity which would slant the test in favor of the Zilog chip.

Apparently, a Zilog Z8000 based computer with a 4 megahertz clock could do more useful work than an Intel 8086 based computer with a 10 megahertz clock.

Graph 4 shows a disk intensive test for the same two machines. Both machines degrade quite dramatically, however, the Zilog based machine is still a little faster than the Intel based machine.



Graph 3 Graph 4

EXAMPLE 3: 8086 vs. 80286

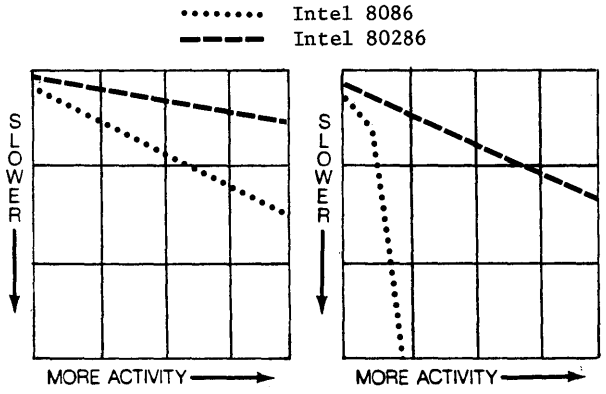
The next comparisons are for two Intel based machines.

One uses an Intel 8086 chip and the other uses an Intel 80286 chip.

Both machines ran Xenix, and both machines were manufactured by the same company. I felt the 80286 based machine was created as an "upgrade" product for the customers that already owned the 8086 based machine. I wanted to see how much improvement the customers might expect if they choose to upgrade.

Graph 5 shows calculation type work, and it is apparent that the 80286 based machine (represented by the dashed line) is running almost three times faster than the 8086 based machine.

Graph 6 shows disk intensive work, and in this case the improvement is even more dramatic.



Graph 5 Graph 6

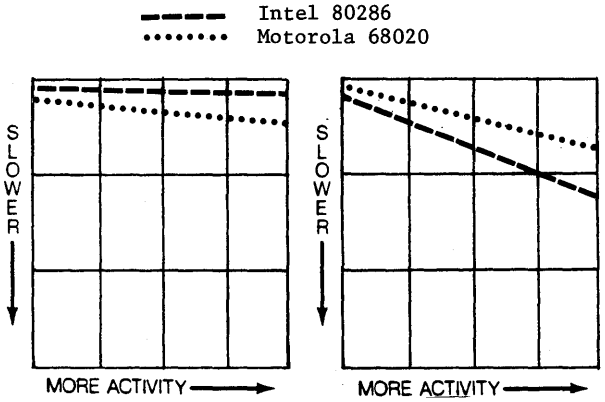
EXAMPLE 4: 80286 vs. 68020

Another interesting question is, "Who makes the most powerful chips?" For example: is a computer using an Intel 80286 faster than a computer using a Motorola 68020?

The next two graphs represent comparisons of machines which are the same in many respects. They are made by the same manufacturer, they have the same memory size, they use the same disk drive and disk controller.

Graph 7, however, shows that for calculation type work the 68020 based machine (represented by the dashed line) is dramatically faster.

Graph 8 shows that for disk I/O the relationship is reversed. The 80286 based machine is almost 25% faster.



Graph 7 Graph 8

These graphs illustrate my most basic conclusion after benchmarking over 100 computers: Don't assume anything. Test and measure everything, then draw a conclusion.

The 68020 is running with a 16.7 megahertz clock (more than twice the 8 megahertz of the 80286), and yet, calculation work is much more than twice as fast. They are both 32 bit chips. These machines are built with interchangeable parts for the backplane, disk controller, and disk drive. Why is the 80286 25% faster on disk I/O?

I don't know the answer, but it must be something to do with the efficiency of the compiler, the Unix port, the disk interface routines, and so forth.

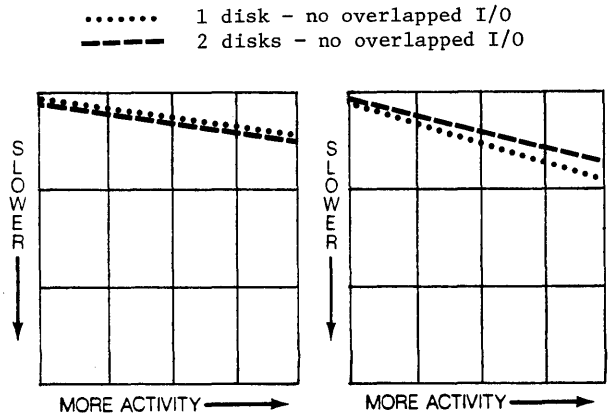
What I do know is that there are significant differences which contradict what would be expected based on clock speed, access time, etc. I have concluded that everything must be tested.

EXAMPLE 5: FILES ON MULTIPLE DISKS

One more question is, "What performance increase will result from spreading disk work files over two drives rather than having them all on one?"

Graph 9 is calculation type work on two systems. One system is configured with all work files on one disk, while the other has the work files evenly spread over two drives. Both lines are the same, which is correct, since this test does no disk I/O.

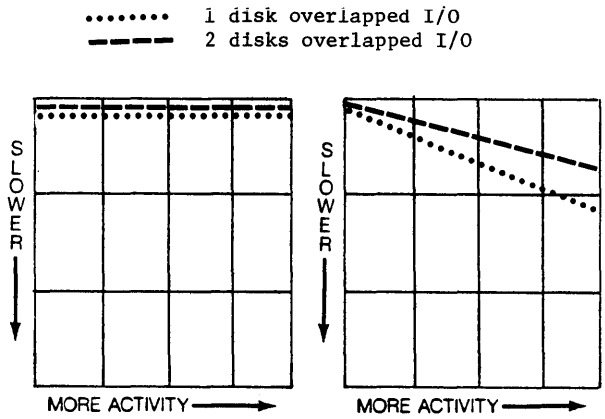
Graph 10 is the disk I/O intensive test, and we see a modest (15% to 20%) improvement. This is somewhat disappointing. Both disks are connected to the same controller. I called the manufacturer and learned that this machine does not do overlapped seeks. Hence the modest improvement.



Graph 9 Graph 10

Graph 11 shows calculation type work for a pair of 68020 based machines from the same manufacturer. These machines have the same disks and disk controller as the previous 80286 based tests. There is no difference in the graphs for calculation type work, which is expected.

Graph 12 shows a 30% to 40% improvement in disk throughput when the files are placed on two drives (still one controller). These are the same disks and same controller as in the previous example where there was a 15% improvement. I made another call to the manufacturer and learned that the controller is capable of overlapped seeks, and that the 68020 version of Unix from this company can support overlapped seeks, so on the 68020 machine they download different microcode to the controller and do overlapped seeks.



Graph 11 Graph 12

You might understand now why my rule is: "Benchmark first, ask questions later."

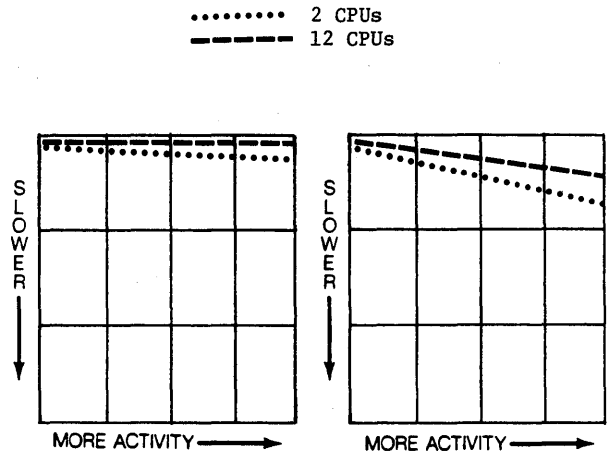
EXAMPLE 6: TIGHTLY COUPLED MULTI-CPU

How about one of these new tightly coupled multiple CPU computers where they put a dozen small CPU chips in a box and get them all working at the same time?

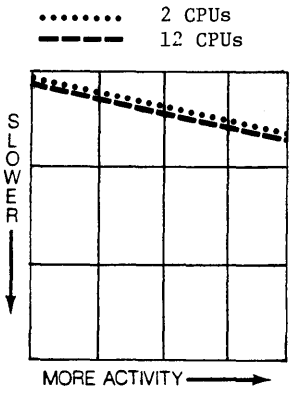
Graph 13 shows a comparison of two configurations for one of these multiple CPU machines. One configuration has 2 CPU's and the other has 12. Graph 13 represents calculation intensive work, and although the resolution of the graph doesn't show it, the 12 CPU machine shows almost zero degradation up to twelve copies, and at twenty copies it is running exactly 600% faster than the 2 CPU configuration. This is exactly what we would hope to find.

Graph 14 is a disk intensive test of the same two machines. It shows that the 12 CPU machine is twice as fast as the 2 CPU machine, but no longer six times as fast.

Graph 15 is a test where random seeks are performed, and this test is almost always limited by the seek time of the disk. The same two machines on this test show no improvement, which illustrates that if your application is bottlenecked on random disk I/O, adding more CPU's is not necessarily going to help.



Graph 13 Graph 14



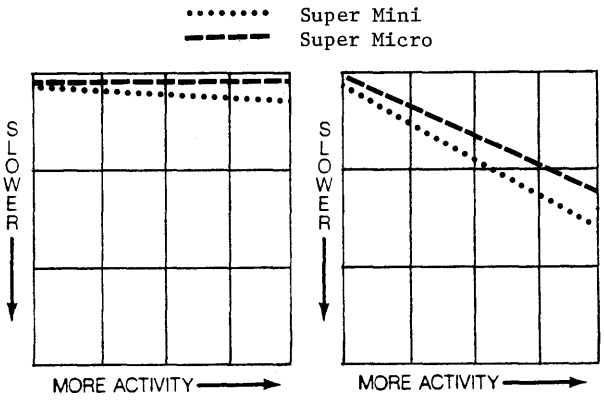
Graph 15

EXAMPLE 7: SUPER MINI VS. SUPER MICRO

O.K., so let's compare a $150,000 super mini to one of those $30,000 super micros which have been claiming to be faster at a fraction of the cost.

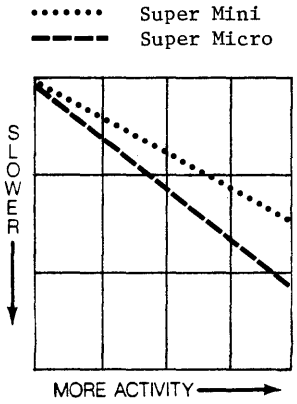
Graph 16 shows calculation type wrok where the dashed line is the micro and the dotted line is the mini, and indeed, the cheaper machine is actually running faster (quite a bit faster).

Graph 17 shows disk intensive work with an assortment of sequential and random I/O. The cheaper machine is still 25% or so faster.



Graph 16 Graph 17

Graph 18 is the random read test, and in this case the mini is faster (which apparently reflects the faster access time of the disks).



Graph 18

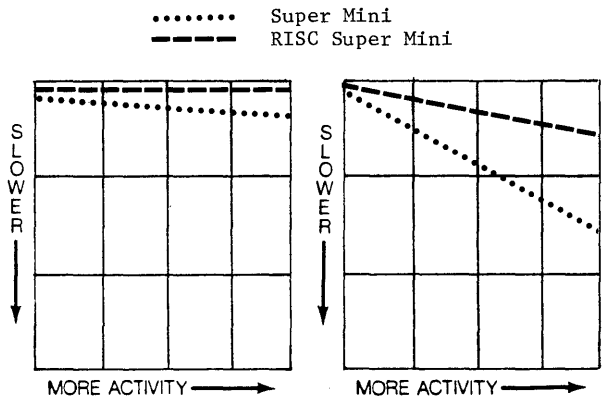
This was not a true "apples to apples" comparison because the mini had much larger disks and many more ports than the micro. But in terms of pure speed and price, it is sort of an eye opener. You could buy a lot of disks and some extra ports with that $120,000 difference in the prices.

EXAMPLE 8: SUPER MINI VS. "RISC" SUPER MINI

How about a test of a super mini which uses the RISC (reduced instruction set computer) architecture compared to a super mini which uses the conventional instruction set architecture. Is the RISC machine better?

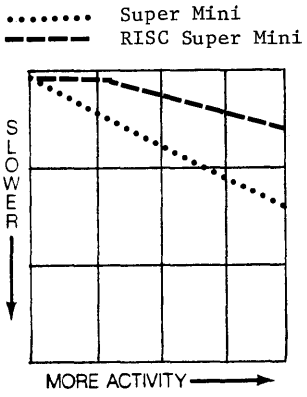
Graph 19 shows calculation type work for RISC versus Super Mini, and indeed, the RISC is faster by a wide margin.

Graph 20 shows disk intensive work, and again, the RISC machine is a lot faster.



Graph 19 Graph 20

Graph 21 is the random access test, and the RISC machine is over twice as fast.



Graph 21

This was a true "apple to apples" comparison. Both machines had comparable numbers of disks and ports. The memory size was different, but neither machine would begin paging during these tests, so that would not affect the results. In fact, both machines were running Fujitsu Eagles as disk drives with the same access time, so it is interesting that the RISC machine did so much better in random disk I/O. It is apparent that it is just a better machine.

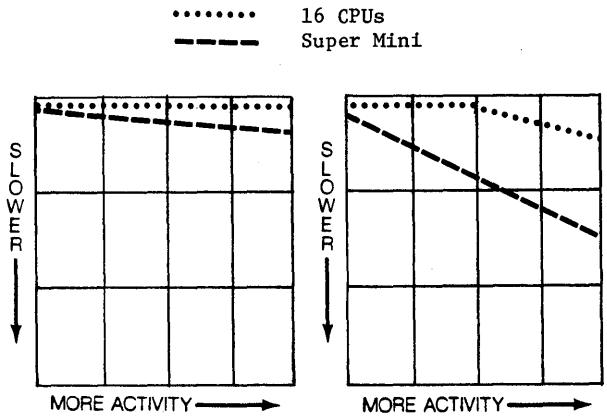
One interesting footnote is on the random test where the RISC machine showed almost no degradation up through the sixth copy. Upon investigation I learned that the RISC machine was configured with several megabytes of disk cache buffers in memory. Up until the sixth copy no disk I/O was actually done because all of the requested records were already in memory. It is only after the buffers were saturated that we actually saw the slope of the curve for the RISC machine.

EXAMPLE 9: MULTI CPU SUPER MICRO VS. SUPER MINI

The next three graphs show what happens when sixteen microprocessor chips in a tightly coupled machine gang up on a classical super mini.

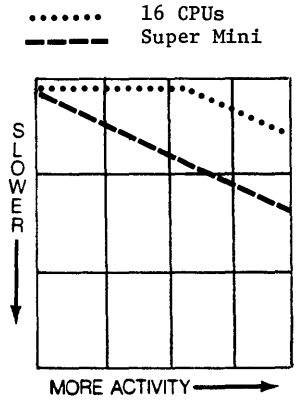
Graph 22 shows that the multi CPU machine is superior for calculation types of work.

Graph 23 shows that the multiprocessor is faster for disk intensive work, and again, we see the effect of very large disk cache buffers in memory.



Graph 22 Graph 23

Graph 24 shows the multiprocessor to be faster in this random access test as well.



Graph 24

It must be remembered, however, that multiprocessors may only be superior in cases where large numbers of users are doing different tasks. If the work load dictates that single users will run big jobs, all but one of the micro processors might sit idle while one of them struggles along. It is essential to think about the application and intended use of the computer before making a final choice.

CONCLUSION

The conclusion that we have come to, and the conclusion that we urge upon our clients, is to think about the intended use of the computer. Will it be single or multiuser, calculation, scientific, office automation, database, accounting, communications? Just what will be the normal use of the machine?

Then, find a benchmark which effectively measures that type of work and test each machine which seems interesting. Don't place faith in the clock speed, MIP rating, bus width, access time, cycle speed, memory size or anything else. Measure it with an appropriate benchmark, and there should be no suprises when the machine is placed in service.

STORAGE PERFORMANCE -- AN EIGHT YEAR OUTLOOK

Stephen Goldstein
International Business Machines Corporation
General Products Division, San Jose, California

ABSTRACT

This paper treats I/O subsystems in moderate to large commercial MVS installations from the perspective of performance requirements. It examines requirements over the past several years and projects them into the foreseeable future. Movitated by a 1985 customer study, the projections recognise two categories of data; "system data" which is commonly shared among all tasks and "user data" which is typically application specific. Having projected requirements, the paper suggests a device and attachment structure that would support these requirements.

1.0 INTRODUCTION

This paper treats I/O subsystems in moderate to large commercial MVS installations from the perspective of performance requirements. It examines these requirements over the past several years and attempts to project them into the foreseeable future. Three specific parameters are addressed: storage capacity, thruput capability, and response time. These parameters are tracked historically from 1980 to 1985 and then projected into the future with specific snapshots focused at 1990 and 1995. The basis of the projections is a combination of the historical trends observed and an allocation of those trends to fundamental causes -- "driving forces" that may either strengthen or weaken over the next several years.

Having made the projections, the obvious and interesting question is; "What will (or must) the technology be in order to support these requirements?" This question is addressed with some fairly simple performance modeling combined with some conjectures on where technology might be.

2.0 PROJECTIONS BASED ON CUSTOMER STUDY

As stated above, projections will be based on trends observed between 1980 and 1985. The 1985 picture is developed from an extensive customer study including measurements, traces, and system programmer interviews conducted in the spring and summer of that year. Ten commercial MVS installations are represented.

At each installation, measurements were taken at typical peak periods during the day, usually between 10 to 11 in the morning and 2 to 3 in the afternoon. These measurements included RMF (Resource Monitor Facility of MVS) and GTF SIO trace (the General Trace Facility's Start I/O trace). In addition, during off-shift, each installation cooperated by running a VTOC snooper program that collected detailed data set information for each volume in the I/O subsystem.

Without revealing what specific commercial installations were involved in this study, it is useful to at least generally identify the type and size of account and applications that were included.

Installation(s)	Application(s)
Aircraft Manufacturer	Manufacturing support
Integrated Oil Co (2)	Credit card processing Program development
Auto Manufacturer	Graphic design Program development
Heavy Equipment Manf (3)	Parts data base Program development
Life Insurance Co	Policies, claims and billing
Regional Telephone Co	Billing and inquiry
Regional Bank	Customer account files

These installations averaged 37 MIPS (millions of instructions per second) across one or more processors attached to an average of 140 GB (gigabytes) of DASD. For ease of comparison, an IBM 3090-200 is nominally 28 MIPS and a box of IBM 3380 single capacity storage contains four devices totaling roughly 2.5 GB of capacity. So the average system surveyed was the equivalent of 1.3 3090-200's with 56 boxes of single capacity 3380's attached.

Projections for both capacity in GB and I/O rate in accesses per second are normalized to the aggregate processing power of the installation. That is, GB/MIP and accesses/second per MIP are the parameters of interest; the data presented will support scaling to processor power.

2.1 Capacity

Figure 1 shows that an estimate of 3.7 GB per MIP fits quite well with data from the ten installations included in the 1985 Customer Study. Since a linear relationship exists the data supports the scaling of capacity to processing power. Historical data since 1971 indicates that while the large system GB per MIP ratio has been very nearly constant over the past several years, an extended period of growth occurred between 1972 and 1978. This historical trend is displayed in Figure 2 which represents a large sample of high-end computer installations including storage devices and processors from a number of vendors.

To forecast the relationship of GB to MIP over the next several years, it is useful to

contrast the period of the late 70's, when a growth in GB/MIP was occurring with the early 80's, a rather stable period (figure 2). Over the time period from 1972 to 1978 the GB/MIP value increased at 15% CGR (Compound Growth Rate). During those years, many installations converted their operations from batch applications that loaded data sequentially from tape and ran sorted, batched transactions against it to integrated on-line data bases processing randomly arriving transactions in real time. In essence, the method of real time transaction processing pioneered by the airlines in the 60's became standard practice for many installations in the 70's.

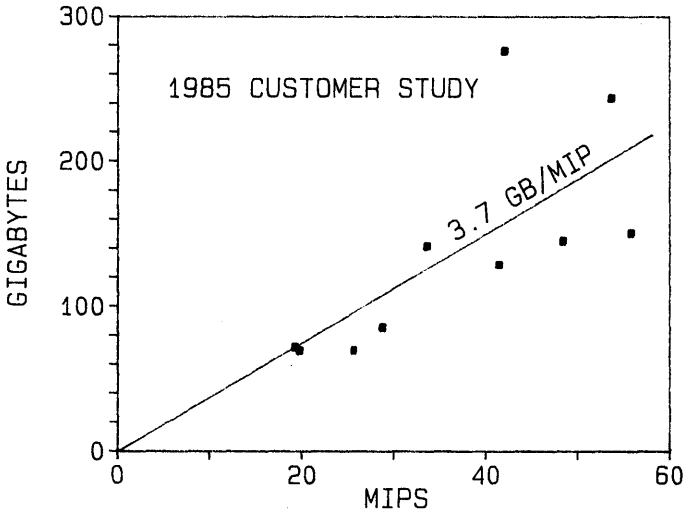


Figure 1. GIGABYTES PER MIP

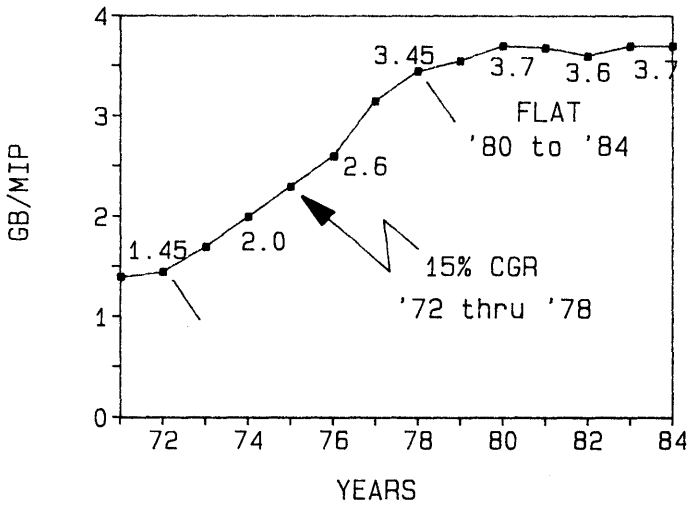

Figure 2. GB/MIP HISTORY

At the same time a technology revolution was occurring. Auxiliary storage devices changed from individually owned removable media (e.g., IBM 3330's) to system owned fixed media (e.g., IBM 3350's). Operating systems participated by introducing facilities to enable the use of fixed media as a repository of permanent data. These simultaneous changes in the nature of large system applications, storage technology, and control programs combined to support significant and extended growth in GB/MIP.

From the recent stability in GB/MIP, it would seem as though the ratio of GB to MIPS is likely to remain near 3.7 until some new forces come along to alter the relationship -- in the applications arena, a couple of changes are on the horizon. One change is the "office of the future" or paperless society where large volumes of inherently non-digital information are captured, digitized, stored, retrieved and displayed as needed. By its nature this type of information is relatively more demanding of storage space than processor power. Its incorporation into storage subsystems will almost certainly increase the GB/MIP ratio. Another application change with the potential to increase GB/MIP is the use of the large "glass house" system as a repository for information which is created and processed on personal computers and intelligent work stations. The impetus would be to take advantage of the economy of scale that persists in large capacity storage devices as well as the inherent efficiency of installation-wide backup and recovery. Backup and recovery is both cheaper and more reliable when done routinely and automatically across a large installation, rather than replicated across many individual users each with relatively slow and expensive backup devices.

On the technology side, complementary developments are pending. The cost of storage is dropping and may drop more dramatically if optical technology fulfills its promise. Even without introducing a new technology, the cost of storage may drop as cache supplies performance and frees magnetic DASD designers to optimize to lower dollar per MB design points without undue concern for performance bottlenecks.

GB per MIP projections

These forces portend a rise in GB/MIP, but that rise will be tempered by inertia. The rapid, extended 15% CGR in GB/MIP that occurred in the 70's operated on, by today's standards, a very small base. Recall that the state-of-the-art drive of the early 70's was a 100 MB 3330, roughly the capacity that many personal computers will have in the next couple of years. As a result, my projection is that GB/MIP growth will resume in 1988 and continue over the next several years at a modest CGR of 2% per year.

2.2 Access rate

Figure 3 represents data from the 1985 Customer Study and shows that an I/O access rate of 15 accesses/second per MIP fits the data quite well. Again a claim that access rate is linear with processor power is supported. Investigation was done on the one non-conforming point on the far right in Figure 3 to see if its installation had any unique characteristics. It did. While all the other installations were heavily into on-line real time processing, that individual installation primarily processed in batch mode and using extraordinarily large block sizes even during the measured prime shift peak period. A good history for access rates was not easily established. One customary complicating factor is the exclusion of paging from the I/O subsystem, as this paper does. In the late 70's and early 80's, paging was universally considered part of the normal I/O workload.

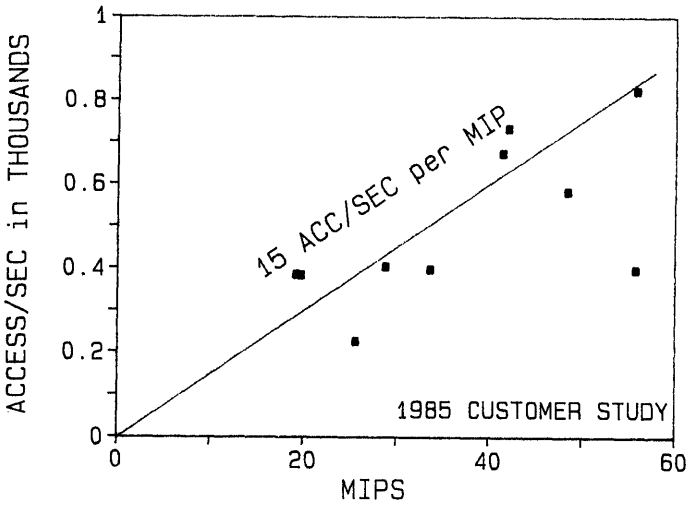

Figure 3. I/O ACCESS RATE PER MIP

The data here is based on an article in the IBM System Journal (1) and discussions with its author. The I/O access rate in 1980 for large systems is estimated at 25 access/second per MIP. The drop from 25 to 15 represents an annual rate of reduction of 10% over the 1980 to 1985 time period.

Several forces were almost certainly at work to fuel this dramatic reduction; they include more processing per I/O, exploitation of bigger processor memories, user friendly applications, and transaction processing. More processing per I/O is a phenomenon closely related to using larger block sizes on DASD and cost as a function of block size. Large block sizes allow more efficient use of DASD space and hence are desirable. Their use naturally increases the amount of data transferred per I/O operation and reduces the access rate per million instructions executed. Reinforcing the exploitation of large blocks is an argument from the cost of an access perspective. Transferring large blocks of data is efficient, because most of the device time expended in accessing a block is fixed overhead.

For example, in current technology, accessing a 4K byte block of data from a DASD devices results in roughly 20 ms of device busy time of which less than 1.4 ms is data transfer. Other elements of device busy time include seek, latency, search, RPS reconnect and protocol. They are, for the most part, independent of the amount of data transferred. If an 8K block (or two consecutive 4K blocks) is retrieved device busy time would rise from 20 ms to 21.3 ms, an increase of about 7% for twice the amount of data retrieved. If the additional 4K bytes retrieved is useful, this is indeed a bargain that should not be overlooked. The trend to larger blocks, and therefore more processing per block transferred, will continue although natural barriers, specifically the Law of Diminishing Returns, limits its growth.

Exploitation of larger main memories is a strong factor in the decrease in I/O rates per MIP. Over the past several years, operating systems and major applications have concentrated on this. For example, consider data base buffer pools. Data base applications have built elaborate lookaside buffer schemes to reduce the need for physical I/O accesses to storage devices. The dramatic fall in the cost of processor memory, driven by larger and larger capacity chips, is fueling the trend to utilize processor storage to reduce the need for accesses to auxiliary storage. It will probably continue and may intensify over the next several years.

At first glance it might not seem apparent that user friendly applications and transaction processing have been "drivers" of the reduction in storage access rates; they have. Both of these factors have worked in a similar way, by diverting a substantial amount of the processors power away from the main stream application and into activities that require few I/O operations. In the case of user friendliness, many instructions go into screen manipulation. Transaction processing diverts processor resource to network control and message processing. I forecast no change in the demand for user friendliness and on-line processing; however, the transition is largely done and as forces for change, they will have a diminished effect over the next several years.

I/O Access Rate Projection

To summarize the I/O access situation, exploitation of larger processor memories will strengthen, more processing per I/O trend will continue to reduce access rates, while effects of user friendly applications and on-line transaction processing will abate. In net, I/O access rates per million instructions executed, which fell 10% per year from '80 to '85, will continue to fall but at a slower annual rate of 7% per year.

2.3 Response time

In the 1985 Customer Study, response times varied widely from customer to customer and data pool to data pool with no particular correlation to the processing power of the installation. In Figure 4, there is one vertical bar for each installation; they are arranged according to increasing average response times. The upper end of the bar represents the highest average response time among the installation's data pools; correspondingly, the lower end on each bar represents the lowest average response time among that installations data pools. The length of the line is a measure of the variability of response time within the installation.

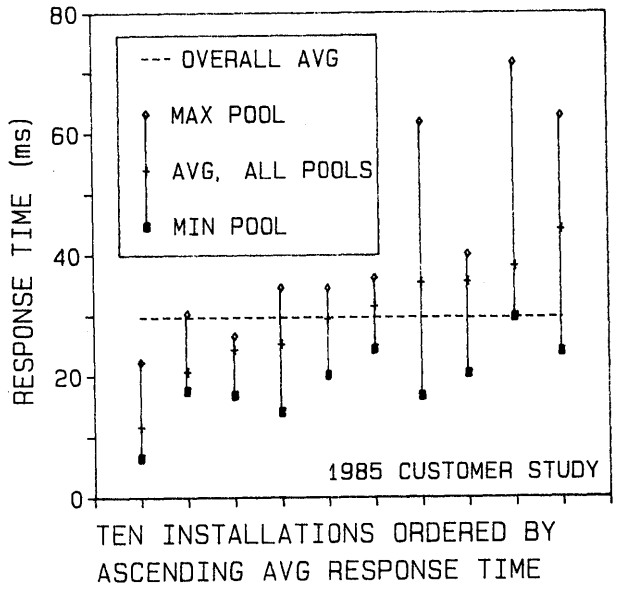

Figure 4. RESPONSE TIME RANGES

A couple of specifics are noteworthy. The installation represented by the left-most bar enjoys the lowest response times in all three categories, and is mostly cached. The next three installations all spend substantial resource in tuning and balancing their I/O subsystem and appear to achieve a measure of success in return for their efforts.

Looking back to 1980, the workhorse DASD device was an IBM 3350 and its compatible equivalents along with some IBM 3330 model II class devices. From my recollections and those of my colleagues, and from the review of a few previous internal studies, the typical response time in the peak busy period was in the range of 40 to 60 ms. In this paper, I have elected to use 46 ms as the 1980 representative value. This represents an annual rate of reduction of 9% when compared to the 30 ms average response time of the 1985 customer survey represented as a horizontal line in Figure 4.

The forces decreasing response times from the I/O subsystem are application, system, and technology based. From the application perspective, a desire to simultaneously increase transaction complexity and improve end user productivity supports the requirement for lower DASD response times. The system perspective is that high DASD response times require high levels of multiprogramming to utilize increasingly faster processors. But high levels of multiprogramming introduce their own inefficiencies, such as long queue searches and increased resource and lock contentions; they are to be avoided if possible. Fast DASD response times mitigate the need for higher levels of multiprogramming. From the technology perspective, lower DASD response times are achieved through the exploitation of electronic technologies to improve connectivity, speed data transmission between the spinning magnetic media and processor memory, as well as to provide high speed outboard RAM for caches and solid state devices.

Response Time Projection

The forces to reduce I/O response time will accelerate over the next several years. Particularly as data bases move to the increasingly popular relational approach, the pressure for faster response times will increase, and it is likely that technology can rise to the challenge through expanded use of electronic switching and storage technologies. Overall system average I/O response time will fall at an estimated rate of 13% per year over the next several years. However, the wide variations observed in the 1985 Customer Study are likely to continue. Not every application requires the same response time and, while low response time never hurts, it may not be free.

2.4 Summary of the Analysis of Change

This completes the analysis of parameters; their historical trends and forecast course are summarized in Table 1.

Table 1. Summary of Workload Changes

	ACC/SEC MIP	GB MIP	RESPONSE TIME
'85 BASE	15	3.7	30
'80 to '85 (History)	-10%	0%	-9%
'85 to '95 (Forecast)	-7%	2%	-13%

All percentages represent annual rates of change.

Now it is only a math exercise to convert this table into what an the average customer from the 1985 study would look like over time. For this exercise, we'll arbitrarily assume that an "average installation" grows its MIPS at a 30% annual rate.

Table 2. An Average Installation Over Time

	MIPS	GB	ACC/SEC	RESP TIME	ACC/SEC per GB
1985	35	130	525	30 ms	4.1
1990	130	510	1387	15 ms	2.7
1995	483	2092	3708	7.4 ms	1.8

3.0 TWO CLASSES of DATA

While Table 2 presents a good picture of average rate and response times across an installation, it gives no hint of the wide variations that were apparent in the response times of Figure 4. The Customer Study, with detailed access rates and response times by pool, provides some interesting insights. There appear to be two general types of data in these installations. The busiest type is "system data" comprised of the key system, spool, and scratch data pools; less busy is the "user data", a combination of primary application, secondary application, batch, and off-line data pools. With some installation

variation, the system data averaged close to half the accesses while occupying only 14% of the capacity. It had an access density of 13.3 accesses per second per GB compared to the user data at 2.6 accesses per second per GB (see Table 3, column 4, 1985 heading). With this disparity in access density, a factor of more than 5, it is necessary to work with the components rather than try to draw conclusions from to overall averages. The distinction between system and user data will be made in the upcoming discussion that matches devices to workloads.

Examining the Customer Study data reveals a weak trend that suggests larger systems have slightly less system data proportionately than smaller systems. Over time the exploitation of large memories should lead to the increased capture of very active system data. For example, ten years ago much of the task, resource, and network management information now commonly held in processor memory was shuffled back and forth to DASD. In this paper, system data is projected to grow only 75% as rapidly as user. Table 3 depicts the scenario.

Table 3. Details of an Average Installation Over Time

1985 35 MIPS	GB	ACC SEC	RESP TIME	ACC/SEC GB
SYSTEM DATA	18	242	34	13.3
USER DATA	111	284	26	2.6
	130	525	30	4.1
1990 130 MIPS	**GB**	**ACC SEC**	**RESP TIME**	**ACC/SEC GB**
SYSTEM DATA	53	638	9	12.1
USER DATA	457	749	20	1.6
	510	1387	15	2.7
1995 483 MIPS	**GB**	**ACC SEC**	**RESP TIME**	**ACC/SEC GB**
SYSTEM DATA	158	1706	4.9	10.8
USER DATA	1934	2002	9.3	1.0
	2092	3708	7.4	1.8

The ACC/SEC apportionments between system and user data, allocated according to the prior discussion, tend to more user and less system access over time. The allocation of response times between system and user data in '90 and '95 was determined by assuming that the system data will be mostly cached in '90 and 100% cached in '95. The Customer Study captured only limited usage of cache for system data and correspondingly several of the highest pool response times in Figure 4 are for key system data. Caching studies have consistently shown that key system data is a prime candidate for cache. The assumption is that all key system devices will be attached through cache controllers by 1990. Since the bottom line overall response time is determined from the previous trends discussion to decline 13% annually, the user data response is uniquely determined.

It is interesting to observe that while 30% per year MIP growth is less than many large computer installations have experienced over the past ten years, it generates a processing capability of nearly 500 MIPS in 1995, awesome by today's terms. Further, even though the I/O rate growth is assumed to be slower than that of processing power (-7% per year in ACC/SEC per MIP), it grows to over 3700 accesses per second; another remarkable number when measured against today's systems. Meanwhile, we project I/O subsystem capacity will have grown to over 2000 GB; or measured in terms of single capacity 3380s, that is about 800 boxes or 3200 actuators!

This completes the workload projection portion of this paper. A discussion of devices and their attachment in view of the projected loads follows.

4.0 DEVICES IN THE 90's

The obvious question is: "How will storage devices in the 90's change if these projections come to pass?" This paper concentrates on the 1995 installation and deals with system and user requirements separately. Experience teaches that new DASD products are fully integrated in large installations roughly two years after their availability. The devices to handle the 1995 workload will need to be available for installation by 1993.

4.1 Devices for System Data

System devices in 1995 can achieve a response time of 4.9 ms. Assuming the data is cached, a good quick estimate is:

Resp Time = P(cache hit)*RT(for a hit) + P(miss)*RT(for a miss).

There are infinitely many sets of numbers that satisfy this relationship and yield 4.9; we need to narrow the selection with some knowledge of technology. Current caches are typically achieving read hit ratios of .87 to .92 on system data; writes are not cached. I assert that by the mid 90's, the technology to get cache equivalent performance for both reads and writes will exist and further that the combined hit ratios for both will be at least as good as is achieved today for reads. So for P(cache hit) pick .9 and for P(cache miss) pick .1 (1-.9). A higher hit ratio based on larger caches and improved designs could be argued for, but with some of the more frequently used system data migrating into processor memory, a conservative .9 is prudent. Today, cache hits are satisfied in about 5 ms. This includes device queueing, device and channel protocol, cache directory search and data transmission time. Improvements are attainable in each component, and by the early 90's a cache hit response time of 3 ms is a reasonable expectation. Filling these estimates into the equation for Resp Time above and solving for RT(for a miss), we get 22 ms. This is the response time required from the backing DASD device if an overall 4.9 ms response time is to be achieved. To see one way it might be reached, consider Table 4.

Table 4. Components of response time for a typical DASD access to system data, uncached in 1985 and a cache miss in the early 90's.

	1985	Early 90's
Device Queuing	10	4
Start I/O delay	1	1
Search and Protocol	3	2
Seek	5	5
Latency	8	7
RPS Delay	5	2
Transfer	2	1
	34 ms	22 ms

The 1985 seek estimate of 5 ms reflects the well known fact that seeks are not random. Most installations measure actual seek times ranging from 20 to 35% of published nominal seek times where the nominal are based on truly random seek patterns. The seek time estimate remains constant at 5 ms in the early 90's estimate. While device seek mechanisms will get faster, caching tends to eliminate proportionately more of the short and zero seek accesses, thus raising the observed seek time. Holding the seek time constant from the '85 to the early 90's assumes that technology improvements and the effect of caching balance out and no net change occurs. With other components showing moderate improvements in technology, the response times of 22 ms for cache misses, composed of 17 ms service time and 5 ms device and path queuing, will be reached.

Now the question is: "How much data can we place under the arm of one of these devices?" From the 1995 projection, system data at the typical installation was receiving 1706 accesses per second and occupying 158 GB of space (Table 3). Of the 1706 accesses, 90% are picked off by the cache and the remaining 10%, or about 170 become real physical accesses to the DASD devices. Next we ask: "How many accesses per second can an arm produce?" The naive answer is 1/(service time per access) = 1/.017 = 58+ accesses per second. This answer is wrong on three counts.

First, 1/(service time) assumes 100% device utilization, which is impossible to achieve and inconsistent with 4 ms device queuing. Experience teaches that an average device utilization of 15% is a good operating point for DASD in large MVS systems. Device skew (the phenomenon that some devices are much much busier than others) limits the average. Second, on a cache miss, the amount of data transferred is much greater than one record as the remainder of the track is transferred following the target record. For cache misses, use two times the latency as the transfer time; in this example the service time estimate becomes 30 ms. Starting with the early '90's base in Figure 4, remove queuing delays and transfer time and then add twice the latency (22-4-1-1+14). Third, handling writes in the cache implies some destaging will occur as updated tracks fall to the bottom of the LRU stack. While these destages are not seen as part of device response time they do increase device busy just as staging the remainder of the track after a miss does. Without a derivation I will claim that a good approximation to the probability of destaging is:

P(access causes a destage) = P(write)*P(miss)

This is not an exact formula, but under normal conditions is reasonable. In the current example, P(destage)= (.125)*(.1)= .0125. So device busy time of 30 ms for misses must be increased by 30*.0125 = .4 to account for destage activity. This is not within the range significance for a "back of the envelope" calculation and will be ignored. It could become significant with lower hit rates or lower read-to-write ratios.

Putting these factors together gives a more accurate but still back of the envelope estimate of access rate per arm of .15*/.030 = 5, and to service 170 requests per second requires 34 arms.

How much data per arm? 158 GB of data on 34 arms implies we can afford 4.6 GB per arm and still accommodate the average system! However, a design to just satisfy the average system is not prudent. For DASD, a margin of twice the average seems to cover almost all of the MVS installations. By this rule, a volume with 2.3 GB is indicated as reasonable for cached system data.

This allowable capacity per arm for the 1995 workload is large by current standards and sufficiently interesting to warrant further investigation. One cross check is to look at the 1985 workload in the same way and find an allowable capacity under the arm for it. With no caching and an I/O rate of 242 accesses/second spread across 18 GB of system data, an average device utilization of 15% and a service time of 23 ms, we get: .15/.023 = 6.5 accesses/second per arm. The 242 accesses/second require 37 arms and spreading 18 GB across 37 arms gives an allowable capacity of .5 GB per arm. Comparing .5 GB calculated with the 3380 single-capacity devices at .63 GB indicates that the fit is roughly correct for the average system; but uncached 3380's holding purely system data may be a little too big for some systems. This matches quite well with contemporary customer experience where many installations currently use cached single capacity devices for system data. A design point at half the requirement (i.e., .25 GB per arm) would not be a cost effective solution. The cost of such a device would be much greater than half a current single-capacity device and cache is quite effective for those systems in the upper half of the requirement range.

A note of CAUTION: The methodology above is only an approximation. It is not a valid capacity planning methodology but a "ballpark" estimate of what type of storage devices might be appropriate to match against a broad class of demand.

4.2 Devices for User Data

While system devices were projected to have an average response time of 4.9 ms, user devices are projected to reach 9.3 ms. First, some caching is certainly required to achieve this objective, since the 1995 projection for cache misses on system data is 22 ms. User data having lower access rates may experience less device queueing. However, since we are looking to configure large capacity devices and run them at comparable utilizations to the devices

holding system data, the queueing delays will be comparable. To get an idea of how much caching is required, suppose that user data, being somewhat more unpredictable than system data, experiences a cache hit probability of .87. Then if we use an extension of the analysis for system data we get:

```
User data RT = P(cached access) * RT(for cached
               data) + P(uncached access) *
               RT(for uncached data)

   RT(for cached data)=P(hit)*RT(for a hit) +
                       P(miss)*RT(miss)
                      = .87  * 3 ms   +
                        .13  * 22 = 5.5 ms
```

RT(for uncached data) is the same as response time for a cache miss except that a slightly lower seek time is expected per the prior discussion. Using a seek time of 4 ms rather than 5 ms in the cache miss case in Table 4 gives 21 ms total. So

```
User Data RT = P(cache)*5.5 + (1-P(cache))*21
             = 9.3
```

This gives P(cache) = .75. It means that 75% of the accesses to user data have to be to cached devices, but not necessarily that 75% of the devices will be cached.

Since the expectation is that wide variations in response time will exist from installation to installation, it is interesting to look at both the cached and uncached devices in terms of arms required and how much data can comfortably go under an arm. Consider cached devices first.

From the system data analysis, an arm can handle about 5 cache misses per second. With a hit ratio of .87, that gives a total rate of 5/.13 = 38 accesses per second to the logical device. The 1995 table indicates that user data experiences 2002 accesses/second, so 2002/38 = 52+ user devices are required for thruput. If the projected 1934 user GB are spread over 53 devices, that would yield an amazing 36.5 GB per access mechanism for the average system. The half size rule to cover most systems yields a capacity of 18 GB. In all likelihood devices will not be nearly that large. If they were, seek and latency might have to be much bigger as the physical dimensions of such a device would likely dwarf today's HDA's (Head-Disk-Assemblies). Optical storage might produce such capacities, but current technologies give little promise of meeting the 17 ms (22ms RT - 5 ms device queueing and SIO delay) service time projected for magnetic DASD and required to make this projection methodology valid.

For uncached devices, things are more as we expect. At 15% utilization and with a service time of 16 ms, we get .15/.016 = 9.4 accesses/second per device as compared with 36 for cached devices. The projected 2002 access rate requires about 213 arms. Spreading 1934 GB across 213 arms yields 9.1 GB per arm for the average system, and the half size design rule gives 4.5 GB per device. That is almost four times the data per actuator of double capacity 3380's.

Another sanity check against the 1985 data is in order. Table 3 shows 1985 user data at 111 GB with 284 access/second. Uncached devices in 1985 have a service time of 23 ms and can handle .15/.023 = 6.5 access/second. Thus, 44 devices are required (284/6.5); and with a capacity of 111 GB this translates to 2.5 GB per arm. This is roughly two times the double-capacity 3380E and corresponds exactly to the rule of thumb for a DASD design to cover the broad range of requirements by having about half the capacity that would just satisfy the average installation.

Remember, the 1985 and 1995 workloads are for average large system MVS configurations during daily peak time periods. Many installations have above average workloads or average loads with above average peak stress periods. Good design dictates that a somewhat over qualified product is far more desirable than a marginal one. One further caution, VM systems appear to generate higher ACC/SEC per MIP workloads. While the general methods presented in this paper are applicable for VM, the specific values are not.

5.0 CONCLUSIONS

This paper forecasts that I/O subsystem workloads in large MVS installations will continue to grow over the next several years. While growth in capacity will exceed growth in MIPS, growth in access rates will not keep up with the growth in MIPS. I/O response times will continue to improve. To accommodate these trends, DASD devices and their attachments will evolve. The primary effects will be movement to cached subsystems and larger capacity devices. This is summarized in Table 5.

Table 5. Evolution of DASD Workloads and Devices

WORKLOAD	1985 to 1995
ACC/SEC per MIP	52% REDUCTION
GB/MIP	22% INCREASE
RESPONSE TIME	75% REDUCTION
DEVICES	**1993**
GB/ACTUATOR	
System Data	2.3 GB (Cached)
Users Data	Up to 18 GB (Cached)
	4.5 GB (Uncached)

6.0 ACKNOWLEDGEMENT

This paper draws heavily on a customer study done by Marti Henley and several people in her department including Ingrid Lue, Bruce McNutt and Kendall Wright. Without that study, this paper could not have been written.

CACHE MANAGEMENT IN A HOSTILE ENVIRONMENT

Rob Wells
National Advanced Systems

ABSTRACT

A discussion of the problems facing management to reduce response times in an unfriendly software environment and the strategies adopted to overcome these problems is presented. The implementation of a cache DASD subsystem is an integral part of this plan.

The significant benefits obtained were predicted with the use of empirical methods. A discussion of the additional tools required to implement cache support in such a hostile environment will also be presented.

1.0 INTRODUCTION

All data processing organizations experience performance problems at some point or another, but what alternatives are available for those users that are behind in their implementation of software technology? Examples of this are users continuing to use outdated or unsupported operating systems, like VS/1 or DOS/VS.

This paper discusses a case of a VS/1 user maintaining continuity with hardware advances that are reportedly not supported. First is a discussion of the problems facing management in a "hostile" user software environment, and an approach that was undertaken to alleviate it. As part of the approach, a case is built for the implementation of a cache controller. Second, a discussion is presented describing the implementation of a tool to support cache in a hostile unsupporting VS/1 environment. During each of these discussions, a description of the operation of a cache controller is presented.

2.0 PROBLEM DEFINITION

2.1 SYMPTOMS

As in most installations, when the phone begins to ring, it is usually the first indication that there is some type of problem. In the computer industry, most problems relate to either service or performance. Problems relating to performance are broken into two categories, perceived and real.

Perceived problems are usually caused by a lack of service level agreements with the users. Without them, user satisfaction can vary greatly, based on almost anything, including what day it is. On the other hand, real problems are caused when the service level is not met, whether the agreement with the users is implied, verbal, or written.

In the case of the installation from which the study is drawn, the problem is real, and the service level is implied. Dissatisfied users were experiencing an online terminal response time of between 15 and 30 seconds.

2.2 PROBABLE CAUSE

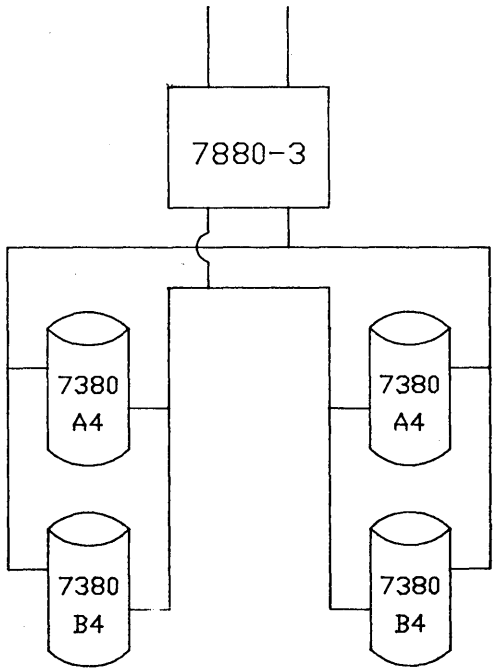
Discussion of the processing profile of a typical online inquiry transaction revealed that the I/O processing involved a complex search of a data base index, and this was responsible for the major proportion of the transaction response time within the CPU. Confirmation of this process being a major bottleneck causing excessively long and variable response times was undertaken using basic queuing theory. The queuing analysis revealed that a mere 10 percent reduction in the total I/O response time for the index search was likely to reduce the transaction response time to an acceptable and stable 4 seconds.

2.3 THE ENVIRONMENT

Before considering possible solutions to the problem, it was necessary to understand the environment in which it arose. The environment in this case was made up of three sections, the software environment, the hardware configuration, and characteristics of the index search.

2.3.1 **The Software Environment.** The software environment was potentially a problem in itself. Knowledge of the intimate details of the operating system, VS/1, and the software applications was possessed by very few. The software was already highly modified for local purposes and poorly documented. This situation could be seen as a hostile internal environment in that there were limited resources to resolve a difficult problem.

2.3.2 **The Hardware Configuration.**



2.3.3 **The Characteristics of the Index Search are:**

- Device type	7380
- I/O's per search	multiple
- Access Method	EXCP
- CCW's	Chained
- Blocksize	3520
- Blocks/EXCP	12
- Threading	Single
- Granularity of lock	Whole Index

3.0 POSSIBLE SOLUTIONS

It was necessary to develop a list of possible alternative solutions to the problem and then determine the impact of each. Due to the technical nature of the problem, the list was comprised of possible technical solutions. Without explaining each in detail, they are all suggestions made by the technical staff that concern improvement to the search of the data base index. There were:

-split the index across multiple volumes

-provide separate index I/O path

-reduce lock granularity

-introduce multiple threading

-make index (parts) resident in real CPU memory

-introduce cache controller

4.0 EVALUATING THE ALTERNATIVES

4.1 MANAGEMENT ISSUES

Once the problem was confirmed to be real and its likely source isolated, management had to begin to take steps to correct the problem in both the short and the long term. The next step in the process was to identify the management issues involved in its resolution. In this case, they were rather simple:

1. **User Satisfaction**. Users were frustrated and potentially hostile to the extent that a slow terminal response time was occurring. Only crucial work was being performed and productivity was low.

2. **Service Level Improvement**. To enhance the environment it was necessary for the service level to improve to stimulate productivity.

3. **Service Level Maintenance Once Improved**. Maintaining the service level was important for planning purposes. It was expected that in addition to normal growth, there would be a high degree of latent demand due to a potential increase in the productivity level. The thought behind this was, enhancing user productivity would stimulate use of the system.

4. **Resources Required to Resolve the Problem**. This consideration was felt to be significant because in this installation the quantity of technical staff was limited. Alternatives such as consultants could be considered to complement the lack of staff, but time, cost, and availability were factors especially due to the existence of an outdated VS/1 based system.

5. **Cost Effective Solution**. Cost in any environment is a consideration. Cost here is made up of three important entities: time, materials, cash, and staff resources. The need for each would be weighed accordingly to their respective usage in the possible solutions. Cash resources were available provided total costs could be identified in advance.

4.2 TECHNICAL ISSUES

4.2.1 **Understanding Cache Concepts**. Before much is said regarding a case for cache, a brief description of what cache is and its operational characteristics is required. A cache is defined in general terms as a hiding place, typically for treasures or provisions. As it is used in the computer industry, it is a high-speed buffer for the transfer of data from a slow medium to a faster one. In its original use, cache acted as a buffer between the CPU and Real Memory to improve the performance and throughput of the system. With the reduction in cost in producing high-speed memory, cache has been implemented in the DASD I/O subsystem to benefit its performance.

Cache in the DASD I/O subsystem resides in the controller between the high-speed channels and slow, rotating disk devices. Cache's performance benefit is based on the assumption that a sufficient portion of the data being retrieved resides in the cache buffer. Given a high proportion of data being found in cache, the effect on performance can be overwhelming. The DASD I/O response time for a typical 3380 subsystem can be reduced from around 25 milliseconds to 3 milliseconds, if the record being read resides in cache. The average response time can be halved. Based on a reduced average response time it is possible to achieve higher channel utilization in cached DASD subsystems than in non-cached subsystems, while retaining acceptable response times.

There are four basic operations that can occur in a cache environment. They are:

Read Hit

This is the most important of the cache operations. A read hit occurs when the record of data being read exists in cache, and therefore can be passed immediately to the channel, resulting in a minimum response time for an I/O operation. In this case, no access to a disk is required.

Read Miss

For this operation, the record being sought is not in cache; therefore, a read operation from a disk volume occurs. In addition to the record being read, stored in cache, and simultaneously transferred to the CPU via a channel, a prolonged operation transfers either the rest of the track or the entire track into cache, and makes all of that data available for possible READ HIT retrieval later. The reason for doing this is that the probability of requiring another record from the same track has been observed to be high; therefore, the next read operation is likely to result in a read hit operation and the overall average response time will be reduced.

Write Hit

For a write hit operation the record being written exists in cache and, therefore, is updated in cache and on the disk volume simultaneously. For data integrity reasons, the proper condition code of the write operation is not issued until the write operation to disk is completed. If the record is reread immediately, then the record is found and retrieved from cache in a READ HIT operation.

Write Miss

In a write miss operation, the record does not exist in cache. Cache is completely bypassed and the record is written to disk only.

4.2.2 **Software Support of Cache**. The above functions occur transparently to user programs, and the operating system. For this reason, cache operations can be implemented in environments that are normally thought of as not supported, such as VM non-HPO, DOS, or VS/1, provided that caching of the volumes of interest or in need of cache support can be achieved without the usual operating system software. In practice, this proves to be possible.

It is important to note that the default situation in a cached environment is that all volumes behind the cache controller are cached. Whole tracks containing records read are moved into cache as described in READ MISS, and subsequently the benefits of READ HIT can be obtained for associated volumes. As a consequence, the selection of volumes to reside on the cache string must be more careful than usual as the achieved Read to Write Ratio has a significant impact on performance, as does the Read Hit Ratio. If acceptable levels of the two ratios are not maintained, performance can be adversely impacted.

Given that VS/1 does not support a cache DASD controller, this is another reason to define the environment as hostile.

5.0 THE CHOSEN SOLUTION

When making any decision, the alternatives must be weighed against the issues that have been defined, and then one chosen that satisfies most or all of the requirements with the least impact on resources.

It is not the purpose of this paper to report on the evaluation of each of the alternative solutions considered. Several of them have been implemented over a period of time. Rather, the solution which was considered likely to be the fastest and easiest to implement, and therefore to be attempted first, is discussed in detail.

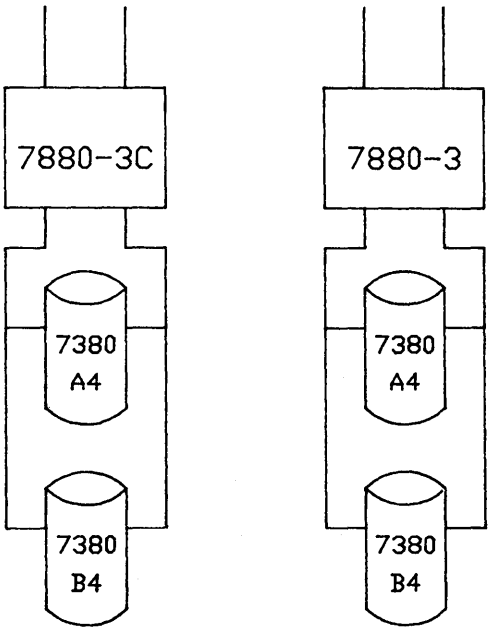
The introduction of the cache controller was accepted as the first alternative due to the potentially beneficial impact on performance, minimal staff involvement required to implement it, and the speed with which it would be achieved. The controller could be delivered quickly and an experiment could be developed and conducted to prove its effectiveness.

6.0 TESTING AND EVALUATING THE INITIAL SOLUTION

Given an understanding of cache and its operation, it is easier to understand the following case that is presented as a successful implementation in the rather hostile environment; hostile in the sense that the selectable functions of cache controllers are not supported by VS/1.

6.1 CONFIGURATION CHANGE

The diagram that follows shows the change to the configuration with the introduction of the cache controller. With this addition, there are the effects on performance of two changes. First, there are extra paths to the current devices, and second, there is the existence of the cache itself.



6.2 EXPERIMENTAL DESIGN

The dramatic improvement of response time is usually a simple thing to measure. First, all the user complaints stop and so does the ringing of the phone, but that is not a good justification for purchasing equipment. To keep things simple and to satisfy manpower constraints, it was agreed that a full scale online test was not necessary to measure the effect of a change. A simple design was agreed upon to measure the effects of implementing a cache controller. A batch job was selected that performed a partial restore of the data base, because it closely replicated the profile of the online system's data base index activity. Performance of the job running stand alone would be measured on elapsed time only. The percentage of improvement between different executions using different DASD I/O configurations was expected to give a general indication of relative performance for those configurations in the online environment.

First, a Base Line of performance was determined to establish whether improvement or degradation occurs. Second, a method was established to measure the effects of the changes. In this case, three change effects were measured:

1. **Base Line.** Both the index and data base were located on volumes on one DASD string headed by a non-cache controller. This was essentially equivalent to the pre-existing configuration described in section 2.3.2.

2. **Configuration Effect.** The addition to the DASD I/O subsystem of another controller in itself has an effect, so this has to be measured. The configuration effect test placed the index on one string, and the data base on the other string. The cache was disabled by hardware means, and (index) I/O performance difference was reflected in the changed job elapsed time. This provided a measure of the configuration effect alone.

3. **Cache Effect.** To enable the effect of cache on all the data being accessed, both the index and data base were placed on the same string connected to the cache controller. Here any change in elapsed time for the job was attributed to the existence of the cache alone.

4. **Combined Effect.** To measure the combined effect of the configuration change (second DASD controller) and the introduction of cache as a presumed improvement to the index search I/O processing performance, the index was placed on the string with the cache, and the data base was placed on the string with the normal controller. This was done knowing that the index was a file that was being read significantly more than it was being written, with several records being read in sequence.

6.3 RESULTS OF THE EXPERIMENT

TEST EFFECT	ELAPSED TIME	PERCENT IMPROVEMENT
Base	29:34	--
Config	29:05	2
Cache	23:36	20
Both	21:51	26

6.4 EFFECTS ON THE ONLINE SYSTEM

After completing the experiment, the cache controller was left installed for use in the online environment. The online response time was reduced from the 15-30 seconds at peak times to approximately 4 seconds during these peak periods, a minimum of a 75 percent reduction.

As predicted through the queuing theory analysis, just a slight improvement to the service in the data base index queuing had a large impact to the overall response time.

6.5 EVALUATION OF THE INITIAL SOLUTION

The introduction of the cache controller proved to be very effective. It satisfied the users, provided a significant service level improvement, and staff resources required to implement the solution were minimal. The costs involved were effectively limited to those involved in purchasing and installing the cache controller. Consequently, the implementation of the solution chosen initially, satisfied the dual constraints of minimal use of site staff and limiting the cost to a predicted level.

Additionally, an unexpected benefit was realized with this implementation. With the bottleneck in the I/O subsystem now alleviated, the CPU Utilization dropped slightly. This permitted the delay of a CPU upgrade for several months, effectively buying back CPU capacity, also offsetting the cost of the cache controller.

7.0 FOLLOW-UP

7.1 OUTSTANDING ISSUE

The alleviation of the DASD I/O bottleneck may have satisfied and calmed the users, and also stopped the phones from ringing, but one major management issue still needed attention. This issue is maintaining the service level once it is improved. In a stable environment, and with the removal of the bottleneck, one could expect that the problem would not resurface. In this installation, however, the business growth rate is approximately 15 percent per year. With this in mind, it can be expected that the problem would return, either in the same form or perhaps as a new and different bottleneck, as the demands for access to the data base increase.

There were two parts to this problem. First, there was a need for periodic monitoring of the performance of cache to ensure that correct data with the right usage characteristics was being cached. Second, a method was needed to control or select the devices under the management of the cache.

To accomplish this, a method to provide directions to the new controller had to be developed, since VS/1 does not support cache commands. In fact, VS/1 prevents the issuing of cache commands. There were several problems that native VS/1 caused, which brought back the issue of the hostile software environment. The major problem that was discovered was that the operating system was validating the CCW commands prior to executing them. This meant it was not possible to issue commands either to select volumes for caching individually or to read out usage statistics maintained by the controller hardware and microcode.

7.2 CACHE OPERATION

Prior to describing the approach to these issues, a further discussion of the operation of cache is required. In addition to the types of I/O operation discussed earlier, there are three modes in which a cache controller can function. The modes as described below are selectable at the disk unit level and are used to control the performance of the device in accordance with the type of data on the volume and the way in which it is being used. They are:

Basic Mode

In basic mode, all records are considered to be randomly accessed, although the probability of accessing two or more records from the same track successively is considered high. Records and the remainder of the track where they reside are read into cache, replacing data in cache on a Least Recently Used basis.

Sequential Mode

When records are being read in sequence and a record is brought into cache, the controller pre-stages additional records by also reading into cache up to four tracks, depending on the manufacturer. With continued pre-staging, data can then be transferred more quickly from the controller without waiting on the spinning device.

Inhibit Mode

Under inhibit mode, cache operations are completely bypassed. This mode is selectable at the device level or on a whole subsystem basis.

7.3 CACHE SUPPORT

When an operating system supports cache, software is used to control the functions described above. The supporting environments are MVS/SP or MVS/XA with IDCAMS, and VM/SP HPO and SF. The functions that are performed by software interfaces can be broken into two categories:

1. Those functions that enable or disable the use of cache when accessing data at the disk volume, or entire subsystem level. These functions offer the capability to optimize the cache access environment.

2. Those function which collect statistics regarding the number of accesses to cache in each mode of operation, and also collect byte counts for every access type. This information is transferred to the system in response to special channel commands and is useful in developing operating and performance ratios of cache for each enable volume.

These functions are implemented via special channel commands. There are five primary commands to control the new functions:

1. **Define Extent**. Specifies access range and access modes for cache. The command code is '63' and it transmits the access area and mode.

2. **Set Subsystem Mode**. Determines availability of cache memory for pertinent devices or the whole subsystem. The command code is '87' and transmits enable or disable information.

3. **Sense Subsystem Status**. Logs cache status information indicating the operating status of cache. The command code is '54' and the controller transmits 40 bytes of information.

4. **Sense Subsystem Counts**. Logs input/output operations counter data indicating the operating status of cache. The command code is '74' and the controller transmits 80 bytes of information. This information is discussed later.

5. **Set High Performance Storage Limits**. Bind all records in a specified area from a nominated track in cache or release that binding. This function is only implemented on the model 13 controller. The command code is '3B'.

7.4 CACHE STATISTICS

The statistics that are maintained and retrievable provide valuable information for the tuning of the cache subsystem. The types of data that are collected and retrieved via the Sense Subsystem Counts channel command are:

For Both BASIC & Sequential MODE

-Read I/O count

-Read Hit I/O counts

-Write I/O counts

-Write Hit I/O counts

Other Counts

-Load Inhibit I/O counts

-Read I/O on bound tracks

-Write I/O on bound tracks

-Cache load count

-Byte count from Read Hit

-Byte count from Read Miss

-Byte count from Write Hit

-Byte count from volume to cache

These statistics can be used in the development of Read to Write ratios, READ HIT ratios, and monitor the load on and performance of the cache. Without describing each statistic in detail, it is important to know that these values are available and important in maintaining optimum throughput in the cache subsystem.

7.5 GOOD CACHE CANDIDATES

With an understanding of the ability to control the operation of cache, it is now important to understand the characteristics of those volumes which make good cache candidates. In general, the following characteristics make for excellent eligible devices:

1. The number of READs is high compared to WRITEs, where the device is reading greater than 65-70 percent of the time.

2. The frequency of access is high, approximately 2000 I/O's per hour or greater.

3. The tendency of completely random access is not very high, proximity of reference is close.

7.6 OTHER BENEFITS OF CACHE

With the capability of inhibiting the use of cache on unfavorable volumes, installations can maximize I/O throughput given proper management of the I/O subsystem. In addition, the cost of an effective megabyte of storage can be reduced by enhancing the following tendencies:

1. Increase the number of devices on a string to the maximum.

2. Enable the use of double capacity devices.

3. Increase both the allocated and effective usable space on each volume.

In the absence of cache controllers, installations usually limit the number of devices on a string to eight or twelve, and the number of controllers per channel to one, for performance reasons. In addition, installations use a general rule of having a maximum of 80 percent of the space on a volume allocated in an effort to provide for performance benefits.

With the introduction of cache, these limitations can be minimized or eliminated, thus recovering data space on devices, for example, and reducing the overall cost of storage.

8.0 THE FINAL APPROACH

8.1 UPGRADE THE SOFTWARE

The installation was also looking to install VM/SP to support a development virtual machine and an 'E' model double capacity disk. The need to issue cache commands was another reason to do so. Although VM/SP non-HPO also does not support cache commands, it introduced a means to get around CCW validation. Non-HPO VM/SP was selected because of its low cost relative to the HPO version.

A program was created to parse input from a console and issue the new channel commands to the controller. The intention was to closely simulate the function that IDCAMS performs when it controls cache under MVS/SP and VM/SP HPO. The program development was not as timely as the implementation of the cache controller itself; however, costs were minimal.

Immediately the two problems were solved, controlling and managing the devices on the string, and collecting statistics on the operation of the cache.

9.0 SUMMARY

Management succeeded in addressing all of the issues that were originally defined. The dissatisfaction of the users subsided with the reduction of the terminal response time. The service level improved to a point that it facilitated enhanced productivity and was acceptable. Maintenance of the service level was enhanced by the development of a program to support the solution, providing the capability to plan and monitor demand. Staff resources required in the implementation were minimal, and finally the costs involved were held to a predictable and reasonable level.

Overall, the implementation was highly successful and provides a model for other installations in the same hostile software or hostile user environment. The experience was informative in understanding the operation of cache, and how advances in technology can continue to lend solutions to better business and increase productivity.

10.0 ACKNOWLEDGEMENTS

Special thanks are due to Jeff Perkins who assisted greatly in the development and implementation of the cache program under VM. Thanks are offered also to all the technical staff who worked hard to conduct the experiment, and to John Temperly who assisted greatly in the editing of this paper.

LASER OPTICAL DOCUMENT MANAGEMENT SYSTEMS AND THEIR CAPACITY PLANNING IMPLICATIONS

David E. Y. Sarna
International Systems Services Company
New York, NY

ABSTRACT

Laser optical imaging has emerged from the laboratory and is being productively used in a growing number of commercial sites. Scanning of images and their subsequent storage and retrieval from laser optical disk subsystems presents opportunities for revolutionizing document processing. At the same time, it poses challenging problems in capacity management, requiring new metrics and instrumentation, while also drawing on the profession's accumulated experience in hierarchical storage management.

This paper will present an introduction to these devices, their performance considerations, and related cost metrics, and will report on our experience with several pilot installations.

INTRODUCTION

A subscriber calls an insurance company. He asks the status of a claim. The customer service representative asks the subscriber for a name, and date of birth. Within seconds the service representative has the entire file available, and tells the subscriber that his claim was received yesterday, but that he did not sign his claim form. A facsimile of his form was mailed out yesterday evening for him to sign and return.

Too expensive? Impractical? A revolution going on right now in document processing is expected by many to have a more profound effect on American business than even the personal computer revolution which took place at the beginning of this decade.

The mail arrives. Automatic equipment opens it, and removes and batches tax return documents. Documents of all shapes and sizes are carried by a moving belt. As they reach a scanning head, forced air holds them flat, and they are scanned on both sides. Some of the returns have been typed or prepared by computer. The image of these forms will be sent automatically to intelligent optical character recognition equipment, which will read and extract the text where possible. The returns and supporting documentation data will be compressed and then stored on an optical laser disk. After completing any additional data entry, an expert system will review the documents' extracted text, and if there are any questions it will send the file electronically to a tax examiner. If a return is incomplete or rejected, a letter will be generated to the taxpayer together with a facsimile of his return with the incorrect or missing data clearly highlighted on the facsimile. It will be possible for authorized personnel to review the entire file, without ever touching or routing paper.

The technologies that make these scenarios possible and cost effective are:

- High-speed optical scanners,
- Intelligent optical character recognition equipment,
- Laser optical disk storage and juke box device handlers,
- Image compression hardware/software,
- Laser printers,
- High-resolution display stations,
- Fast PC-based workstations, and
- Expert systems software.

What is another example of a potential use for this technology?

An ambulance driver wheels a patient into an emergency room. An orderly keys in a name and date of birth. Within seconds, an electronic version of the patient's file, showing his two previous admissions, is available. The patient's allergy to a particular drug is immediately noted, and his vital signs can be automatically compared to his past history; charts, electrocardiograms, etc. can be added to the electronic file throughout the patient's stay.

How can all of the hospital's patient files be economically kept for retrieval quickly without prohibitive cost? A single removable laser optical disk has space for about 50,000 documents. But a single juke box can hold several hundred disks "near on-line". Like the old fashioned juke boxes, a "near on-line" pack can be picked and mounted in a matter of seconds. Any of ten million documents can be retrieved quickly from a single jukebox, and multiple jukeboxes may be controlled by a single system.

The foregoing are but a few of thousands of potential applications of the advanced usage of intelligent workstations. There are five key features of this type of application which represent a major advance over earlier optical disk-based archival storage and retrieval systems:

- Full *integration* of the process with conventional mainframe-based application systems,
- Use of embedded *expert systems* techniques, where appropriate,
- Use of integrated *optical character recognition* techniques, as appropriate,
- Processing based around *industry-standard hardware and software*, and
- Tailored *application systems* capabilities based on in-depth industry expertise.

Technical factors have emerged, which – in combination – have the potential for dramatically increasing the capabilities of intelligent workstations. Among these are:

- Mini/micro computer price performance has improved dramatically,
- Optical scanners have improved in both speed and accuracy,
- Optical laser disk storage has become practical for mass storage,

- Local Area Networks (LANs) have improved minicomputer, microcomputer, and mainframe computer inter- and intra-connectivity, and
- Expert systems techniques have found their way into practical business applications.

An illustrative example of the integration of these technologies in an advanced scanning, editing, and computer-assisted retrieval application is shown as Exhibit 1.

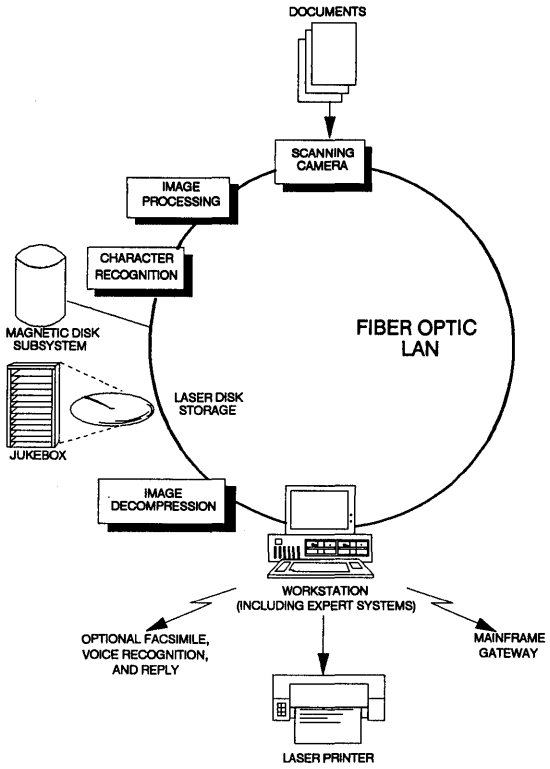

Exhibit 1. Document Management Systems.

Many believe that laser optical technology will, by 1990, have a more profound effect on society than even the advent of the personal computer in the 1980s, and according to Rothschild Consultants, will result in a $5.8 billion market.

Laser optical systems,when fully integrated with information processing, hold promise for finally eliminating the duality which has plagued the information processing industry since its inception. Everywhere we find high-speed electronic systems for retrieving and processing a subset of an organization's information needs. In parallel, each organization maintains a totally separate and manual system for processing, filing, and retrieving paper-based documents. Although computer-aided microform retrieval systems have been on the market for a number of years, they have never been fully integrated and have had limited impact. Enter Document Management Systems. Advances in the technologies discussed above have, in combination, made possible cost-effective and technologically feasible automated Document Systems. Feasibility analysis of these systems has begun in many organizations. In particular, traditionally large users of microfilm (e.g., in the financial, insurance, and banking industries as well as in the public sector) have been experimenting with this technology in pilot programs for the last several years. Within the next twelve months we can expect to see several large-scale implementations come on-line, with additional systems being implemented at an accelerated pace over the next several years.

Automated Document Management Systems require an understanding of several new technologies, and present a number of novel capacity planning problems. This paper provides an overview of each technology from the points of view of the capacity planner, performance engineer, and systems architect, and suggests key issues which must be addressed in order to build a successful system.

SYSTEMS OVERVIEW

The typical system shown in Exhibit 1 shows all of the technologies in concert. From the end-user's point of view, the key difference between this approach and the classical terminal is apparent in the delivery vehicle, which is usually a PC-based workstation connected to a high-resolution screen suitable for displaying documents. Workstations are linked via an optical local area network. Files are stored on laser optical disks contained in automated juke boxes. Documents typically enter the system directly from the mail-room, where images are captured on high-speed optical scanners. Intelligent optical character recognition processors can be used to extract text from the scanned images. Expert systems are in use throughout the process to reduce the need for manual or special processing, and to increase accuracy. Laser printers provide facsimiles of images wherever a "hard copy" is required. Each of these technologies is discussed in more detail in the sections which follow.

SCANNERS

Documents typically enter the system by being scanned, through a process known as "image lift." A wide variety of scanners are available ranging from desktop systems costing under a thousand dollars, to high-speed, heavy duty units costing upwards of seventy-five thousand dollars. In selecting a unit, there are several issues to keep in mind:

- resolution,
- compression,
- grey scale,
- slew rate,
- feed mechanism,
- face and size of image lift,
- duty cycle, and
- overall capacity.

Resolution

A scanner basically transforms images to bit patterns. In general, the greater the number of dots used to represent an image, the more faithful the resolution. Typically, resolution is expressed in dots per inch (dpi), and typical scanning resolutions are 400, 300, 150, 100, and 75 dpi. Most scanners are capable of scanning at multiple resolutions, under program control. Quality typesetting is usually accomplished at a resolution of at least 1,200 dpi; today's laser printers generally have a maximum resolution of 300 dpi, with 600 dpi units just emerging. Why not always scan at the highest resolution possible? The answer lies in the size of the bit-mapped image which is generated. An 8-1/2 X 11 inch document has 93.5 square inches. A resolution of 400 dpi, therefore, requires 160,000 bits per square inch, or nearly 15 million bits (nearly 2 megabytes) per page. On the other hand, at 75 dpi the same document requires only 64 Kbytes. While the tradeoff of resolution and memory must obviously be evaluated for each application, typical systems capture images at 150-300 dpi.

Compression

Most scanners format the images in accordance with the standards for facsimile transmission, with the most prevalent being the CCITT standards for group 3 and group 4 transmission. These standards provide for a means of bit compression, taking advantage of the fact that if much of a document is white space (at least 70% in most instances) then rather than recording each picture element as a binary zero if white and a binary one if black, it is possible to record only state changes from black to white, and the distance between one state and the next. Such compression techniques, particularly for higher scanning resolutions, can frequently achieve reductions of between 10:1 and 20:1, depending on the amount of white space on the page, and the compression technique used. The group 4 algorithm, while usually more effective, is substantially more complex.

Hardware compression boards for PCs are available, based on the AMD chip, but they are still expensive, costing about $1,500. These perform compression and decompression in about one second or less. Software compression algorithms which we have tested have varied in speed from 28 seconds or more to as little as three seconds on an 8 MHz IBM PC-AT, based on the effectiveness of the implementation technique.

Grey Scale

Line drawings and text are represented as either black or white, while pictures obviously need to be presented in shades of grey. Using a process known as half-toning, which is the method used to present pictures in most forms of printing, several scanners are available which can preserve a grey scale, using either 16 or 64 shades of grey. Of course, the greater the number of shades of grey the greater the number of transitions between black and white, and the less the image can be compressed.

Slew Rate

In some scanners, the document is held in a fixed position while the scanning head moves over the paper, a line at a time. In others, the scanning head is stationary and a transport mechanism carries the document. The rate of travel is known as the slew rate and is typically measured in inches per second. It is one element in the calculation of throughput per hour, and is typically in the range of 1-6 inches per second.

Feed Mechanism

Inexpensive scanners may be completely manually fed. More expensive units are automatically fed with a feed capacity of 20- 50 documents. High-speed, heavy duty units often have a vacuum (suction) feed, and are thus less subject to misalignment. They may also have high-capacity feeders and hoppers. The highest capacity, highest cost units use a continuous feed process.

Face and Size of Image Lift

Scanners have either single- or dual-sided image lift capabilities. Dual image lift may be considered even in applications not requiring storage of the second side, so that the problem of upside down feed is eliminated. Most scanners have a capacity of documents up to legal size; larger units can accept 11 x 17 or even larger D-sized engineering drawings.

Duty Cycle

The number of documents per month determines the duty cycle. Light duty machines may scan rather quickly (e.g., 3 seconds or less per document) but may only be rated at 20,000 documents per month, implying aggregate use of under twenty hours per month. Heavy duty units will be capable of sustained round-the-clock operation.

Overall Capacity

The capacity of a unit in documents per hour is, of course, a function of document length, slew rate, start and stop times (feed times), and unoverlapped compression time (including the time for transmission of the uncompressed image to the host processor), and may be expressed as:

$$\text{CAPACITY DOC/HR} = 3600/\left(\frac{\text{document length}}{\text{slew rate}} + \text{start and stop times} + \text{unoverlapped compression times}\right)$$

The arrival rate in documents per day divided by the number of hours effectively available for scanning divided by the scanner's capacity per hour provides the number of scanners required. To provide a reserve for peak conditions, a 60% utilization factor is typically applied. The number of units required can be given as:

No. of UNITS = (Documents per day/scanner hours per day/capacity * Utilization Factor)

In addition, backup capacity should be considered, since an entire processing operation may be shut down if documents cannot enter the system.

Scanners today are typically attached to host processors using a SCSI interface, and the documents can therefore be transmitted to the host processor at a rate of 10 megabytes per second. In most cases, the uncompressed image is sent to the host processor which then sends the image to the compression hardware, if available. In some cases, the compression hardware is built directly into the scanner.

OPTICAL CHARACTER RECOGNITION PROCESSORS

Many documents are prepared which contain printed,typewritten, or computer printed text. These can be reliably interpreted by optical character recognition (OCR) processors, which may be contained either within a scanner's covers or as a separate peripheral.

Use of OCR Processors

The OCR processor accepts as input a scanned image, and produces as output ASCII representations for characters which were extracted from the image, together with an indication of uncertainty for characters which cannot be interpreted with confidence. Many OCR processors also append a bit-mapped image of the uncertain characters, for use in a subsequent "repair" or correction process. Under optimal conditions, a valid read rate of 98-99% can be achieved, significantly reducing data entry costs. Maximum benefit can be achieved if forms and manual procedures can be redesigned so that the machine's capabilities can be optimized. For example, unwanted text on the form can be printed in optical drop-out ink. A minimum rate of 85% is considered necessary for cost-effective use of this technology.

Capacity of OCR Processors

Commercially available OCR processors can extract text with throughput speeds in the range of 200-2,000 documents per hour. Thus, since the scanner speed may well exceed that of the OCR processor, more than one OCR processor may be required per scanner. Mid-range OCR processors now cost about $20-30,000 at the low end to more than $100,000, but prices are falling rapidly.

There is no standardized interface between OCR processors and host processors, but several units use medium-speed communications protocols, e.g., Ethernet, and in these cases document transmission time between host and OCR processor may be significant, and may reduce achieved throughput by 10% or more. Calculation of throughput rates for an OCR processor is best done using controlled benchmarks which are reflective of the quality of the material to be used in the proposed application.

LASER OPTICAL DISKS

Laser optical disk drives are now being shipped in commercial quantities from a variety of manufacturers. At the present time all commercial shipments are of the non-erasable variety known as WORMs (Write Once Read Many), although eraseable laser optical disks are expected to begin shipping within the next six months. In any event, for many document management systems, the lack of erasability is no impediment, as the need is primarily for an archival or permanent record.

Currently, WORMs are available in 12 inch, 8 inch, and 5-1/4 inch formats. One vendor also offers a 14 inch size. Their primary attractions are high capacity, removability, and low cost. The 5-1/4 inch WORMs currently have a capacity of 200 MB, 8 inch media can hold up to 1 GB, and 12 inch units are commercially available at up to 2.6 GB and have been announced with capacities of 3 GB per side. The 8 inch size has a very limited following and is not expected to prevail. Significant improvements in storage density are likely to be achieved over the next several years.

Exhibit 2 shows comparative cost data, and it is clear that WORMs provide the lowest available cost for directly accessible storage.

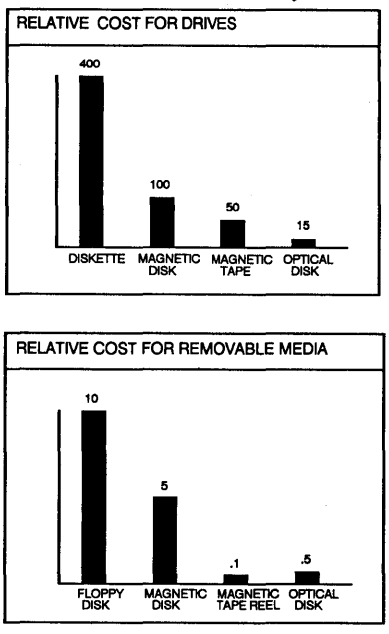

Exhibit 2.

WORMs have not yet achieved the performance of magnetic disks, owing to the greater time required to physically burn the binary representation using the laser, as well as greater settling and positioning times. Still, typical access times are in the range of .2 to 1.5 seconds. Data transfer is at this time almost universally accomplished over a SCSI interface running at 10 megabytes per second. However, more intelligent controllers, which can be directly channel-attached at speeds of 3 MB/s are reportedly on the drawing boards.

Assuming that an image is stored in compressed form at 20 Kbytes, a typical 1 GB WORM can store 50,000 non-erasable images. It is customary to use WORMs in conjunction with conventional magnetic media (disk drives) for staging and for storing indices. In some applications, file space may be preallocated, resulting in less than full utilization.

Early WORMs exhibited potential corrosion problems which led to projections of media life of under ten years; with today's reformulated compounds, manufacturers are currently quoting a 20-30 year life expectancy for data.

JUKEBOXES

Document management systems, with their relatively large record sizes (typically 20-50,000 bytes per image), can fill even 1 GB media in a short time, in high volume applications. Jukeboxes are an automatic mechanism for storing multiple platters (typically up to about 100) in a storage frame containing slots for each platter, in much the way trays are stacked in a cafeteria. Platters stored in the jukebox are known as "near on- line", and when a request is made to read a particular platter it is picked by a robotic arm, inserted into a drive, and made resident.

The control processor for a jukebox is typically a super- micro or mini-computer (e.g., a Sun workstation or a DEC VAX) with up to four jukeboxes under the control of a single control processor.

The retrieval times experienced for a "near on-line" pack is on the order of 10 seconds, while a resident pack may be accessed in about 200-500 MS. In addition to the robotic motion of 1-5 seconds, WORMs have spin-up, spin-down, and settling times of 4, 5, and 1.5 seconds respectively for twelve inch media, and 2, 3, and 5 seconds for 5-1/4" media. The steps required for configuration of jukeboxes will be familiar to capacity planners with mainframe experience. Essentially, we have an additional element in the memory hierarchy. After the number of platters has been determined, the ratio of resident drives to packs must be calculated based on access patterns. A typical strategy might be to configure a jukebox with four drives. Two might be made permanently resident, and used for storing new images, while two would be dedicated to servicing the near on-line packs in the jukebox. If a non- resident pack is requested (a 98% probability for randomly distributed inquiries based on 100 packs and two drives) then servicing the inquiry requires that one of the currently resident packs be removed and the new pack picked and made resident, a process which takes about 10-15 seconds. Ultimately, infrequently accessed packs will be stored totally off-line. Some implementations "copy over" a small number of still active files to an active disk before archiving the pack off-line, thus freeing up a juke box slot without a significant performance penalty.

PERFORMANCE IMPROVEMENT STRATEGIES

It is desirable to design a pack management strategy for a particular application which increases the probability of a request being serviceable from an already resident pack, since this pro-vides at least a twenty-to-one improvement in response time. In many applications, the probability of a retrieval request decreases with the age of the data. In one example for a claims processing system, it was determined that over 95% of the inquiries were for data under 90 days old. In such a scenario, it would be optimal to maintain sufficient resident capacity for data created in the last 90 days, even at the expense of not totally filling a jukebox to maximum physical capacity, thus ensuring that, in this case, 95% of the inquiries can be serviced with subsecond response time.

OPTICAL LOCAL AREA NETWORKS

We have noted before that even compressed images required 20-50 Kbytes each. Depending on the rate of image processing within the system, the capabilities of conventional local area networks (LANs) can be quickly outstripped. The best strategy is to draw the configuration and then determine the throughput rate (in images per second) which need to travel through the system. A network must then be constructed which can support this load.

Typically, the critical bottleneck is the jukebox control processor. Since each WORM drive can theoretically handle upwards of two images per second, and up to four drives can be installed in each jukebox, a four-jukebox system could be maximally processing 32 images per second, requiring a data rate of 1.6 megabytes per second.

A typical Ethernet, because of collisions and its small packet orientation (under 1,500 characters per packet), achieves a data rate of only 110,000 bytes per second in image-based applications, in our tests, even though it is nominally rated at 10 megabits/second. On the other hand, a token-ring, though nominally rated at only 6 megabits/second, can reportedly achieve a 60% utilization level (3.6 megabits/second) without excessive queueing delay. This rate is probably adequate for a single jukebox imple-mentation, but would present a bottleneck in our 4- box example.

Fortunately, fiber-optic local area networks have been introduced with nominal capacities of 80-110 megabits/second, which is more than adequate. Unfortunately, fiber optic LANs are still very expensive, priced at least five times the per-node cost of a typical conventional LAN ($1,000-$1,500 compared to $5,000 to $10,000). However, it is possible to intermix conventional and optical LAN technology in a network, using the broader band width only when required.

DISPLAY SCREENS

Designers of document management systems have benefitted from the desktop publishing revolution which has created tremendous demand for high-resolution, full-page display terminals. Display of an 8-1/2 by 11 inch document at 150 dpi resolution requires a display resolution of 1,275 dots per line and 1,650 lines, while 300 dpi would require 2,550 dots x 3,300 lines. At this writing, low cost (e.g., about $700) high-resolution displays are available at about 100 dpi, with 150-300 dpi displays expected to become available at moderate cost within the next twelve months. However, the memory required to support these high resolution displays will limit their use until operating systems become available which support the large memory spaces technically possible with the newer microprocessors (e.g., Intel 80386). In the meantime, 100 dpi is likely to remain the standard for page display. Optional software- or hardware-supported zooming features capable of showing a magnified portion of an image at a more readable 300 dpi are generally provided to overcome this limitation.

LASER PRINTERS

Typical laser printers can produce images at 300 dpi, although because of memory limitations some printers can image only half a page at maximum resolution. A point sometimes overlooked is that laser printers often communicate at 9.6 Kbs or 19.2 Kbs, which means that nearly ten seconds can be required just to transmit a full range image to the printer. However, special hardware boards are available which allow the laser printer to directly access the image in the microcomputer's memory, thus eliminating this bottleneck. Laser printers operating at speeds of up to 30 pages per minute are available, but the cost rises sharply above ten pages per minute. In addition, higher resolution (up to 600 dpi) printers are now becoming available. Duty cycles for laser printers must be carefully considered, since many are limited to 20,000 documents per month.

EXPERT SYSTEMS

Expert systems have many roles within document management systems. They are especially useful in the data validation phase. A general discussion of expert systems is, of course, beyond the scope of this paper. However, in sizing the work station, possible use of expert systems should be allowed for, suggesting the need for more powerful processors, additional memory, and a hard disk capability. It is also possible to maintain the expert system capabilities on a mainframe, but in many cases the required functions can be provided less expensively at the workstation.

SUMMARY

Optical technology, while posing new challenges for the capacity planner, builds on all of the accumulated experience gained in the last decade for mainframe capacity planning. As the volume of document management systems grows, we can expect a demand for more automated data gathering and modeling tools, but for now this is still a pencil and paper effort.

MAGNETIC CARTRIDGE TAPE CONFIGURATION MANAGEMENT

Anthony R. Guerrero
National Advanced Systems

ABSTRACT

If an organization decides to install a Magnetic Cartridge Tape Subsystem (MCTS), there are various aspects to consider in developing a good configuration and migration plan.

This paper explores the performance characteristics and capacity management needed to integrate this new subsystem into a computer complex. It also discusses tools and methods to assist installations in understanding their configuration needs and translating them into Magnetic Cartridge Tape units.

Other aspects are discussed, such as magazine loader use, productivity, operations, and Service Level management.

1.0. INTRODUCTION

This subsystem is the answer to the needs of today's Data Processing business. This new hardware architecture is a departure from the technology that uses 10.5 inch reels. It incorporates new features that have been needed to make magnetic tape a better price performer, but that were previously impossible to implement due to architectural restrictions. The architecture provides higher data transfer rates, datacompression/de- compression done through hardware, buffer/data management, and a much better media vehicle, chromium oxide tape, enclosed in a square cartridge.

Note: Refer to section 6.0 for a description of the hardware components.

Planning the installation of an MCTS requires a good understanding of the architectural implementation of the hardware functions and how they interface with other portions of the complex. In addition, the installation plan requires a working knowledge of the applications that will use the hardware. Completing the plan must include considerations in the use of Service Levels to better measure how well the equipment performs.

2.0 SUBSYSTEM OPERATION

There are some very important differences in the way in which the MCTS functions in comparison to the previous tape subsystem technology.

2.1 SUBSYSTEM FUNCTIONS

The control unit contains four megabytes of storage area which is shared by all drives. This area temporarily stores the read and write data as it goes to and from the processor to which the control unit is attached. The control unit architecture alleviates the effects of the tape mechanical motion by having the ability to disconnect from the channel while attempting to process a given request. In this manner, the MCTS is capable of reading or writing several blocks of data or servicing several requests, all in one tape motion cycle.

With such buffered storage, the control unit processes data in an overlapped fashion. That is, it is capable of transferring data from the buffer to the channel while it is transferring data from the buffer to a drive unit.

Tape buffering should not be confused with tape caching. The function of tape buffering, in the 10.5 inch reel technology, is to improve channel utilization by providing a means of balancing the faster channel speed with the slower tape storage device. On the other hand, in the cartridge tape technology, tape caching is the "intelligent" management of I/O operations and the transfer of data to and from the host to each individual magnetic cartridge tape. That "intelligence" also provides error recovery capabilities that are superior to the software initiated recoveries provided in the 10.5 inch reel technology.

The Subsystem functions in a Block Multiplexor Channel similar to the mode of operation for a DASD control unit. When the previous tape technology control units perform a function in behalf of a processor request, there is no disconnection until the tape drive sends a status on the completion of the request. This is the result of not having buffer and buffer management capabilities in the control unit.

With the introduction of buffer management, the control unit has the ability to disconnect from the channel immediately after the data has been transferred from the channel. And, by improving the control unit and tape drive speed for data transfer, the data exchange is no longer bound by the limitations of the control unit or tape drive, but by the speed of the channel.

2.2. SYSTEM ALLOCATION

The Subsystem can be attached to more than one Central Processing Unit. It may be "configured" through the VARY command, which assigns and unassigns the number of drives in the configuration for each processor.

While earlier tape subsystems obtained drive assignment through operator intervention (a mixture of software commands and manually thrown switches), manual switches are not used in this hardware. This is because of the large number of switches that would be required to accommodate all the possible combinations from eight tape units, one control unit and four channels, to the possibility of sixteen tape units, two control units, and eight channels (Dual Controller Coupler option).

2.3. SIMULTANEOUS DRIVE OPERATIONS

The architecture of the subsystem permits the overlap of operations. In other words, the control unit can transfer data from one drive to the processor while it sends data to another drive from the processor.

2.4. DRIVE MAINTENANCE

The required drive cleaning has been drastically reduced due to the enclosed nature of the hardware. The recommended drive cleaning schedule for an environment with low tape utilization is one time per week. This will help productivity when it is done on "scheduled time" rather than when it is actually needed.

When tape drive activity is heavier than anticipated, and cleaning is required before scheduled time, the hardware will display a "CLEAN" message. This signifies that the cleaning cartridge must be inserted in the drive to remove the

accumulations from the Read/Write assembly, and will be displayed after a drive has processed at least 50 cartridges. The tape drive cleaning cartridge contains non-abrasive material which removes the residue deposited by cartridge activity.

3.0. CONFIGURING THE SUBSYSTEM

Data centers have often planned and installed excess configuration when using previous technologies. This is due partly to the difficulties related to architecture, reliability, performance and capacity limitations that the hardware had to offer. In addition, the priority focus on growth management has always been on DASD. Magnetic tape cartridge technology has increased the need to develop a consistent methodology for configuration and growth management regarding tape drive units.

To properly configure each subsystem string with an adequate number of tape drive units, the number of concurrently active drives needs to be established. It is possible that with multiple active drives the effective data rate can decrease. This situation is created by sporadic interruption in drive data streaming, buffer management overhead, or as you add drives, an increase in buffer management and data transfer activity. It is also important to remember that when a drive is not transferring data, but still active (rewind, forwarding, etc.), the control unit cannot transfer any data until that particular activity finishes.

The maximum string configuration for concurrent drive operations is 4 drives units, or up to eight drives per subsystem. But, a general guideline cannot represent sound business, unless it bridges the need to maintain an acceptable high level of service. For a dual coupler MCTS, the above still holds true except that the dual coupler will be capable of doing buffer and I/O path load balancing. This is especially important when configurations are not properly balanced in terms of the number of drive units attached to each control unit (i.e. four drive units in one string and two drive units in the other).

3.1. THE CONFIGURATION TOOL

The first step in determining what the configuration for the new subsystem should be is to analyze the SMF data for the system to which the tape subsystem will be attached. This analysis can be done by time periods, and at least, for each hour within a shift. This will give a better understanding of the real utilization of a present tape drive configuration.

Furthermore, the installation needs to identify the maximum number of concurrent drives required at a given time. This can also be extracted from SMF and confirmed through system log by the messages issued by the operating system whenever a mount cannot be satisfied due to unavailable drives .

The analysis has to represent the view of the installation regarding Service Levels policies. The data must represent the number of tape mounts to be satisfied (per hour, per shift, etc) in conjunction with the tape usage and identified in hours (or percentage) for the same period.

The data relates to:

- Single volume tape datasets
- Number of records per dataset
- Format, record and block sizes
- Number of drives allocated
- control unit busy
- Tape drive unit busy
- Number of scratch tapes used

The data is found in SMF records type four, five, fourteen, fifteen, thirty and seventy-four. Algorithms are provided to determine the recommended number of drives, cartridges and magazine loaders for a specific environment.

The tool is composed of two phases. The first phase extracts the necessary data to be sent to a personal computer from the SMF records. In this phase, there is also a description of the present physical configuration of tape subsystem(s). It includes pathing data for each tape drive and control unit that are part of a subsystem. This phase executes as a batch job in a host CPU. Its data reporting/extracting capabilities are for time periods or specific jobs. It is also capable of extracting data by shift or work day.

The second phase, which runs in an IBM-compatible personal computer, produces the subsystem, cartridges, and magazine requirements for a particular installation. The presentation function produces reports and graphic output. There are also performance and modeling capabilities to permit further analysis of the proposed configuration.

The entire process should take no more than two hours of a person's time.

4.0. SUBSYSTEM PERFORMANCE

It is very important to have a plan in place to monitor the performance of the subsystem. One of the key areas to monitor is utilization.

4.1. SUBSYSTEM UTILIZATION

An important item to gauge is the ratio of logical control unit disconnect to connect time. To look at percent of channel busy could be misleading, since most of the subsystem disconnect time is spent in the channel, waiting for data transfer to complete from another drive unit. Consequently, when the time spent in transferring data (connect time) is exceeded by the time spent waiting for the control unit to become free, the need to add new data paths becomes important. Situations like buffer-full conditions would reflect here as part of the disconnected time of an I/O operation. However, since the subsystem will be used by batch jobs in the majority of the time, this situation needs to be evaluated in the light of how important it is that the work be completed within a given time window.

5.0. SUBSYSTEM SERVICE LEVELS

Service Level management is the methodology that provides a vechicle for users to communicate their needs to the Management Information Systems (MIS) organization. Also, it allows MIS to respond to those needs by setting objectives in various areas, such as, performance, availability, capacity, reliability, security, and accessibility.

The MTCS poses a new requirement within the Service Levels methodologies. With the advent of Systems Managed Storage to Data Processing, the approach of Logical Service Level management requires a unique view of every cartridge volume and its data content.

5.1. LOGICAL SERVICE LEVELS

Logical service levels define the performance, and availability objectives for a given application.

Those tape cartridges which contain the files for an application must be part of a Logical Service Level agreement. There can be one agreement per application which may contain multiple volumes.

Since a volume can be used by multiple applications, there can be multiple logical service level agreements for a given volume.

Most applications require that their data be readily available and accessible when needed--thus, the basis of a Logical Service agreement per application. Each agreement must contain one or all of the three elements that cartridge tapes should "live" by: availability, accessibility, and reliability

5.1.1. **Availability and Accesibility.** Although there can be many ways to implement this measurement, the most important choices are based on: a) the amount of time it takes to process a mount request. (This would include the amount of available drives at a given scheduled time.); and, b) how long it would take to get a new copy if a dataset or volume had to be recovered.

5.1.2. **Reliability.** In this category, it is important to understand that the user is dependent on the technical input from Data Processing. However, this is a management gauge to determine how well the maintenance procedures and media quality control methods are working. Some of the items in this category are: a) errors per processing run b) permanent errors per volume per run c) number of abends and reruns caused by I/O errors atributable to tape maintenance or media quality

6.0. SUBSYSTEM DESCRIPTION

This subsystem is the product of the technological advances made in the last twenty years. Its design incorporates the needs of the DP community and the knowledge gained from Large Systems in the last ten years.

6.1. THE CONTROL UNIT

There is one control unit for the Magnetic Tape Cartridge Subsystem. Its standard features are one channel interface and a data rate of three megabytes. Options include six megabytes data transfer rate, data compression, and up to three additional channel switches. Additionally, another control unit with eight tape drives can be connected to the primary control unit.

Each subsystem can have up to eight drives (four drive units) attached to each control unit. When paired with another control unit, this number increases to sixteen drives (eight drive units).

6.2. THE DRIVE UNIT

The drive unit has two drive transports as a standard feature. Optionally, it can have an automatic cartridge magazine loader and an eight-cartridge magazine. The magazine is a productivity enhancement. Its rack mount design permits up to eight cartridges to be automatically fed into a tape drive.

A tape drive can rewind a cartridge tape in approximately forty-eight seconds. Its load/unload time is approximately seven seconds, plus an additional 1.5 seconds for insertion or extraction from the unit. It moves the tape at 78.7 inches/second (two meters/second).

Each tape unit contains a microprocessor which makes new functions available. While these functions are being performed, the drive is disconnected from the control unit, thus enabling its control unit to perform other functions in overlap.

A display panel on top of each tape drive is used by the hardware and the software for messages regarding volume activity, errors and drive maintenance.

6.3. THE TAPE CARTRIDGE

The tape cartridge can contain approximately 200 megabytes of data when written in 24k blocks. This data is stored in 18 tracks at a density of 38000 bytes/inches. The cartridge dimensions are approximately 4" x 5" x 1". Its size is approximately 75% smaller than a 2400" tape reel.

The cartridge is very simple to use. To load it, all the operator needs to do is insert it in the drive, and the tape will be threaded automatically.

It is not necessary to place reflective markers at the beginning or the end of the tape. This need is eliminated because the drive, in itself, determines the beginning or the end of the tape. Since the tape is enclosed within the cartridge, it provides increased protection from physical damage and other environmental factors. The mechanism for file protection is a "thumb wheel" selector which is integrated in the cartridge.

7.0. SUMMARY

This subsystem presents new technological features that will ease tape management requirements and maintenance. At the same time, it presents some options that will increase people productivity at the operational level. The real challenges still reside in the capacity planning and performance management, where there is some work to be done.

END-USER PERFORMANCE MEASUREMENT: AN AUTOMATED PC APPROACH

Gerri K. Martin Flickinger
Chevron Corporation

ABSTRACT

Measuring true end-user response time in complex networks has been difficult in the past. One possible solution uses a PC to emulate user activities to gather response and availability measurements. The merits of this measurement method and how it compares to other network performance measurement tools, will be discussed. Chevron's experience with a PC-based system (benefits, installation, automation) at many sites within a large IBM SNA network will be shared.

1. BACKGROUND: END-USER MEASUREMENT

Past attempts to measure end-user response time and availability have proven difficult. True end-user measurements are extremely useful for service level agreements and performance analysis, however, such measurements can be expensive and technically complex. Following is a discussion of the motivation for end-user measurements and measurement techniques currently available.

Motivation for end-user measurements may come from several sources. There are user concerns that availability and response experienced at their sites' differ from that reported at the central data center. In addition, there are concerns that benchmarks run in the host environment are not comparable to end-to-end service levels. This leads to the concern that service level agreements do not sufficiently account for variation in user location. Finally, Performance Analysts often find they lack accurate information on the impact of hardware and software changes to the end-user.

There are several methods of capturing end-user response information. Some methods use VTAM definite response produced for some applications while others monitor traffic across a certain network component.

If a measurement is taken at the host, a message can be time stamped when it enters the system, time stamped when it is outbound after processing and time stamped when the definite response returns from the control unit as requested by VTAM. This method provides both host and network response time information. Many applications, however, do not use definite response so this measurement technique is not available for these. Examples of products that perform this type of measurement are NPM [1] and MAZDAMON [2]. (See Figure 1.)

If a measurement is recorded at the control unit level, a time stamp is taken when the message is inbound (to the host) and when the response is returned to the control unit from the host. This method only gathers end-to-end response time as far as the control unit. This method is not transaction-oriented, therefore the host response may not be at the logical completion of the applications transmission. Furthermore, there is significant host overhead involved in collecting all the response information from the control units. An example of this type of product is RTM [3]. (See Figure 1.)

Another method is to use a hardware device directly attached to a user terminal that records all terminal traffic. One problem with this method is that the user must make an effort to upload or send the data to a central site for processing. Furthermore, if the user is not busy, the device will not be collecting data even if other users on the control unit are working. An example of this type of device is a TEMPO monitor [4]. (See Figure 1.)

Other methods include hardware monitors on various network components (e.g. RTA [5]) or user questionnaires. Many of these methods are difficult to maintain, only capture a portion of the end-user response measurement or are subjective in nature.

Most of above methods have a major shortcoming; the measurement of availability. Measurements based on definite response or terminal monitors require that user work is being done. Not only does this require that a user is active, it also requires that all network components (e.g. control unit, NCPs, etc.) are available. Since availability is a critical component of end-user performance, these methods do not satisfy the entire requirement.

Another concern with these methods is their level of complexity. Generally a Senior Analyst is required to install and maintain such products. There are dependencies upon host and network internals. Since the data is not transaction oriented, its interpretation is frequently complex. Furthermore, these methods can be very CPU intensive and expensive to purchase and maintain.

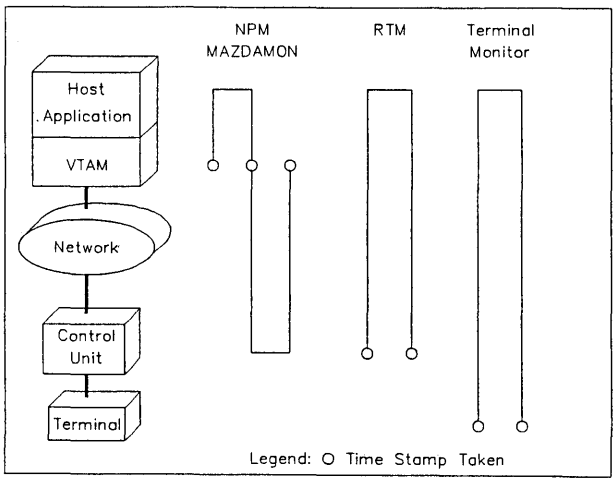

Figure 1. Measuring End-User Performance

2. PC-BASED USER EMULATION APPROACH

An alternate approach is to use a PC that emulates a user. The PC logs on to user applications, performs user-type functions and measures response and availability. Since the PC is independent of the host, network and users, it can reliably record outages as well as response times.

One major advantage of this solution is the increased degree of flexibility. A single PC can test access to several different hosts and applications without regard to the internals of the systems. This is extremely important when determining the delay caused by different components of the network. For example, placing several PC monitors in carefully chosen end user locations, and testing access to a single host, will measure response time on several unique paths to the host. Extremely complex networks can be monitored efficiently because of the flexibility of access.

The PC solution is far simpler since it deals with an end-user viewpoint and does not require special software, hardware or specially coded applications in the host or network. Implementation of such a monitor and interpretation of the data collected does not require an in depth knowledge of host, network and application internals.

Since the PC is performing user-type work from a user perspective, it is transaction oriented. Since the transactions are chosen in advance, consistent benchmarks are available for site comparisons. By placing several PC monitors at key locations in the network, routing and cross-system delays can be approximated.

The PC can retain the data for a period of time and then upload to a host for analysis, thus running unattended and without human intervention. The host overhead associated with each PC is comparable to an additional user on the network. Because of the flexibility in choosing the specific transactions to be measured, the storage requirements and reporting effort needed for this method is far less than for other end-user monitoring methods.

There are several products available that provide a basis for PC user emulation monitors. These products generally provide a script language for specifying keystrokes and recognizing host responses. An example is PECOMON [6] which has a script language that consists of several look-up tables. Another product is MORTII (Monitor of Online Response Time) [7]. MORTII (later referred to as MORT) provides a high-level script language as well as additional features such as global recognition (e.g. if you EVER see a lightning bolt...) and flexible recording capabilities. MORT uses an IRMA 3278/79 emulation card [8] to communicate with the SNA network.

3. CASE STUDY

In response to Chevron's need for end-user measurements, and in light of the shortcomings of previously used methods, a test of MORT in a production environment was planned.

3.1 CHEVRON'S ENVIRONMENT

Chevron's environment under study consists of two major data centers located in the San Francisco area. These data centers support all of the corporate and marketing data processing for Chevron. There are 10 CPUs running 14 system images (MVS and VM) between the two centers. The CPUs consist of 2-IBM 3081s, 7-IBM 3084s and 1-IBM 3090-200. Chevron's SNA network includes approximately 20,000 terminals, and 30 IBM 3725 communications processors, and will soon include about 30 IBM 3708s.

Since numerous hardware and software components may be involved in a single transmission from a terminal to a host application (e.g. possibly several NCPs, CPUs, telephone lines, cross-domain MSNF, etc.), it is understandable that end-to-end response time and availability at a remote location may be quite different than at the central site. Furthermore, many locations perform different computational functions on different CPU complexes, making the establishment of a single benchmark difficult or impossible.

3.2 MORT INSTALLATION

In February of 1986, Chevron began a five month Pilot Project. During this time, MORT was installed at three sites in the San Francisco area and Chevron was able to:

- operate three sites 24 hours/7 days week without human intervention
- validate MORT data
- centralize data reporting
- automate update capabilities
- develop methods for communicating with MORTs directly from the central site
- write 20 different scripts tailored for various user functions and performance measurement requirements
- automate portions of our reporting mechanisms
- provide near real-time analysis facilities
- provide a way to receive "network time" (including VTAM) in addition to end-to-end time.
- develop a plan for PC management
- respond to security concerns

At the end of the Pilot Project, Chevron found that MORT could provide a basis for a powerful and reliable monitor system. Additional sites were recommended that would incorporate most of the remote NCP locations.

Today Chevron has 18 MORTs installed. Sixteen of the sites are considered "permanent". Two of the sites are "portable" and are moved to trouble spots in the network to help diagnose or verify problems.

The following section discusses several key components of the installation and design decisions explored.

3.3 RUNTIME ENVIRONMENT

MORT, PECOMON or any other script language simply provide a means for writing user scripts and not necessarily a complete response monitoring environment. The final monitoring environment at Chevron contained several software components in addition to MORT scripts. Each component is discussed below.

Many scripts were written to address various user applications and host benchmarks. For the VM environment, scripts were developed for PROFS, PL/1 compiles, NOMAD applications and trivial transactions. These scripts are representative of end-user work, such as the PROFS script which logs onto PROFS, writes a note, sends it, opens the mail, deletes notes and logs off. Scripts have also been developed for the MVS environment, specifically for IMS and CICS applications.

All scripts require coding of keystrokes for normal as well as abnormal sessions. The majority of programming time is spent in coding error recognition and recovery rather than normal session keystrokes. An average script is eight to ten pages, 90% of which is abnormal session recognition.

In the case of the MORT script language, the decision of what portion of the session to gather response information on is left up to the script programmer. At any point, timers may be turned on or off, and multiple (overlapping) timings are possible. An example of this is shown below in a section of a MORT PROFS script

```
on <R; T>,*,1   type <PROFS[ENTR>
                begin transaction <PROFS-BENCH-TOTAL>
                begin transaction <PROFS-BENCH-MENU>

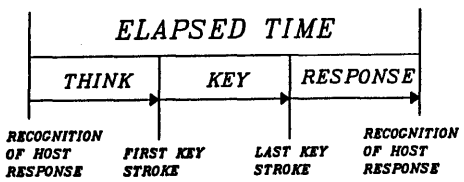
** when we see main menu stop the MENU timer

on <A00>,1,78   clear transaction <PROFS-BENCH-MENU>
                type <[PF4>
                      :
                      :
** perform all PROFs work indicated and then exit
** PROFS and stop TOTAL timer when we are in CMS

on <A00>,1,78   type <[PF12>
on <R; T>1,78   clear transaction <PROFS-BENCH-TOTAL>
```

There are two timers in the above example: PROFS-BENCH-TOTAL and PROFS-BENCH-MENU. When the data file from this script is written out, there will be 1 record for each timer and each record will include an end-to-end response time for the portion of the session timed.

One comment should be made about end-to-end times gathered by MORT. MORT is very careful not to include his own time to type keys or execute script statements into the response time. MORT timings are subdivided as follows:



For the purposes of end-user response measurements, we are only concerned with response time as shown in the diagram above.

A fundamental requirement for a 24 hour, stand alone monitor, is the ability to upload data to a central site. MORT provides an upload facility, although it is extremely slow. A different approach is to use the standard SEND function provided with the IRMA emulator.

Another requirement is to be able to run different scripts at different times of the day and different days of the week.

A reasonable solution that addresses both of the above requirements is to code an EXEC on the MORT PC that is responsible for executing the various MORT scripts at the appropriate times and issue the proper send command at certain intervals to perform uploads. The EXEC (later referred to as the shell) also provides a nice framework for invoking different scripts from different sites rather than writing one large script, with multiple system tests, for each site. Specifically, the shell invokes individual scripts (for example a PROFS script for a specific VM host, an IMS script to test a specific application,etc.) and each script is completely autonomous. Using the shell for overall control insures that the runtime environment is consistent for all sites even though completely different response measurements (scripts) may be taken. From the time the MORT PC is IPLed, the REXX shell is in constant control.

The PC EXEC language chosen for this implementation was Personal REXX [9] because of its power and similarity with REXX on VM.

In addition to end-to-end time, a method of measuring network and host time was desired. Although a PC-based monitor is not designed to gather these figures because of its simple-minded approach and physical location, there are ways to gather these values. One way to perform this for a VM transaction is to invoke the desired transaction through an EXEC that takes time stamps on entry and exit. For example:

```
/* Invoke a VM benchmark, for example       */
/* enter and exit XEDIT.                    */
/* Time this benchmark and print the result.*/

T=TIME('R')
PUSH QUIT
'XEDIT GARBAGE DATA (NOPROF'
SAY 'RESULT: 'TIME('E')
```

(Note that the choice of REXX over EXEC2 in the VM environment provides additional precision.) If the value from this EXEC is retrieved by MORT and recorded with the benchmark end-to-end timing, we can subtract the two values and receive an approximation of network time (including VTAM overhead).

Security was also a concern for each MORT PC and all the associated host IDs. Since the PCs contain scripts with confidential information (IDs, passwords, and procedures), each MORT PC is secured in a lock box that contains the system unit as well as keyboard thus preventing unauthorized access to the information. Unauthorized access of the IDs can be monitored by a MORT script itself. For example, when a script fails a logon because the id is already

active on another node (LU), the script retrieves the LU name from the screen and records it in the data file. A listing of all security breeches is produced daily as part of standard reporting.

A final, yet crucial, concern with any monitoring system is the cost. This includes the one time cost for equipment and software (see Appendix I) as well as runtime costs, disk space and manpower. Considerable cost analysis was performed before placing MORT in production. Following are some considerations:

Cycle Time: how often does each script need to run? The Chevron installation determined every 10 or 30 minutes, per script, per site, based on application.

Time of Day: what time of day (and day of week) do we need to test? This is based on scheduled application hours at Chevron.

Disk Space: what timings do we need? Remember each timing cuts a record. The Chevron installation found that individual transaction timings are generally not necessary, but rather timings for a set of transactions that make up a meaningful work unit (e.g. logon, order entry).

Manpower: how much manpower are you willing to spend? For each MORT site and each script there is manpower to monitor the MORT, diagnose problems, run reports and analyze data. The manpower required for the initial installation and ongoing support is critical to providing the most useful and effective MORT data. Because of this, sincere management support is crucial for such a project.

The PCs used for the MORT sites are IBM PCs with 640K of memory. Hard disks were added to all PCs to allow file space for multiple scripts (approximately 19K per script), the REXX shell (12K), additional software such as the MORT interpreter, IRMA Terminal Emulator, SEND, Privacy Plus and Personal REXX (approximately 470K) and data (approximately 13K per hour). There was no need to run the MORT monitors on any larger or more expensive machine. PC displays, although not necessary for the operation of MORT or any other software used, are included with the PCs for the analysis or trouble shooting of MORTs.

Although the Chevron Installation used VM IDs for data collection and reporting, the MVS environment would also provide the same flexibility.

3.4 MAINTENANCE AND SUPPORT

Immediately it was realized that with 20 unique scripts and 18 sites, (over 150 scripts total) maintenance needed to be automated. The solution was to write a series of programs that would modify scripts and generate new ones automatically. These programs were written' in Personal REXX and depended upon macros written for KEDIT [10] (the PC equivalent of XEDIT). These execs reside on a PC/AT located at the central site where MORT maintenance is performed. The entire set of routines is approximately 35K.

The first step to automating maintenance was to develop script templates for each application. These templates do not include system, id or password information. After these are in place, a program can be run that leads the user through script setup. The user specifies the desired MORT number (a unique site identifier) and desired system. A new script is generated using the template, the user site information and id lookup table. Following is one' of the menus generated by the setup routines.

```
---------- M O R T   S E T - U P ---------------
------- (property of Chevron Corp.) ------------
--------------------------------------------------
------------- MORT number: 01 -------------------
----- Directory for new files: C:\MORT\M01 -----
--------- Set-up type : new site ---------------

      The following are valid scripts:

VM       1.........PROFS benchmark
         2.........CASE benchmark
         3.........SCORE benchmark
         4.........VM short benchmark

CICS     5.........Credit Card benchmark

IMS      6.........COS Well Inquiry
         7.........CPS Bulk Order
         8.........CPS Marketing
         9.........CHEM Order Entry
        10.........CHEM Additive Order
        11.........CHEM Accounts Receivable

UPLOAD  12.........LOGON to upload account
        13.........LOGOFF to upload account

         0.........EXIT (no script set up)
```

After generating a script, the problem of how to get it to the remote site was raised. The first solution was to write the script to a floppy, mail it, wait for the site to receive it and wait for someone to load it onto the PC. A faster method is to send the update through a dial-up connection or the existing network to the remote PC. Both of these options were explored.

Dial-up access was attempted using Carbon Copy [11], a PC-based asynchronous communications package that allows one PC to take control of a remote PC to send files, etc. Unfortunately, Carbon Copy and Personal REXX both utilize the same interrupt vectors so they cannot run on a PC simultaneously. An additional concern with any dial-up access method is security. Furthermore, a modem is one more piece of equipment to purchase, maintain and troubleshoot.

The second alternative, sending files through the already existing network was developed. The new script is generated on a PC at the central site. It is uploaded to a VM host and sent to the upload (data accumulation) id of the destination MORT. When the MORT PC logs on to upload response data, an EXEC on the host receives files from the reader onto the host id. The shell on the MORT PC receives the updated script and compiles it. If a new shell is sent, the current shell receives it and loads the new shell into memory destroying itself. Any file can be sent using this method. The entire process is automatic from the time the upload is requested on the central site PC. (via a menu option)

An additional safeguard of encrypting all scripts is in place. Encryption is done at the

central site PC after the script is generated, and de-encryption is performed by the MORT PC at the remote site. Again, the entire process is automatic, and no human intervention is required. Privacy Plus [12], a PC-based encryption scheme, is used for this process.

3.5 DATA REPORTING

Data reporting on end-user response data as described above is primarily a post-analysis process. Based on cost analysis and the impact on the network of data transmission, MORT data is uploaded every 1/2 hour. This provides an opportunity for data analysis within a 1/2 hour of data gathering.

An EXEC runs on the VM host every 1/2 hour that checks data from all MORT sites. It scans the data for outages, high response times, abnormal situations or missing data. The EXEC produces a log summarizing these events and also sends messages to appropriate Performance Analysts for investigation of notable conditions (including maintaining MORTs operation). This method provides near real-time analysis (1/2 hour old data). Following are some examples of the type of warnings generated and sent to appropriate analysts. (See Example 2.)

On a daily basis, all MORT data is read into SAS datasets for consolidation and reporting. Daily online reports are available to all PROFS users an example of which is shown in Figure 2. In addition to the daily online reports, monthly reports for management are produced. These reports include trend analysis and discuss any unusual or interesting response characteristics of our network, hosts or applications.

A variety of data can be extracted from the MORT data gathered. Figures 3 - 6 contain examples of graphs and plots that illustrate the diversity of some of the data.

```
16:00 MORT 05  HIGH  Host Response, COVMA : 0.163017 at 15:32:06
16:00 MORT 07  HIGH  Host Response, COVMA : 0.153470 at 15:30:45
16:00 MORT 08  8 occurrences of No VTAM Banner since 15:30
16:00 MORT 11  HIGH End-to-End      CPVMB : 10.055 at 15:44:01
16:00 MORT 15 12 OUTAGE records, Chem/SFIMSP since 15:30
16:00 MORT 15  8 OUTAGE records, COS/SFIMSP since 15:30
16:00 MORT 16  NO DATA SINCE 9/3/87  14:34:29
```

Example 2. Near Real-Time Alerts

Figure 2. Daily Online MORT Reports

4. BENEFITS REALIZED

End-User measurement has some obvious benefits in isolating components that cause outages or degrade response. End-user emulation has provided a unique perspective into the performance of Chevron's host, network and applications. Following is a discussion of some benefits of end-user measurements that have been experienced at the Chevron Installation.

4.1 Technical Performance Analysis

MORT is surprisingly useful in testing new hardware (e.g. IBM 3090, 3174, channel extenders, LANs, etc.). As an example, during a period when channel extenders and 56KB line performance was being compared, MORT showed some very convincing response time figures in favor of the channel extenders.

A related use for MORT is in analyzing the impact of new software, on the end-user. Recently Chevron installed VM/VTAM on all their VM hosts (replacing VS1) and MORT data was used to verify that there was little user impact caused by the change in network software. Of course there are other sources for some of these measurements such as the use of TPNS [13], although such methods only simulate an end-user environment.

Another area MORT data has proven useful is network configuration. MORT data helped alert and isolate several performance problems in our network related to network configuration. One such occurrence was caused by unequal loads on multiple gateway NCPs, causing certain users (and MORTs) to experience very degraded response, while providing other users (and MORTs) excellent response. Once the loads were balanced, the response time for all users across the gateway stabilized an uniform level.

A similar problem occurred with NCP virtual route definitions that were set too low. Certain locations experienced long periods of unavailability when trying to cross this particular gateway. After the limit was modified, access across the gateway was no longer inhibited from any site. The data that MORT gathered, from its various network perspectives, has helped alert, verify and isolate this type of problem.

The routine tuning changes that are frequently made to improve system performance, can now be viewed from the end-user perspective. Performance Analysts, after making a system parameter change, often review MORT data to ensure that there has not been an unexpected impact on end-user performance.

Frequently, when responding to serious user complaints about response time or availability, MORT data is used to support the claim and help isolate the problem to a data center, host, application or network component.

Surprisingly, using a PC as a "perfect user" (i.e. the PC does not hit the wrong key) we have found some deficiencies in some of our applications. We have isolated several problems that were attributed to "user-key" error in the past. When MORT nodes were

traced, we were able to verify (from a host perspective) that the PC was sending the correct characters, and the problem was within the application.

Besides these technical and support uses for MORT data, we find that ordinary outages can be verified. Occasionally, the duration of an outage at the data center may be considerably different from that felt at remote sites. MORT data alerts us to procedural problems in recovering from outages at the central site; sometimes we inhibit remote users for longer than is necessary.

Utilizing the near real-time alert method described in Section 3.5, Performance or Operations Analysts can be notified of interesting or unusual data so that corrective action, if necessary, can be taken as quickly as possible.

4.2 Service Level Agreements / Capacity Planning

In our design of MORT scripts, we attempted to provide two fundamental classes of data:

BASELINE BENCHMARKS

- Benchmarks useful to Performance Analysts for network-wide evaluation.
- Benchmarks that are identical for all sites.
- Provide end-to-end, network and host time.

APPLICATION / USER-GROUP BENCHMARKS

- Benchmarks "meaningful" to users (i.e. user-type work, CICS and IMS applications, PROFS, etc.).
- Benchmarks that vary from site-to-site based on business function.
- Generally provide only end-to-end time.

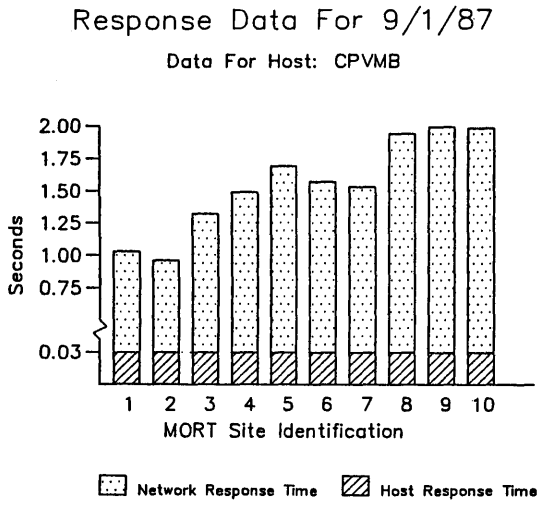

Figure 3. Host and Network Response Time

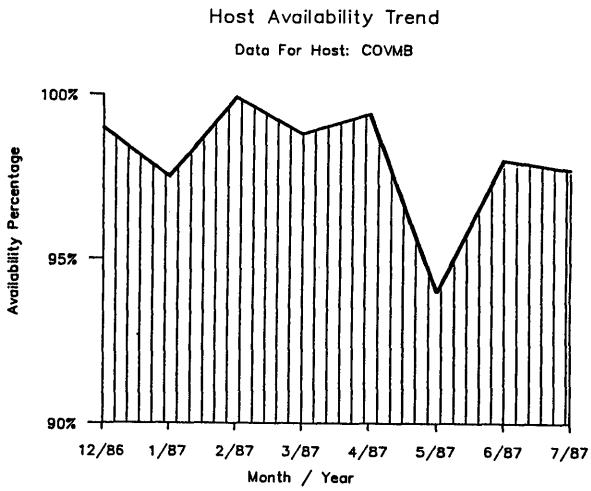

Figure 4. Availability Trends

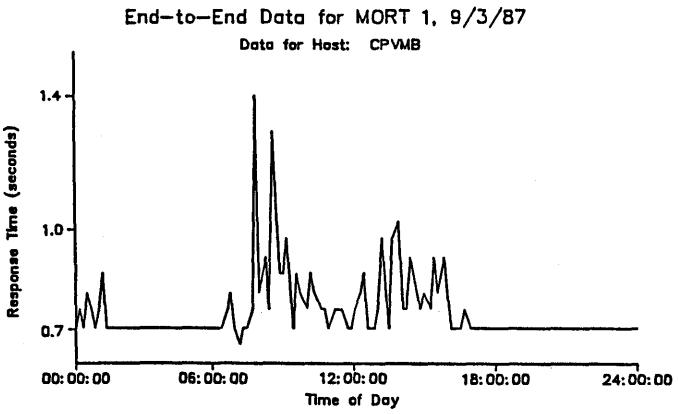

Figure 5. Daily End-to-End Response Curve

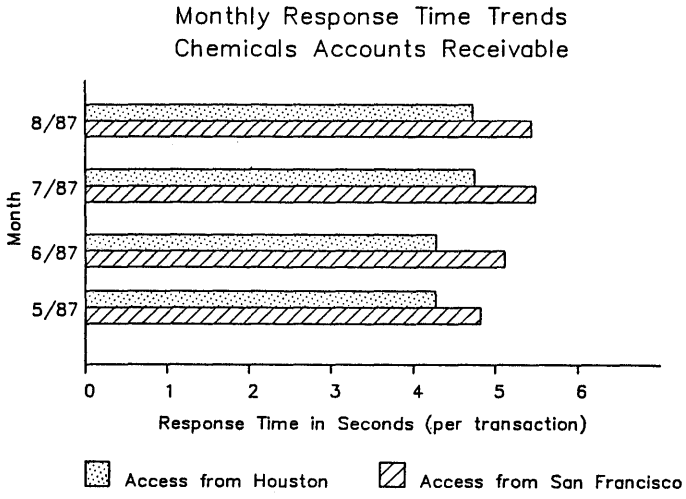

Figure 6. Application Response Time Trends

MORT is a unique tool that can help determine the current levels of service we are providing based on location and specific application as well as generalized service levels computed from baseline benchmarks (e.g. what is the impact on response time of 1 NCP? 2? etc.). Both of these measurements seem valuable for Service Level Agreements. It is important to have benchmark figures that management and users can equate to "real work" at their sites and it is also important to have benchmarks that provide comparisons between all sites. Both of these needs can be fulfilled with the type of scripts we have designed and implemented.

As the load on the network and hosts change, we can also view the impact on end-user performance. This can be very useful for capacity planning. Although products such as IBM's TPNS provide a host-based stress test for capacity planning, MORT provides a measurement of true end-user response time. The analysis of MORT data can be valuable in determining at what point increased capacity is needed based on end-user response and availability requirements.

5. CONCLUSION

MORT provides advantages that some other end-user measurement methods lack. Availability at the end-user location can be measured. MORT does not require a Senior Analyst with extensive knowledge of host, network or application internals, to be effective. MORT has very flexible measurement methods and a high-level script language. Overall, MORT provides a very straight forward solution to a historically difficult problem.

The Chevron installation provides a complete end-user response and availability monitoring environment. Concerns of script generation, data gathering, site maintenance, automated reporting, and trend analysis have been addressed. The entire system relies upon several software components including REXX, MORT, Privacy Plus, KEDIT, and REXX on VM. Several aspects of the maintenance and runtime environment have been automated including script generation, update distribution and near real-time alerts.

Placing PC monitors at key user locations can provide end-to-end response and availability data vital for technical performance analysis, service level agreements and capacity planning.

Overall, MORT has been very useful in analyzing the data processing services we are providing the end-user. No other monitor tool has been able to provide the same unique perspective into our network, host and application environment.

INCORPORATING DATA NETWORKS INTO A PERFORMANCE AND CAPACITY PLANNING STRUCTURE — A CASE STUDY

Hugh Smith and Dyna Wilson
CoreStates Financial Corporation

ABSTRACT

Given the growth in the number and importance of on-line applications, one can no longer afford to ignore the impact of data network performance and availability on end user service. Internal response times and host/application availabilities alone are not sufficient to identify or to predict performance problems in an on-line transaction environment. It is imperative that end user service levels include the impact of data network performance and availability.

A case study is presented in which data network issues are incorporated into an existing Performance and Capacity Planning structure. The environment consists of an on-line transaction volume of 1,350,000 transactions daily originating from more than 8000 terminals, ATM's and point-of-sale devices.

Central to the structuring of network issues is the recognition that two distinct areas must be addressed: Availability and Performance. Although each of these areas requires monitoring, reporting and planning functions, the responsibility for these functions may be best suited for different organizational elements within an institution. A methodology for the structuring of network performance and capacity planning is evolved based on the ongoing efforts of one institution.

WHO IS CORESTATES:

CoreStates Financial Corporation is currently the 36th largest bank holding company in the United States when measured in assets. However, we are in the top ten of the largest Visa issuers, international funds transfer banks, and check processors. We are the proprietors of MAC which is either the first, second, or third largest shared ATM network in the country, depending on which measure you prefer. We process over a million IMS transactions a day through three IMS systems. In addition, we do approximtely 250,000 TSO transactions each day and 100,000 CICS transactions a day. Our internal networks connect over 8000 devices spread over 4 continents to our Philadelphia systems center. The majority of the 8000 devices are located within a 150 mile radius of Philadelphia.

WHAT IS CAPACITY PLANNING:

It used to be that we could plan for increased capacity in our mainframes by adding a processor when we reached between 70 and 90 percent of the capacity in the system. Over the last several years, however, our mainframe applications have had very rapid, very large growth which has lead to an occasional short lead time to address a capacity issue. If we begin to exceed our capacity constraints, the result is that established businesses suffer increased response times or missed deadlines due to new businesses being brought on or existing businesses growing. We had such a situation at CoreStates about three and a half years ago. At that time we determined the way to stop this from happening was to split the responsibility for performance and availability. By availability I mean, "Is the machine up and running?" By performance I mean, "How fast is the machine running?" We not only must give our users dependable service, but we must also give them a level of service which allows them to be effective at their jobs.

PERFORMANCE VS AVAILABILITY:

In the three years since implementing this split in responsibilities, we have noted several things. We know that the people responsible for availability (technical services and data communications groups) usually know exactly what to do to make the machine run fast. They ordinarily have a good idea where the bottlenecks are and they know what they have to do to solve the bottlenecks. However, the availability people have two problems. First, they don't have the time. They are buried by the burden of day-to-day operations and the press of production problems. Other priorities are often seen as more important that capacity planning. Second, they typically have no inclination to do the detailed data collection and data analysis that is required to study the problem.

Performance management at CoreStates consists of two fundamental activities. First, we create "wizards". "Wizards" know their area of expertise intimately and are not tasked with operational responsibilities. A "wizard" can recognize small disturbances in detailed data and knows the implications of these disturbances. By identifying abnormalities at this level, big problems are not allowed to develop without warning. "Wizards" are created implicitly through the data collection and reduction activities. By writing the data collection programs, maintaining these programs, and building reports, the person responsible becomes a "wizard" in that area.

In addition, performance management means developing a partnership with those people responsible for availability — the technical services people or the data communications group. As performance analysts, we are enjoined from making any changes in the machines or networks directly, since any change could impact availability. Thus if we wish to see our recommendations manifested in the world, we must convince the availability people that our recommendations need to be implemented. And the side effect of this is a viable system of checks and balances.

This way of doing performance management works well. In the last three years, we have quadrupled our total transaction load (400% increase), cut our response time by 70%, and only increased our hardware by something less than 200%. So with substantially less hardware per transaction, our response time has actually decreased. We have also avoided crises in capacity.

APPLICATION TO NETWORKS:

Networks are critical to the delivery of our services, whether it be ATM's, home banking, funds transfers or any other thing our users might be doing. The way the users measure their service is by the time it takes for them to get their response back. The networks are the major component of the response time. In some cases, they are the overwhelming component of response time. If we squeeze another tenth of a second out of our IMS response time by tuning DASD, our users would not notice. We will have accomplished nothing for the user. But, if we cut a 4 second communication delay in half, the user would notice.

Due to growth in new and existing business over the past two years, we have doubled the number of networked terminals (from 4000 to 8000 devices). As we installed networks to meet these additional requirements, we had to keep the initial networks in place to meet established business needs. Typically, there wasn't time for a planned consolidation or the protocols were incompatible or expenses were perceived as too great. Due to the extremely rapid and large growth in attached devices, we have networks which overlap and contain architectural paradoxes. And it is these networks that are the largest contributor in most cases to how our users perceive our level of service to them.

Our networks are in the same situation that our mainframes were in several years ago during our more severe capacity situations. The networks are very complex and have grown very rapidly in a short period of time. The people who are keeping the networks running know how to make the networks run and run fast. These people, however, have neither the time nor the inclination to do performance engineering. A separation of responsibility for performance and availability is required.

We believe performance management of the networks is critical to our business goals. Past experience dictates that the key to network performance management is the spawning of a wizard through detailed collection and analysis of data and the forming of a partnership with the people who are tasked with network availability.

NETWORK PERFORMANCE:

We see that there are fundamentally two components to network performance management and capacity planning. The first component is clearly throughput, which is a function of workload and topology. Methods to increase thoughput are well known and in fact, we've had some successes in this area already. The second, and perhaps less obvious, component of network performance management is cost performance.

It is in this costing regard that networks are significantly different from mainframes. Mainframe cost performance is a function of capital costs. We would like to defer or skip altogether buying another mainframe as our workload grows. Expenses are typically very small in relation to the capital cost. The only major recurring cost is depreciation, which has really already been paid. With networks, on the other hand, the initial capital cost is quite low with regard to the monthly recurring costs, typically on the order of 3-4 months of recurring costs. It is this recurring cost, the out-the-door money each month, that we wish to minimize in the network environment.

Our approach at CoreStates is to look at the network throughput and the network recurring costs, both separately and together.

In the throughput analyses, it is useful to look at factors which affect terminal response time in detail. These factors include terminal workload by application, inbound and outbound message size, peak workloads, line characteristics, line speed and utilization, and the physical layout of the network such as the number of drops per line. In cost analyses, it is necessary to examine in detail the tariff for each drop and compare the costs per terminal within network, by area, and across all networks.

SUCCESSES:

Our first success in throughput analysis was in our Bank of Delaware operations. When we looked at the sustained transaction rate, the linespeed and the average message size, we found that the response times that our line monitors were reporting were not possible. Given the amount of work that had to flow through the lines, the people had to be waiting longer. When we investigated, we discovered queuing at the control unit. After the users hit the enter key, they were waiting some length of time before the message disappeared from the screen. The technical services group installed a super-optimizer to further compress both inbound and outbound messages and the data communications group changed the line characteristics to full duplex. When this bottleneck was eliminated, the response time dropped about 50% and there was an immediate increase in throughput by about 20%. We anticipate this will have a direct impact on revenue because these transactions are being generated by our Visa collectors.

We have also had some success in reducing network recurring costs. First, we must recognize that the tariffs in this country for leased line service are very complex. Now, in every jurisdiction, there are anywhere from three to five ways, depending on how clever you wish to be, to price leased line service. Since tariffs are so variable and disagree with each other so much, that it has proved worthwhile to have someone who understands these tariffs in detail in those geographical areas in which we have active networks. On the first network that we looked at, we examined the tariffs in detail and we were able to reduce the cost of the network monthly recurring costs sharply. We found that the tariff that had been installed was not the tariff that we had designed. The reduction in leased line costs effected by this detailed examination was on the order of 20%.

CONCLUSIONS:

Capacity planning is not a function done for the benefit of the capacity planner nor for the benefit of technical services group or data communications group. Capacity planning fundamentally must be a function done for the benefit of the business. The impact of good capacity planning is to generate more revenue or lessen expenses while allowing the same or greater level of service to our customers.

It is the partnership between the availability and performance teams which allows for effective capacity planning. In this environment, the capacity planning group looks good only when the people who use the results of capacity planning look good. When the technical services group and the data communications group are able to be more effective at their responsibilities because of the work we have done, then we have been effective as capacity planners and users benefit.

SOME EXPERIENCES OF DATA CENTRE RELOCATION

Brian Day
Harwell Computing Centre
Harwell Laboratory

ABSTRACT

Relocating part or all of a Data Centre can be a traumatic experience; and if the move is to be successful, it requires careful planning and implementation by a team of skilled people.

This paper will focus on two actual cases:

* the migration of work to a new computer system running a new operating system;

* splitting an existing Data Centre, with the consequent migration of a large portion of the workload.

The issues discussed, both technical and management, will range from site planning through user/data migration to a new production environment. The specific experiences will be used to illustrate more general principles.

INTRODUCTION

Change is a fact of life in the computing industry, and there can be few installations which have no upgrades - either hardware or software - during the course of a year. In fact many "simple" changes will most likely be routine scheduled events tracked by the standard change control mechanisms in place at the site.

However, the relocation of work, either across dissimilar processors or from one site to another, can result in extremely complex problems; especially if continuity of service is a paramount requirement. This requires a high level of project management, extremely careful planning and implementation by a team of skilled people.

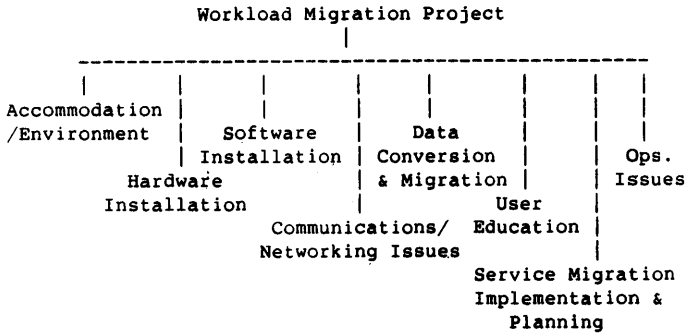
The remainder of this paper will focus on the planning and implementation phases of workload relocation, and will be illustrated by two specific examples.

RELOCATION STRATEGY AND PROJECT PLANNING

As mentioned above, careful planning is of the essence; and some form of project control methodology is vital. However, this does not automatically mean a computer based system. In the planning phase the computer can be an aid to successful project management - but it is not an alternative to really understanding the problems, serious thought and careful planning.

In principle, the project manager should focus on the goal he wants to achieve, and to establish the route to the goal; not (yet) think in terms of how it will be achieved. This definition should produce a set of milestones, which if well chosen will be independent of the method of achievement. For example, with reference to data centre relocation, a milestone might be: "when the user data has been migrated"; however the method of migration need only be determined when earlier tasks are completed and a better picture of further requirements is known. In this way a plan can be built through a hierarchy of milestones with objectives planned and achieved with a minimum of revision of implementation details.

Viewed from another perspective, the project will probably break down into a number of inter-related sub-projects which will have to co-operate in achieving the milestones referred to above. With particular reference to workload relocation, key sub-projects might be defined as follows:



Each sub-area could have a responsible project manager whose job it would be to produce detailed sub-project milestones, activity plans and resource schedules. These can then be integrated to form a total plan.

Obviously this is an extremely complex subject, and one cannot hope to cover it in great depth in a short paper. In addition it is unlikely that any two relocation projects will be the same, being very dependent on site specific detail. However, to illustrate some of the issues involved, the remainder of this paper will briefly discuss two projects the author has been involved in. Specifics of these migrations will be used to demonstrate more generally applicable concepts.

PROJECT ONE: CRAY-1/COS TO CRAY-2/UNICOS MIGRATION

This project involved the installation/upgrade to a CRAY-2 "supercomputer", and the migration of a production workload from the batch operating environment (COS) on the CRAY-1 to an interactive UNIX† environment (UNICOS) on the CRAY-2. Thus in this case not only was the underlying system and management philosophy different, but also the user interface was completely changed requiring a significant level of re-education.

† UNIX is a registered trademark of AT&T.

The education issues were therefore twofold:

* educate and convert the systems support personnel

* educate the end-users.

In our case, the problem was compounded in that there was little or no UNIX experience in house; and since the CRAY-2/UNICOS system was just out of development, the manufacturers documentation was still extremely sparse. There was a high degree of re-orientation requiered by MVS specialists; however, eventually the support personnel became familiar with the new system and even liked some of the features. Education courses were arranged for the end-user, who was often quite receptive. However, our experience shows that one should not underestimate the time taken for education and that since many users treat the computer as a tool, they are not necessarily interested in the "bells and whistles" extolled about the new system. In fact the user population polarised into two camps:

* Those who convered immediately

* and those requiring 'encouragement', and essentially left migration until the last minute

Our other major lesson was that in installing very new systems one has to be prepared to "make do" with less than a complete system. This can cause considerable stress, both for the user, and the support staff. However, on the other hand, at this stage the manufacturer is willing to invest large amounts of effort in you. This means you have a high level of input into how the embryo system develops, and you have direct contact with the developers.

Data migration was another issue during this conversion. Not only the "file-structure" as perceived by the user changed, but even the internal philosophy of handling files changed. This makes data migration a non-trival exercise. Again, there was a heavy educational requirement. However, because we had the luxury of running the old and new systems in parallel, both of which were accessible via the same front ends, the burden of conversion was done by migrating the files to the front-end processor and re-acquiring them onto the new system. Thus a large amount of the migration was left to the user himself to take at his own pace, although there were a few "carrots and sticks" to help the migration along.

PROJECT TWO: WORKLOAD MIGRATION TO A NEW MVS/XA DATA CENTRE

This project, in many respects, was the more "usual" in that it involved the relocation of a significant user population from an existing MVS/XA environment to a new MVS/XA data centre. This involved the construction of a new machine room complex, the installation of the hardware and software, data migration, and a "sudden death" cut-over which was to be transparent to the end-user.

Firstly, consider the environmental and construction phases. The complexity of this phase is very dependent on the size and location of the building. Some may be lucky enough to have a "green field" site; or, as in our case, we were in the position of constructing a machine room within an existing aircraft hanger! This hanger was about 400 feet from our existing room, and we were to convert one corner into a functional machine room to accept a IBM 3090-200E within 135 days. As usual we encountered the normal problems in clearing the site; however we also had to be cognisant of experimental facilities operating in the rest of the hanger. This posed problems because of their affect on us; however we also had to be aware of the effects of our construction work on them. These experimental facilities included a nuclear reactor(!), and an experimental rig capable of producing high levels of RF radiation. Thus before building could start, radiation surveys - both nuclear and RF - had to be undertaken. Following this, safety walls were erected to give a nuclear radiation free area, and the construction of the machine room had to be modified to incorporate shielding into the walls to produce a Faraday cage to shield the computer from the RF radiation. Other issues in the construction phase mainly revolved around delivery schedules, and the general requirement to co-ordinate the sub-contractors.

Our experience shows that no problems are insurmountable, and after accepting these challenges we now have a fine new machine room, which was constructed within the prescribed period - much to the credit of the contractors involved.

The other main issue of this conversion was the mechanism of data migration. The user group being transferred consisted of about 300 scientists and engineers working on the JET Joint Undertaking at a sister site 10 miles away. The experiment produces large quantities (>400 Mbytes per operational day) of data which was previously stored and processed on an IBM 3084Q. The migration to the 3090 would involve the copying of this raw-read only data, as well as migrating the large amounts of processed and analysed read/write data. For a number of different reasons, the target 3090 machine was to be located at Harwell but would not share DASD in the final configuration. In addition, the machine room separation precluded the sharing of an MSS which housed much of the experimental data. Thus how should migration be achieved?

Obviously the read-only data can be copied at any time, and is in many ways the easiest to handle. It was copied into a second MSS and onto 3480 tape cartridges attached to the 3090 system. This process also allowed the data to be re-validated. However, how could the "user data" and processed data which was updated in a volatile TSO environment be migrated, while maintaining a production service throughout. A number of senarios were discussed, but the two serious contenders were:

* to transfer the active user data over a "week-end" with the users and set up some mechanism to automate the transfer of the rest of the data on request;

* to share some DASD between the 3084 and 3090 on an interim basis, so that data could be moved to the shared DASD, and after user relocation the access would be from the new CPU.

Naturally the second senario is conceptually the simplest, and was the one chosen. We were extremely fortunate in the proximity of the two rooms!! In addition we had sufficient space in the 3084 computer room to allow the early installation of some of the 3090 DASD. Hence preparation for the migration was started prior to the 3090 delivery.

The alternative senario would probably have worked if the rooms were separated by a longer distance, however experiments over a CTC link between a 3084 and 4381 showed that the data throughput rate was significantly less (100Kbytes/sec) than the theoretical speed of the link. In addition, the CPU consumption during the transfer was rather prohibitive.

Using existing 'backup' communication lines, and with the aid of some 'borrowed' kit; it was possible to set up parallel communications links between JET and the 3084 and 3090 systems. Thus in the end the "sudden death" cut-over, which had been dreaded was rather an anti-climax, as it was possible to switch between the systems, and switch back should major problems have

been encountered.

In practice, the cut-over went extremely smoothly, and the project completed ahead of schedule. This was due in no small part to the extremely close collaboration between Harwell systems support, IBM, and JET data management staff. Without this close co-operation, success would have been impossible.

CONCLUSIONS

The examples above show that there is an extremely broad spectrum of requirements in relocating large portions of a workload. The variations on the requirements are only matched by the variation in the solutions. In the CRAY conversion the user migration was phased, and much of the migration was user initiated using information and tools supplied by the data centre. In the JET case, the migration had to be 'en mass' because of data sharing requirements and were done by systems and JET staff. However, in both these dissimilar cases, acceptable solutions were found to the problems.

I hope this paper has shown that workload relocation can be exciting and challenging, and that with proper planning and involvement of skilled people, the probablility of success is high and the risk can be minimised.

ACKNOWLEDGEMENTS

I should like to acknowledge the work and effort of all the people involved in the projects referred to above; not only those in the Harwell team, but also to CRAY Research, IBM, and JET staff who collaborated on these projects. In addition I should like to thank Harwell and JET for permission to discuss their migration experiences.

THE ROLE OF CAPACITY PLANNING IN CONSOLIDATIONS, ACQUISITIONS AND MERGERS

Holly E.K. Verbil
Bank of New York

ABSTRACT

Economics, which reflect the business environment also effect the requirements for the service needs of any organization. In the current business climate, mergers, consolidations and buyout situations are becoming a common mode for businesses to increase their assets. As Data Processing is generally considered a liability to the organization, the burden of proving the viability of any consolidation should be on the Data Center (because of its service orientation), specifically, Capacity Management. This paper will discuss the life-cycle of the consolidation/merger plan with emphasis on the role of Capacity Management. Topics include: reporting requirements on key workload indicators (before, during and after the consolidation/merger), characterization of applications (historic profiles), resource requirements (identification of hardware and software requirements necessary before, during and after the consolidation/merger), the use of modeling throughout the process, critical paths in workload movements, and budgeting properly for reserve capacity after the move/consolidation.

INTRODUCTION

The Bank of New York is currently going through a Data Center consolidation effort. During the same time period, we also followed through with the acquisition of another bank. As many businesses are finding, ventures such as mergers, acquisitions and consolidations are financially economic ways to expand business. This paper reflects the internal efforts of Data Processing on behalf of the management decision to consolidate or merge in order to increase business assets.

HISTORY

The Bank of New York, through years of growth, political, and economic changes ended 1986 with 4 multi-user Data Centers, all within a 50 mile radius of New York City. Several (14) single user mini computer satellite operations also fell under this umbrella. Though an interviewing process found that independent users felt that this decentralized distributed Data Processing environment was an acceptable situation even one to be envied, the majority of users were frustrated by the inconsistency of the processing services they were receiving. For senior management, Data Processing has always been a necessary evil, and a reduction in bottom line cost of services to support the Banking Operations was an intriguing idea for them to consider.

Financially, a plan to consolidate the Data Processing function, and coordinate hardware and software by product lines offered a cost effective method for providing efficient and effective service. Thus was born the consolidation.

Clearly, much time and research went into the consolidation decision, but the idea was left to be planned, organized, and carried out by the Data Processing Division of the Bank. The initial group of D.P. managers (representatives from the four major centers) were presented with the challenge of consolidation along with a concise breakdown of certain financial conditions. Facts included; cost per square foot of Data Center space in each of the four locations, an overview of the processing effort within each Data Center, the processing power (MIPS) for each, and the last year's budget figures for each Data Center. With these facts, they were to form a plan. In the following session, they devised an overall strategy which states the objectives of the consolidations.

The strategy established four major goals;

- Improve service quality: It was felt that the structure of Data Processing hindered the quality of service to its users.Specifically, the strategy established the requirements for the newer standard environment software common to all Data Centers, improved controls and management disciplines that focus on both accountability and responsibility, and a reduction in the complexity associated with controlling more than one major multi-user Data Center.

- Reduce operating costs: Redundant positions, inefficient usage of hardware and software resources, and the ever-rising expense of office space in New York City are some of the areas where costs could be reduced. Specifically, the strategy identified net personnel reductions, net reductions to hardware/software and improved facilities and telecommunications.

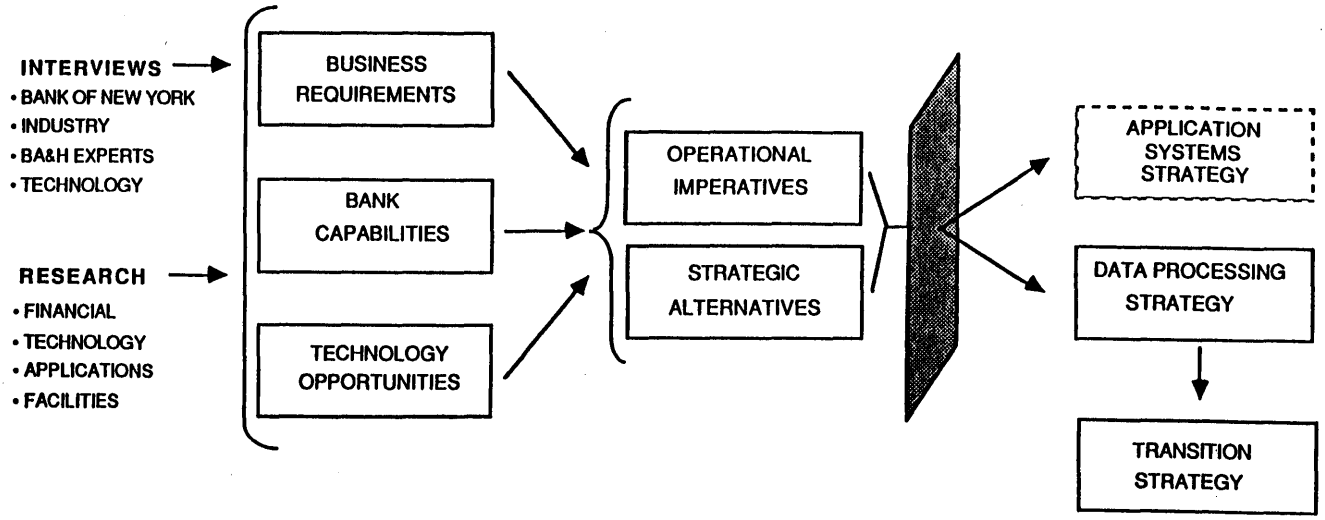
- Increased information availability: Inconsistencies in software and hardware options available reduced the effectiveness of the applications programming department and was severely limiting the ability of users to access critical business information. Specifically, the strategy establishes a common environment, a common set of standards and tools, and the development of a focal point to ensure that satellite user computing is effectively used.

- Improved Product Innovation: Barriers built up through years of unreliability and inflexibility prevented the Bank from taking advantage of newer and more innovative technology. Specifically, the strategy removes these barriers and provides a more flexible standard environment.

The initial strategy called for a phased approach to the consolidation. The first phase involved the consolidation from four to three major Data Centers. Financially and business wise the redistribution of one of the New York City Data Centers made the most sense. Using this as our direction, we proceeded to divide the applications (on a global scale) by product line back through two of the remaining Data Centers. Our motivation for moving applications to specific locations carried forward that idea. All of the Trust/Security processing related applications were to move to one location and the Bank Operations and General Business applications were to move to another location. The other New York City Data Center was left untouched by this phase of the consolidation for future strategic plans.

APPROACH...

THE STUDY FOCUSED ON IDENTIFYING BUSINESS DRIVEN IMPERATIVES AND ON DEVELOPING APPROPRIATE DATA PROCESSING AND TRANSITION STRATEGIES TO SUPPORT THESE IMPERATIVES...



APPLICATIONS SYSTEMS, WHICH ALSO ARE AN INTEGRAL ELEMENT OF HOW INFORMATION TECHNOLOGY CAN SUPPORT ACHIEVEMENT OF BUSINESS OBJECTIVES, WERE OUTSIDE THE SCOPE OF THIS STUDY...

As the significance of this project began to sink in throughout the bank's D.P. community, we launched into implementing the plan. Everyone realized at once, there were to many unanswered questions, too many unknowns. This brought us to the first step in the plan, "data gathering". We identified several things we needed to know about each of the Data Centers before we could do much more work. Our checklists called for lists of software and releases, hardware inventories, major workload characteristics and some basic CPU utilization statistics. Other things such as lists of applications, number of jobs per day, week, and month, number of tape amounts, type of job scheduling, library structure, type of cataloging, JCL handling, data security procedures and naming conventions were also identified. With most of these things gathered from unknown sources (each Data Center manager brought back his own information), validation of some of the information was required. This task was performed by Capacity Management, where there was a general request to gather SMF data from all of the Data Centers.

Organizationally, Capacity Management reports through each of the Data Centers to independent Data Center Directors who report to a common MIS Director. Their continuity is managed solely by their efforts to remain in sync with each other. The consolidation brought with it the need to manage a combined resource database through which general information and special requests could be handled in a standard way. All of the individuals involved with Capacity Management for the bank agreed that a central repository for our resource data (SMF, RMF, CMF, and IMS) was necessary in order to manage the large amount of data accumulated. Through the data, CPU utilization statistics, major workload characteristics and profiles, and job statistics were tracked by application. Start I/O's, tape mounts, and transaction counts were also reported. All of the Data Centers had established different levels of tuning, from the very basics to forecasting and modeling, so the idea of gathering all of the data together did not constitute any major procedural changes for the Data Centers. Capacity Management worked with the software systems group to modify the IPS (Installation Performance Specifications) on each of the systems to select and identify report performance groups which could then be tracked to indicate any changing trends. The information most difficult to ascertain included physical inventories of both software and hardware and terminal transaction relationships. On the communications side, we needed to learn about how the Data Centers were connected, what kind of data was going across the lines, and how much of it there was, what the anticipated changes would bring, and how much of it there was, what the anticipated changes would bring, and how quickly they needed to meet the requirements of the transition moves.

A detailed plan was developed by which each "application family" would move into its new location. The approach was to follow the plan (as best it was possible), move the first family, then reevaluate and resolve any differences, and modify the plan accordingly. The assumption was that every application had similar basic characteristics, with modifications only in the quantity to which particular things applied. The plan called for checklists, task lists and schedules to be created and maintained. It called for scheduled meetings and the irrevocable commitment by the Data Centers to meet the requirements of the transition with a minimal impact on the current services available.

During the first four months of the project, Capacity Management began the data collection process. Since this was still the planning phase of the project, during weekly meeting charts and graphs depicting some of the Data Centers workload characteristics were distributed. Some statistical reports were developed to assist the D.P. managers in understanding the impact of the consolidation efforts on their particular Data Center. While the resource database continued to increase, a trending history began to

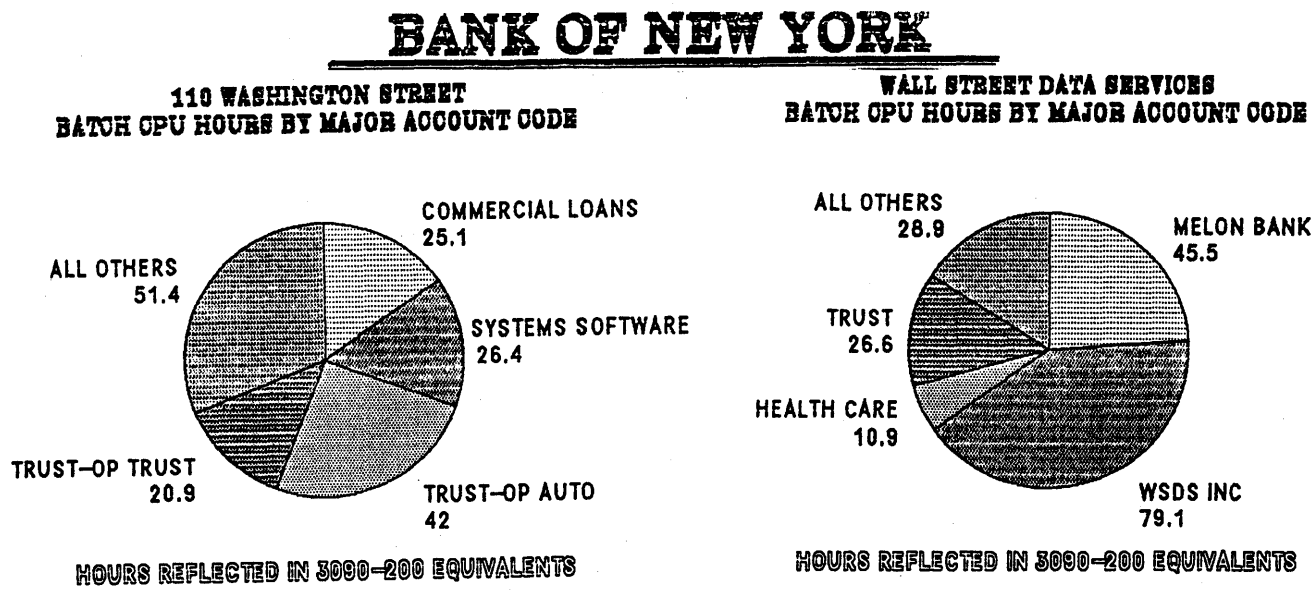
develop for each of the families. This information would later be used to assess the impact of each of the moves. Capacity Management's expertise was also required for the next step of the project. Profiles identifying all of the resources for each of the applications needed to be defined. Interviews with users, application programmers, and group leaders were an important step in the background history included in the profiles. As the history accumulated, profiles were built and validated to insure accuracy. We felt that by developing a solid historical base for each of the application families, we would be best prepared to move an application family to its new location.

A major campaign to inform the other divisions of the bank about the consolidation was developed. This was a twofold mission, to enlist support from them in regards to problems with logistics, and additional procedures required and notify them of the transition changes and what impact it would have on each of their divisions. These were high level meetings designed specifically to deal with divisional concerns. An orientation brochure about each of the Data Centers was distributed to introduce the divisions who had never been directly involved with the Data Centers to them. The meetings canvassed Data Center users feelings and reservations about the transition moves and reassured them that their current service would not be hampered in the move process. We also met some specific concerns head on by requesting their help with the moves and the historical data gathering. We asked them if they could anticipate any benefits from the moves, by asking them what they found particularly disturbing about the Data Processing service that they were currently receiving. Some of the responses required simple resolutions such as getting printers into user areas, having more consistency to the scheduling of jobs, and the reliability of data provided, all of which we felt confident that we could support.

It soon became obvious that the tasks were growing beyond the limits of the initial group. We began to bring the "doers" into the team. This constituted the end of the planning phase and the beginning of the move phase of the Data Center Consolidation. The new team members were the working core of the team. They were managers of the people who would actually be doing the work, they were the project leaders, and they were responsible for each application family move. I must say here that the individuals chosen were done so with great care and concern. Nothing that we planned could have prepared these people for the extensive work ahead of them. They have done an extraordinary job under incredible circumstances. The group was still limited, and while many people would work on this project throughout time, we had to maintain the day to day environment and make every effort to stabilize the incoming work and quickly fold it into the normal production flow.

As the first move loomed over us, doubts began to surface as to whether strategic planning was the best way to accommodate changes like moving an application. Some wondered if it wouldn't just be easier to move the applications and have it over with. Those of us who were used to planning, had to allow for these frustrations, knowing that eventually the planning would prove to be the survival of an undertaking such as this.

Schedules got tighter, time got short and people got incredibly busy for the next few weeks. The weekend prior to the first move (scheduled for the following Monday), all of the checklists were checked, tasks completed, and schedules updated for a smooth start up. People were in place and ready to respond to any situation as Monday arrived, and the system went live. The batch cycle went relatively smoothly, with the exception of some last minute JCL changes and the on-line work started on schedule. The problems that did surface were manageable and were not considered "show stoppers" to the overall objective.



As the first "debriefing" meeting (after the first move) people were critical of their work, but none the less, the task had been achieved, and to the bank we had done the job as promised. We charged into the next application "family" promising not to make the same mistakes as the first, knowing that we would make different ones instead.

By the time we began planning for the third move, things began to be routine in nature. The application "families" that were moved began to fold into the normal production workload of the Data Center.

Capacity Management remained in the middle of the process by reviewing resource data which revealed the changing characteristics of the Data Centers. Graphs, charts and statistical data were provided to help explain the impact of each of the moves in both Data Centers. Capacity Management was also responsible for reporting on and validating the previously estimated increases in the production workloads.

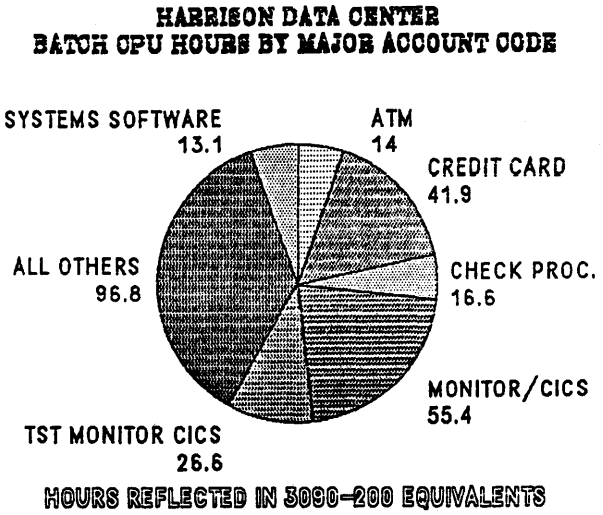
Hardware and support software had to change as well. Additional DASD was required to support the new applications in one Data Center while in another Data Center the DASD requirements dwindled. The problems with one for one movement became obvious when we started researching the methodology used in the DASD space allocation process. The space freed up by the movement of applications was not readily available because of a commitment to backup a moved application for a limited time and because the space was allocated across several volumes with a complicated structure of files and pointers which might jeopardize the remaining applications. We budgeted hardware and support software to be installed and tested at least one month prior to the particular application move they were scheduled to accompany. As equipment was freed up in one location, and was required in another location we chose to take advantage of some short term leasing options to avoid any "push-pull" situations. To compensate for some possible problems in our ability to backup the new configurations, the final Data Center structure called for some mainframe changes as well. This allows the bank to take full advantage of the consolidation to replace older, less dependable equipment with newer, more advanced technologies and position itself to respond to future needs in a timely and cost efficient way.

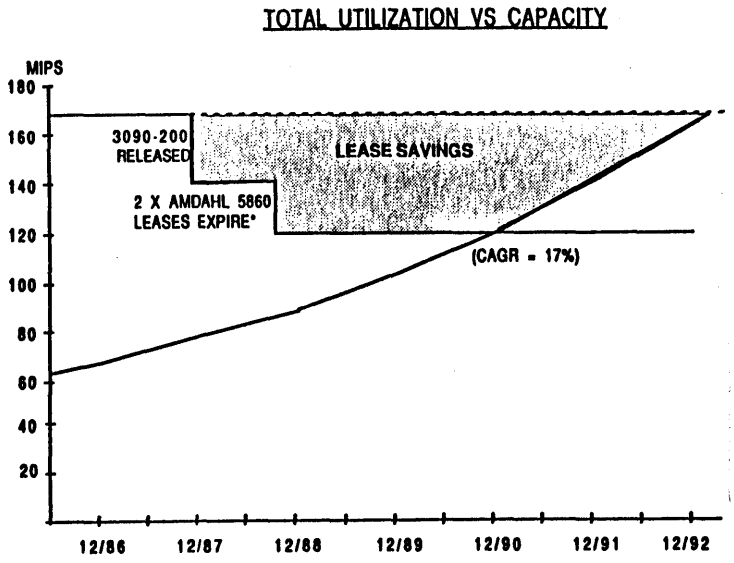
CONCLUSIONS

By involving Capacity Management in the planning phase of this project, we were able to avoid getting caught up in the process by a lot of unanswered questions, and still limit the core group. The planning tasks were made easier by our technical knowledge and our ability to translate the needs of the project into the impacts on each of the current Data Center environments. We were able to help management understand the changes that would be felt by the Data Centers that would be gaining applications by pointing out that it would affect processing windows, on-line timings and that there might be some batch conflicts that would require analysis.

There are a few points that I wish to bring out as I conclude this paper. Capacity Management can make a major contribution to the strategic planning of the business entity known as Data Processing. Our technical knowledge, combined with an awareness of the Data Processing structure gives us a good sense about what is happening within a given complex. In the case of a consolidation, merger, or acquisition, our skills and efforts on behalf of the project offer a wealth of information to management who may not realize the implications of what they are about to commit to until its too late!

As a manager of Capacity Management, your direct involvement in the processes associated with a consolidation should be invaluable to the project. As an employee working in capacity management, you can make sure that your skills and contributions are noticed by providing the right kind of data to your management team in order for them to make informed

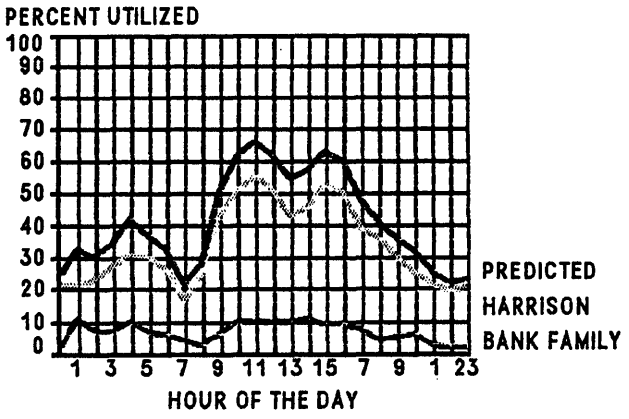


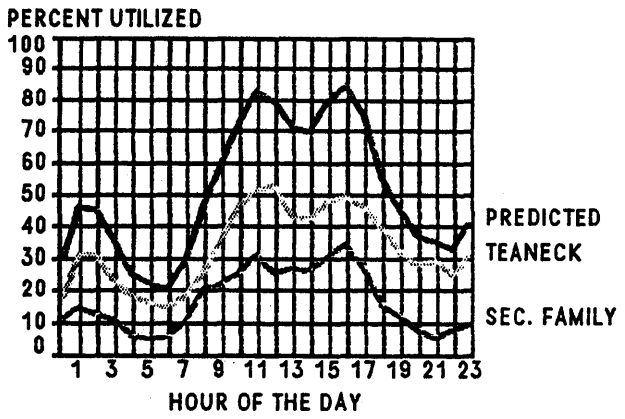


STRATEGY - ECONOMICS...

AVERAGE SAVINGS OF $2.8 MILLION PER YEAR FOR THREE YEARS STARTING IN 1988 CAN BE EXPECTED DUE TO HARDWARE CONSOLIDATION AND MORE EFFICIENT UTILIZATION...

CPU CAPACITY





HARRISON, TEANECK & 110 WASHINGTON

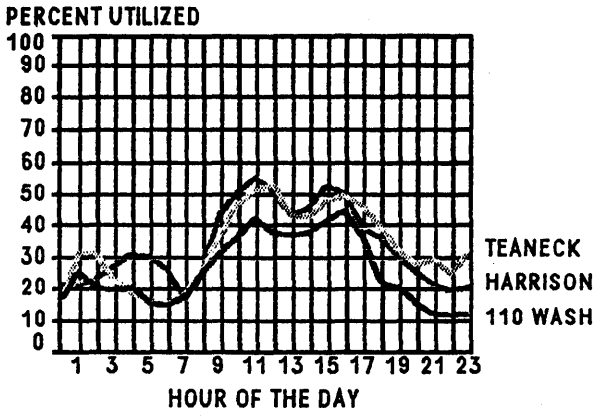
UTILIZATION WAS DERIVED FROM AVERAGE CPU SERVICE UNITS FROM THE MONTH OF FEBRUARY EXCLUDING WEEKENDS AND HOLIDAYS.



business decisions. Capacity Management can support the decision making process by utilizing their skills to provide a statistical information base and analyzing the database for trends, abnormalities, and conflicts. Because the training (backround and education) of an experienced Capacity Management person focuses on the impact of external forces on internal Data Processing functions, analysis of the business decision can be broken down into its integral elements to provide greater understanding of any situation. The business decision can be reduced to facts on both the economic and political levels. Prudence requires a careful weighing of both sides, but the elements of decision can be reduced in such a manner as to provide senior management with the essentials required for informed decision making.

Capacity Management should expand its horizons as well. Consideration should be given to initiating such thought provoking things as consolidating Data Center resources when and where applicable managing the capacity of computer hardware, and exploring the realm of creative finance fall into line as part of the new Capacity Manager's job. Just as you help make management decisions to purchase new equipment, consideration for reducing the bottom line are becoming part of the job as well. Capacity Management has come a long way from the days of blue sky predictions. My point is - in order to achieve the level of being part of the strategic plans of your company, you must begin to be aware of, and understand the elements of business and translate your recommendations, findings, and analysis into sound business proposals.

ACKNOWLEDGMENTS

I would like to thank Charles Barilla for his expert help in the graphics presented within this paper. Also for his help in preparing the presentation of this material. My thanks also to The Bank of New York, Data Processing Division, for providing with a vehicle to challenge my knowledge and further my experiences associated with Capacity Management.

CAN SERVICE UNITS BE USED FOR UNIFORM CHARGEBACKS?

Carl Claunch
National Advanced Systems

ABSTRACT

Many installations determine chargeback fees by using service units attributed to the task by MVS. Multiple processor installations, or those who change the processor complex, may then experience significant variations in charges computed. This paper will discuss the nature of the service units computed by MVS, the causes of variation across dissimilar complexes, and a simple method of minimizing such variation.

1.0 SERVICE UNITS

All service delivered to a user consists of access to a resource. Resources vary in importance, as well as scarcity. The conversion of resource usage into a common measure--the service unit (SU)--allows the installation to manage in a consistent manner the diverse range of services provided to a user's task during processing.

Every resource in the system has an associated rate, which specifies the worth in SUs of each use. For example, requests for Input-Output might produce one SU per EXCP, while a very fast processor complex could produce hundreds of SUs each second of CPU access.

MVS considers three resource types in accumulating SUs:

-Processor (CPU)
-I/O
-Main storage occupancy

The unit of use for these resources is the second of active CPU, the Input-Output (I/O) count, and the number of page frames per CPU second, respectively. MVS/XA recently provided the option of counting I/O resource usage, either by the traditional EXCP count, or by the number of 8.3ms intervals of channel busy. Processor seconds are recognized separately when produced in SRB mode from those seconds spent in TCB mode.

The MVS system applies a weighting factor to these SU values being accumulated. The system options, CPU, SRB, IOC, and MSO in the IEAOPTxx member of PARMLIB, are multiplied by the accumulating SUs of each resource before MVS sums all resource usage. A user can reflect the changing importance of the resources by manipulating these weighting factors. Higher values increase the effective cost of access to the associated resource.

Workloads which use a constant quantity of the resources should be assigned the same total service unit value each execution. MVS provides reasonable repeatability when the underlying resource usage is equivalent. The I/O service units tend to vary the least, while the main storage occupancy values are highly sensitive to central storage utilization and can vary widely between runs. CPU service accumulation is fairly repeatable, but can increase when system loading is high.

Because of the good repeatability of CPU, SRB and I/O service unit consumption in a system, many installations have based fees on the service consumption of the workloads. Departmental charges can be related well to usage.

Many workloads are not reported with sufficient detail to make use of service units. For example, most online transaction oriented systems do not report service units discretely. Individual use cannot be charged back using the consumed service units, and other schemes have to be employed by the data center to recover costs.

2.0 MODEL DEPENDENT CONSTANTS

The number of service units produced by a CPU second cannot be fixed. The range of processor complex speeds is large, with MVS used on systems from 370/158 size up to the largest 3090 class systems

MVS adjusts to the relative performance of the executing processor complex by use of Model Dependent Constants (MDCs). These values define for MVS the number of SUs each second of time on the model is worth. The value for each model is set in a table coded in csect IRARMCPU in the nucleus module IEAVNP10 (see figure 1). When the operating

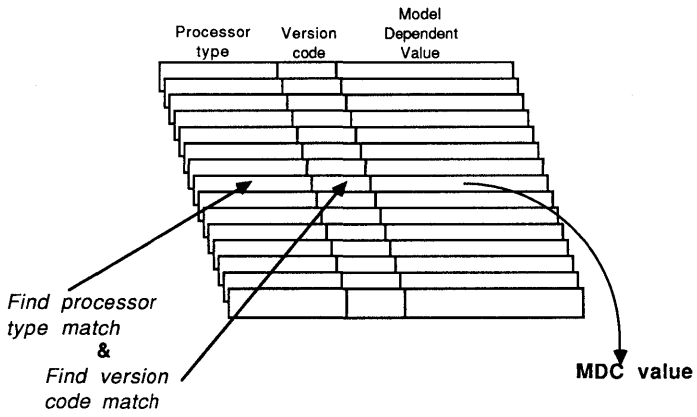

FIGURE-1

system is initialized, the CPU ID of the processor complex is extracted. This ID consists of a machine type and a version code. Combined, these values represent a specific model. The table entry corresponding to the processor type and version is used to assign the SU worth of each processor second (see figure 2).

PROCESSOR	SU/sec	Low Page Rate	High Page Rate
4381 1	122.1	37	48
4381 2	181.0	55	71

3090 600E	625.88	208	262

FIGURE-2 MODEL DEPENDENT VALUES

A related set of constants define the page rate bounds for effective operation. These parameters default to the model dependent constants, unless explicitly provided by the user in the IEAOPTxx member of PARMLIB. These MDCs are the default for the parameters PAGERT1 and PAGERT2.

The page rate values are part of the "happy values", which are used to determine when the overall system multiprogramming level should be decreased or increased. MVS picks the high (or low) priority domain and adjusts its multiprogramming level (MPL) appropriately.

3.0 VARIATIONS IN USAGE

Four factors can affect the repeatability of service units for each workload:

-Changes in the workload itself
-System-wide conditions, such as extreme paging rates
-User changes in IEAOPTxx to the weighting of resources
-Changes in the capability of the resource, such as a faster processor complex.

Different SU totals caused by changes in the task are not an accounting difficulty. The natural expectation is that charges will vary when the work accomplished varies. No requirement is laid on system management to provide repeatable charges for such workloads.

System-wide conditions which change SU requirements tend to be most noticeable in the MSO values. Very few installations utilize the MSO service value in any significant way in the billing process. Increases in charges,when overall system load is heavy, act as an incentive toward off-peak scheduling. This paper will not provide suggestions to offset this generally positive effect.

The IEAOPTxx weighting factors should not vary across processor complexes if comparable billing is desired.

Finally, a change of processor complex that alters the workloads requirement for processor seconds can be further segmented into two effects--a change in the average processor speed which will effect all workloads similarly, and model dependent changes which are different for every workload.

Each processor type is designed with a specific set of hardware capabilities, striking a balance between performance and cost. The cost may be economic, or it may be physical, such as heat or size. The overall goals of the designer are to provide a target average performance at desired physical and economic values. Every machine type strikes its own different set of balances.

When compared to another one, machine type may be quite proficient executing floating-point arithmetic, but less so when moving blocks of data in memory. Variations in machine design result in workload sensitive variations in the rate of execution. Two models may have a single average ratio of performance, but as the workload varies, the instantaneous ratio between the models varies over a large range (see figure 3).

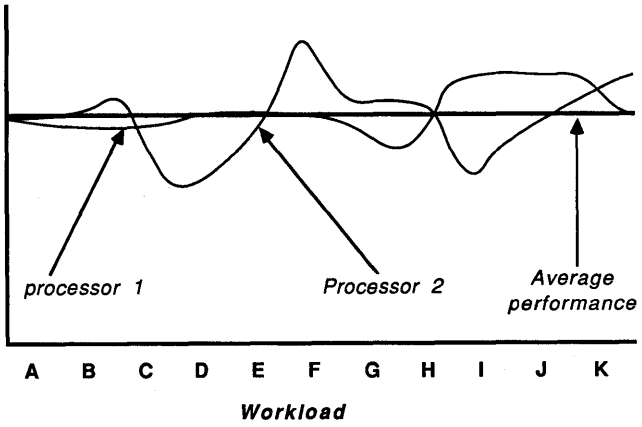

FIGURE-3

The user who upgrades a processor complex may find certain workloads benefit more or less than the overall expectation. Billing charges computed for these workloads will be bigger or smaller than before, yet the underlying work is identical.

The MDC value in IRARMCPU reflects relative performance, so that on the average, SUs accumulated for all work should be constant when the processor complex is changed. When more than one processor complex model is in use, overall SUs for equal workloads should be roughly identical. However, model dependent variations in individual workloads result in non-repeatability across models.

This effect is least noticeable when the models concerned are all of the same processor type, such as 3081 or 4381. The effect is more noticeable if factors other than cycle time comprise the difference between models, as for instance, when the amount of cache buffer is changed. The effect is significant when different processor types are involved, for example, 3081 and 3090 sharing an installation. The effect is most severe when the processor types are not closely related, for instance, with 4381 and 3090.

Since workload sensitive variations occur, the average SU rate of the MDC in IRARMCPU cannot provide repeatable SU sums for all workloads. The installation's mix of work may not average to the same relative capability as the MDC value, and individual workloads will vary by different amounts.

This paper suggests two complementary strategies to minimize the model dependent variation in repeatability. First, adjust the MDC values in IRARMCPU to produce repeatable average SUs between the models involved. Then, identify those workloads which differ due to machine differences, and provide a mechanism to adjust them in the billing process.

4.0 ALTERING MVS VALUES

Figure 4 indicates the manner in which the IRARMCPU value is used to produce a service unit rate. The values are stored in a table with an entry for each model supported by the software release, as well as spare entries

Prepare a change to csect IRARMCPU of module IEAVNP10 in the dataset NUCLEUS. Entries are doublewords; the first two bytes contain the processor type in hex. The next byte contains the version code, and the remainder is the MDC value in hex.

For example, a 3081 processor entry contains:
3081 xx00 0001 9000

An entry for a 3083 contains:
3083 xx00 0001 FC00

SU per second = 43,008,000/ TABLE VALUE

OR

Table value = 43,008,000 / SU per second

Example - The 3083JX has a service unit value of 420.0 which produces a table value of 102,400 decimal.

This corresponds to a hexadecimal value of x'19000'

Example - The table value for a 3083BX is x'1FC00', which is 130,051. This value produces a SU/sec rate of 330.7.

FIGURE-4

The table contains at least one spare entry, which is marked with a FFFF processor type.

5.0 ACHIEVING UNIFORMITY

Select from the installation workloads a set of tasks which are highly repeatable on the same processor model. Mix these tasks in a reasonable approximation of the overall workload mix. The more tasks included, the higher the accuracy.

This set of tasks becomes a baseline with which we adjust additional processor models so the accumulated service units are as close as possible. Calculate the weighted average and deviation. Use as many tasks and observations as practical to increase accuracy. The deviation percentage will reflect the change desired in the IRARMCPU constant service units per second. Adjust this value and monitor the effect. A final cross-check is the overall billing produced in production use, which should be similar when our baseline tasks have produced nearly identical results.

When average billings are repeatable, individual workload variations still exist. Cases where the variation is high, the user is concerned, and the effort is justified, merit a group adjustment. Associate workloads with similar characteristics to a grouping, perhaps by accounting code or job class. All such grouped tasks should have a similar deviation amount (and sign) from the average billing on other models.

Institute an adjustment calculation in the billing process, which applies a model dependent coefficient to the SUs. The model dependent coefficient is determined by the deviation on each model. The billing process would select a model dependent adjustment by processor complex executing the work.

6.0 SUMMARY

The system manager constructs and uses a baseline set of work to adjust IRARMCPU MDCs until average billings are nearly identical. Then the system manager measures the model dependent deviation for selected individual tasks and uses it to adjust the billing process for uniform billing across models.

A USER-FRIENDLY AUTOMATIC ANALYTIC APPROACH TO BUDGET-CONSTRAINED SYSTEM UPGRADE

ABSTRACT

This paper describes the development of a software package to help make computer system upgrade decisions. The package, named OPTIMAL, solves the following problem: given an existing computer system and its workload, a budget, and the costs and descriptions of relevant devices in the market, what is the most cost-effective way of upgrading and tuning the system to produce optimal system throughput? To enhance the practicality of OPTIMAL, the research followed two criteria: i) input required by OPTIMAL must be those system and workload characteristics directly measurable from the system under consideration, and ii) other than gathering and inputting the required data, the package must be completely automated and must not require any specialized knowledge in systems performance evaluation for the user to interpret the results. The output of OPTIMAL consists of the optimal system throughput under the budget constraint, the workload and system configuration (or upgrade strategy), and the cost of the upgrade. Various optimization techniques, including saturation analysis and fine tuning, have been applied to enhance the performance of OPTIMAL.

1 INTRODUCTION

As the computer plays an increasingly dominant role in today's world, a great deal of human and economic effort is being spent on planning computer system configurations to meet the service requirements of a given workload. This process of planning system configurations is commonly known as *capacity planning*; it is a process of continually monitoring a system and its workload, making projections and recommending upgrade decisions to meet performance requirements for current and future needs.

The notion of applying artificial intelligence (specifically, expert system) technology to capacity planning to increase the productivity of performance analysts has aroused much interest recently [9] [11] [15]. In particular, an expert system which uses facts and heuristics on a domain of expertise to solve a certain problem provides a powerful tool for system performance analysis. Previously, most works have been designed for the needs of particular computer systems and utilize tools specific to these systems, e.g., [10] [5] [9] [15] [16], or consider only particular units in a computer system, such as the CPU or the disk storage system [2] [7] [14]. Even for Sevcik's work [17] which considers alternative configurations to replace a system, the study was directed toward a particular case and thus is limited in its application. Furthermore, gathering the required input data and interpreting the output results in most of the suggested approaches require experience and knowledge in computer systems performance evaluation. In the realm of applying expert systems to capacity planning, the problem that we propose to solve for a given computer system is: given a budget, the current system configuration and workload, available devices on the market and their associated costs, what is the most cost-effective way of upgrading and tuning the system such that the optimal system throughput is obtained? This is the system upgrade problem that computing centre managers face from time to time when their systems saturate or approach saturation.

To enhance the practicality of the solution, two criteria are followed. The system under consideration (SUC) is a system already in existence, and the parameters characterizing the system configuration and workload are directly measurable. Furthermore, unlike most currently available capacity planning systems, after the required input data have been gathered and submitted, the solution process is fully automated and no specialized knowledge in performance evaluation is required to interpret the final results.

For the purpose of being able to apply the solution to any system in general, and the fact that analytic models have proven to be able to accurately and cost-effectively reflect the performance measures of a system [3], we have opted

for analytic models over simulation. Specifically, exact Mean Value Analysis (MVA) [13] [8] is used to evaluate system performance. Also, rather than aiming at an absolute highest throughput possible within the budget, we define optimal throughput to be the highest throughput per dollar spent. We also allow a minimum disk capacity to be specified which must be satisfied in the recommended upgrade solution. Furthermore, in almost all systems, depending on the availability of memory, there exists a limit on the number of processes that can be active simultaneously; such a limit is known as *memory constraint* which places an upper bound on the extent to which processing resources can be used concurrently, and thus on the system throughput [8]. Thus, for systems with paging and memory constraint, we further optimize the system throughput with the optimal multiprogramming level with respect to the SUC.

The remainder of the paper describes a software package called OPTIMAL that satisfies the above objectives. Section 2 describes the model and the assumptions used. Section 3 discusses some of the implementation issues. Section 4 discusses the performance of OPTIMAL. Section 5 concludes the paper. A sample session with OPTIMAL is given in the appendix.

2 DESCRIPTION OF OPTIMAL

2.1 ASSUMPTIONS

For simplicity, the SUC is assumed to be representable as a centralized single class closed queuing system model with batch or terminal workload. The possibility of extending the model to include more complex systems such as multiple job class systems will be discussed in Sections 3.1 and 5.

Placement of files on devices with the objective of balancing the load across I/O devices [1] can often improve system performance [8]. Thus tuning, with the above objective, is considered whenever it is possible to move files from one I/O device to another. It is also assumed that such tuning measures do not incur additional monetary costs.

For systems with memory constraint, it is assumed that there exist two system-dependent parameters: the maximum memory size and the maximum degree of multiprogramming. Homogeneity assumptions about the workload are also made, as described below. For swapping systems, it is assumed that with respect to the configuration and workload of the SUC, the mean degree of multiprogramming is measurable and the users share main memory equally. Thus the mean size of memory allocated per job is calculated by dividing the size of main memory available to users by the mean degree of multiprogramming. For paging systems, the size of memory allocated per job actually varies according to the current multiprogramming level of the SUC, but since jobs are assumed to be identical, the mean multiprogramming level of a paging system obtained over some fixed period of time is used. Furthermore for paging systems, it is assumed that the paging device can be either dedicated to paging activities, or shared between regular file I/O and paging activities. The memory reference characteristics of jobs and the page replacement policy of the operating system are assumed to interact with one another in a manner reflected by the programme lifetime function specific to the SUC [8]. It is also assumed that the operating system allocates memory on an equipartitional basis for the current number of jobs within the maximum multiprogramming level supported by the system.

OPTIMAL assumes each device i in the system has a finite number of alternative upgrade devices (referred to simply as alternatives). These are devices (usually faster or larger or both) which are candidates to replace device i or to be added to share the load of device i. In the case of replacement, a resale value for device i must be provided. In the case of addition, alternative j of device i is assumed to have the same set of upgrade alternatives as i. For each existing as well as alternative device, its capability, cost, and whether tuning is allowed are required as inputs. The capability of a non-memory device is assumed to be characterized by the service rate, and may be expressed in various terms. For example, for the CPU, it may be in number of millions of instructions per second (MIPS), or in number of jobs per second; for I/O devices, it may be in number of jobs per second or in number of page frames per unit time. The capacity, in terms of page frames or megabytes, is also needed for primary or secondary storage devices. Workload characteristics of SUC are expressed as visit ratios for I/O devices, mean number of instructions per job or visit ratio for CPU, and the multiprogramming level for memory.

2.2 THE ITERATIVE PROCEDURE

Some of the paramters used by OPTIMAL are listed below:

System Parameters:

Ncents : number of non-memory devices in the system

μ_i : service rate of device i

memsize : main memory size

[1] In the context of tuning, only on-line secondary storage I/O devices are modelled.

max-memsize : maximum main memory size supported by system

Workload Parameters:

z : mean thinktime for transactional workload

v_i : visit ratio, i.e., mean number of service requests made per job, for device i

μ_i : service rate of device i in requests per second

M : maximum multiprogramming level allowed in a memory-constrained system

m : mean size of memory allocated per job

$l(m) = lifetime(m)$: lifetime function for paging system

Economic Parameters

ΔM : unit increment on memory size

B : initial budget

$n\text{-}alt_i$: number of upgrade alternatives for device i

C_{ij} : cost of the jth upgrade alternative of device i

c_i : resale value of device i

B : initial budget

remain : running balance of the budget

OPTIMAL recommends tuning to be done initially if files are allowed to be moved across I/O devices. As mentioned earlier, balancing system load by re-assignment of files has been shown to improve system performance. An I/O device with very high utilization (close to 100%) may be a system bottleneck and improving the capability of other devices may not yield noticeable improvement in system performance. However, if files are re-assigned from this device to others balancing their service demands, utilization of the original bottleneck will be lowered. Thus, if tuning is allowed, it should be done before upgrading. Otherwise, upgrading the original system bottleneck alone is not likely to be the most cost-effective measure to improve system throughput.

After initial tuning (if possible), OPTIMAL operates as an iterative process.

Step 0 Balance load of I/O devices by reallocating files if possible. Find initial system throughput t.

The iterative process:

Step 1 For each device i for which upgrading is considered, and for each upgrade alternative j of device i, $0 < i \leq Ncents$, $0 < j \leq n\text{-}alt_i$:

Step 1.1 Try replacing device i by alternative j: if $C_{ij} > c_i$ and $remain \geq C_{ij} - c_i$, or if $C_{ij} \leq c_i$, substitute capability of alternative j for device i. Balance load of device i with other devices if possible. If replacement is not possible, go to Step 1.4.

Step 1.2 Evaluate system performance and find the throughput t^r_{ij} with respect to the replacement in Step 1.1.

Step 1.3 Restore capability of device i to the state in Step 1. If tuning was done in Step 1.1, restore visit ratios of tuned devices to the state in Step 1.

Step 1.4 Try adding alternative j to system: [2]

if $remain \geq C_{ij}$,
and if $i \neq$ memory and $Ncents < max$,
or if $i =$ memory and $memsize + \Delta M \leq max\text{-}memsize$,
then add a new device with capability equal to that of alternative j to the system. If i is an I/O device, move files to new device such that load is balanced across all I/O devices that can be tuned. If addition is not possible, go to Step 2.

Step 1.5 Evaluate system performance and find the throughput t^a_{ij} with respect to the addition in Step 1.4.

Step 1.6 Restore original system configuration by removing new device, and if $i \neq$ memory, restoring visit ratios to the state in Step 1.

Step 2 Calaculate the cost-effectiveness of each upgrading measure carried out in Step 1, i.e., for each device i, compute:

$$ceff^r_{ij} = (t^r_{ij} - t)/(C_{ij} - c_i)$$

and

$$ceff^a_{ij} = (t^a_{ij} - t)/C_{ij},$$

if the corresponding upgrade is possible.

Step 3 For device i and alternative j where

$$ceff^{action}_{ij} = \max_{i,j,action} \{ceff^{action}_{ij}\},\ action \in \{r, a\},$$

upgrade system by the corresponding *action*, i.e., either replacing device i by its j-th alternative, or adding alternative j to the system as a new device. Balance load of device i with other I/O devices if possible. Increment *Ncents* if *action* is addition of device to system.

[2] Addition of devices is only permitted for memory and for I/O devices for which files can be re-allocated.

Step 4 Record system throughput t with respect to upgrade decision in Step 3 (i.e. $t = t^r_{ij}$ or t^a_{ij}). Decrement *remain* by $(C_{ij} - c_i)$ if *action* is replacement, and by C_{ij} if *action* is addition.

The iterative process terminates when the remaining budget is insufficient for any type of upgrading action for any device. To take total disk capacity into consideration, when the iterative process terminates, the sum of the capacities of the disks in the recommended system is compared to the minimum required specified by the user. If the total in the system is equal to or exceeds the disk capacity constraint, the result is optimal and printed. Otherwise, OPTIMAL back-tracks to the most recent non-disk upgrade decision and replaces it by the most cost-effective disk upgrade. If the disk requirement is still not satisfied, this procedure is repeated until the disk capacity constraint is met or all of the non-disk upgrades have been revoked. In the latter case, there is no solution possible with the amount of money specified and a message is printed accordingly.

2.3 THE OUTPUT

OPTIMAL produces the following output:

1. A recommendation on how to distribute the given budget among the various upgrade alternatives, i.e., which devices to replace in the initial system and which devices should be added to the system.
2. The remaining budget.
3. The system throughput with respect to the recommended system configuration (after fine-tuning if possible).

3 IMPLEMENTATION ISSUES

3.1 SYSTEM PERFORMANCE ANALYSIS ALGORITHMS

Even though we have chosen to build system performance analysis tools for OPTIMAL based on Mean Value Analysis [13] [8], it should be pointed out that OPTIMAL is not dependent on these tools. In fact, given the appropriate analytic modelling tool, other systems, such as multiple class systems, can also be applied to OPTIMAL with minor modifications. Such modelling tools are widely available; for instance, BEST/1 [1] has been widely used in North America since 1979. QNETS [12] analyzes multiple class centralized systems with memory-constraint. Another package, QNAP2 [6], models and evaluates the performance of systems with varied complexities: open or closed systems with single or multiple job class, with or without memory constraint, with local or remote transactions over a network, and non-separable [3] systems with a finite number of processors linked together by a network.

Two notes on the exact Mean Value Analysis as applied to memory-constraint batch and paging systems. For memory-constraint batch systems where the total number of customers, *Ncusts*, is less than or equal to the multiprogramming level, M, of the system, rather than taking the mean throughput over all feasible populations 1,..., *Ncusts*, the system throughput is taken to be that obtained at multiprogramming level *Ncusts*. This is because all processes can be accommodated in main memory and there is no delay imposed outside of the multiprogramming subsystem (refer to Figure 1).

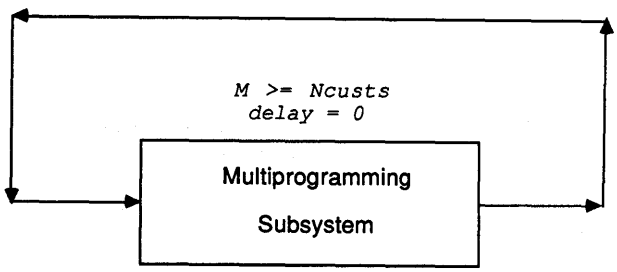

Figure 1: Closed Batch Model with Memory Constraint $M \geq Ncusts$

For paging systems, the visit ratio to the paging device for paging service [3] is dependent on the current multiprogramming level. Therefore, to calculate the system throughput at each feasible multiprogramming level, it is necessary to find the visit ratio and the service demand to the paging device for paging service at each of these levels. This visit ratio at any feasible population n can be derived from the formula:
$visit\ ratio_{pag} = service\ demand_{cpu} / lifetime(m)$,
where, according to the user-specified lifetime function, *lifetime(m)* yields the mean CPU time between consecutive page faults with respect to the memory allocation per job (m) when the current multiprogramming level is n (i.e., $m = memsize/n$).

3.2 OPTIMIZATION

Optimization is carried out in OPTIMAL in the following four main areas: saturation analysis and tuning, calculation of cost-effectiveness, optimizing multiprogramming level, and fine tuning.

[3] Paging devices may be shared between paging activities and regular file I/O activities.

3.2.1 SATURATION ANALYSIS AND TUNING. As mentioned in Section 2.2, a saturated device in a system is not necessarily the most cost-effective device to upgrade. If the saturated device is an I/O device where files can be moved to other I/O devices in the system to balance their service demands, then such tuning action may remove this device as the primary bottleneck. Some other device whose service demand has not been affected by the tuning measure may become the most heavily utilized device in the system and hence emerges as the current primary bottleneck. However, since our upgrade criterion is the ratio of the increased throughput to the cost of the upgrade, cost is also a factor in the decision process, and the most highly utilized device is not necessarily selected for upgrade.

3.2.2 CALCULATION OF COST-EFFECTIVENESS. If for some reason, the replacement cost of a new device is less than the resale value of an existing device in the system, OPTIMAL upgrades this device by replacing it with the alternative before proceeding to calculate the cost-effectiveness of the rest of the devices. The profit made in the upgrade transaction is accounted into the budget. In situations where the capability of an upgrade alternative is equal to or even lower than that of an existing device in the system, OPTIMAL ignores this upgrade possibility and proceeds to examine the other alternatives.

3.2.3 OPTIMIZING THE MULTIPROGRAMMING LEVEL. When memory is added to memory-constrained swapping systems, the multiprogramming level of the system may be increased up to the maximum possible, based on the mean memory size allocated per job for that system (see Section 2.1). System throughput will increase with the multiprogramming level for such systems. For memory-constrained paging systems, however, since throughput is convex with multiprogramming level [8], the optimal multiprogramming level is one at which system throughput is maximized. It is important to note that the optimal multiprogramming level is a function of the current workload and system configuration, including the lifetime function that characterizes the paging activities of the particular system.

As in the case of tuning, optimization of the multiprogramming level for paging systems should be done before the iterative process of OPTIMAL begins. This is achieved by evaluating the system at each feasible population from 1 to the current multiprogramming level, but halting as soon as the throughput obtained at level $M+1$ is less than that at M ($M+1 \leq$ current multiprogramming level). The initial optimal multiprogramming level is then set at M. At every step of 1.2 and 1.5 of the iterative process, optimization is also necessary. The optimization is carried out as outlined below.

If the current optimal multiprogramming level is M when an upgrade possibility is considered, evaluate the system at each multiprogramming level $M, M+1, \ldots, max\text{-}M$, obtaining system throughputs $t_M, t_{M+1}, \ldots, t_{max-M}$. The optimal multiprogramming level is the one corresponding to the maximum throughput rate. However, the evaluation process can stop as soon as $t_{M+n} < t_{M+n-1}$ for some $n > 0$ and $M+n \leq max\text{-}M$. In the latter case, the optimal multiprogramming level with respect to the specific upgrade possibility is $M+n-1$. Optimization is carried out in OPTIMAL so that at every step the most cost-effective upgrade measure is determined based on the *highest possible* throughput for each upgrade possibility.

3.2.4 FINE TUNING. Balancing service demands on I/O devices while keeping their service rates and the sum of their visit ratios constant may often result in non-integral visit ratios [4]. One goal of fine tuning is to obtain integral visit ratios based on the non-integral ones such that the throughput obtained with these visit ratios is at least as high as that obtained with the non-integral visit ratios.[4] As the relationship between throughput and visit ratios is intuitively complex, it is only reasonable to try integral visit ratios in the vicinity of the non-integral ones while keeping the sum of the visit ratios constant. Since the practicability of the *final* recommendations of OPTIMAL is the main concern, fine tuning is required only in the final step of OPTIMAL, rather than after every tuning measure.

4 PERFORMANCE OF OPTIMAL

To evaluate the performance of OPTIMAL, a control programme, CONTRL, was set up to enumerate all possible ways of allocating funds to the upgrading alternatives of a given system. Each possible way results in replacement of existing devices by upgrade alternatives and/or addition of new devices in the system. The optimal throughput produced by CONTRL is the maximum throughput over all such possibilities. The optimal throughput and the execution time are used as criteria for comparison between OPTIMAL and CONTRL. For systems with devices having two or more alternatives that are also candidates to be added to the system, and for a sufficiently large budget, it is obvious that the number of possible

[4]Empirical data from test examples on fine tuning have shown that throughput at least as high is achievable.

ways of allocating the budget is very large. Consequently, for most test systems, OPTIMAL performs far better than CONTRL with respect to execution time, and thus this criterion is of less interest here. The criterion of primary concern in such systems is the optimal throughput. A number of hypothetical systems of different complexities have been tested by both OPTIMAL and CONTRL. We present here four sets of typical results (Table 1) together with the input parameters for System 4 (Tables 2 and 3). In all the runs we have made, the improvement in throughput per dollar produced by OPTIMAL is always at least as good as that by CONTRL, and the absolute throughput is within 1.0% from the highest possible for each system.

	OPTIMAL	CONTRL	Conclusion
System 1			
User time	2.4	42.6	For timing,
System time	0.2	12.8	OPTIMAL is
Elapsed time	00:00:14	00:21:06	slightly superior.

Table 3: System 4 Upgrade Alternatives

5 CONCLUSION

OPTIMAL, a software package which provides upgrade strategy based on maximum system throughput per dollar constrained by a given budget, minimum disk capacity requirement and available upgrade alternatives, has been implemented and described in the paper. Various optimization techniques, including optimizing the multiprogramming level and fine tuning, have been used to enhance its performance. Our results showed that OPTIMAL always gives throughputs within 0.0 - 1.0% of the absolute maximum for each system, and with equal or higher improvement in throughput per dollar spent as compared to that obtained with the absolute maximum throughput. OPTIMAL is interactive, prompts the user for input data, and is very easy to use.

OPTIMAL can be easily enhanced to incorporate a more sophisticated set of system performance analysis algorithms, thus increasing its scope of application to cover more complex systems, such as multiple job class systems, and systems with elaborate I/O subsystems.

5.1 MULTIPLE JOB CLASS SYSTEMS

For systems in which the jobs being modelled have significantly different behaviours (for instance systems with a mixture of CPU and I/O bound jobs), a multiple class model can provide more accurate results. To include multiple job class systems, it is only necessary to modify OPTIMAL to accept the workload characteristics of each job class and to use exact MVA that models multiple job class systems in steps 0, 1.2, 1.5 and 4 to obtain throughput values for each job class which are then summed to produce the system throughput.

5.2 I/O SUBSYSTEMS

Because of advances in VLSI technology, processor, main memory and other purely electronic components of the computer system have outpaced the advancement in I/O subsystems that use rotating device technology. Consequently it is not uncommon for current systems to have bottlenecks in I/O components rather than CPU or main memory. A common I/O subsystem consists of various elements of varied intelligence: channels, controllers, string heads, disks. Being able to locate the bottleneck element in a highly utilized I/O subsystem is a key to improving system performance. The current implementation of OPTIMAL captures the details of an I/O subsystem in the disk service demand obtained from measurement data. Thus a more sophisticated modelling approach, such as the one suggested in [8], is necessary to account for the effect of improving each I/O subsystem component on system performance.

ESTABLISHING USEFUL BUSINESS RELATIONSHIPS

Dr. Leilani E. Allen
Amdahl Corporation

ABSTRACT

Capacity Managers (CM) are constantly placed in the position of negotiation among conflicting interests—be it with vendors, users, peers or supervisors. Thus, it is essential that CM professionals acquire this essential management skill. The key to be a better negotiator lies in understanding basic organizational principles and using them to analyze behavior. This paper describes these principles and shows how they may be used by the CM in a negotiation process.

INTRODUCTION

One of the most difficult problems that CM's face is the need to establish effective business relationships with user departments. More so than many other areas within Information Systems (I/S), CM's must actively seek information about the business to include in their forecasts and projections. They must keep users apprised of the data center's plans, and must often act as the data center's representative in project meetings. CM's very often serve as leaders within I/S as well, getting various areas to agree on longer-term strategies and directions.

To be successful, CM's must acquire solid management skills, including the ability to understand how organizations operate. They must understand what motivates their colleagues to act the way they do. They must learn to work within the organizational culture to achieve their aims. In short, CM's must understand and become adept at organizational politics.

This is especially critical if we understand that probably the most fundamental task of management is negotiation. Negotiation is here defined as "the process for achieving consensus to a common goal, plan or strategy." This is really the key to building more effective business relationships. CM's in particular must learn how to negotiate with peers, superiors, users and external vendors. And negotiation is a learned skill.

This paper is written for managers and planners who seek to improve their negotiation skills. It begins with a discussion of two basic philosophical models that serve to guide human behavior. It then discusses one of these models in greater detail, describing two fundamental organizational principles that can be applied in the context of the corporate culture. Then it describes the negotiation process in detail, illustrating the points by means of a hypothetical service level agreement (SLA) negotiation.

ORGANIZATIONAL MODELS

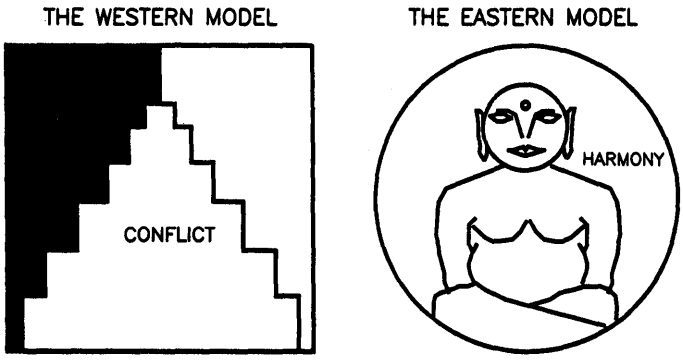
One of the distinguishing hallmarks of any culture is its belief system concerning the way the universe functions. This is as true for the United Nations as it is for the Bushmen of the Kalahari or Acme Enterprises. From this belief system comes a set of norms, or behaviors, that are tolerated within the culture.

The belief system usually includes a philosophical mode. Most models are fairly simplistic and can be summarized in a few key phrases. This is precisely what gives these models their power—they do not require extensive analysis or intellectual effort.

Two fundamental models have been with us since the dawn of civilization. One arose in the East, in Asia, and was based on the view that the universe was a whole.

Man was simply a part of the whole (and sometimes not even the most important part.) the goal in this belief system was to seek harmony between the various elements of the universe--Harmony with Nature, Harmony with God, Harmony within Oneself, Harmony with Others. The fundamental behavior was to seek "cooperation" to maintain this harmony.

FIGURE 1: TWO PHILOSOPHICAL MODELS



The other model arose in the West, in Mesopotamia. The Babylonians and Sumerians viewed the universe as divided into the opposing forces of Light and Darkness. Each side struggled for supremacy, with human beings becoming involved in the struggle almost as pawns. This Conflict Model was adopted by most major Western belief systems, variously characterized as God versus the Devil, Man versus Nature, Democracy versus Autocracy, the Good Guys versus the Bad Guys, Us against Them. It is still the fundamental organizing principle for most Western institutions.

I wish to emphasize that either model can be applied in any culture. Indeed, it can be argued that Sweden has largely adopted the Cooperative model, while the Chinese since 1948, have largely operated on the basis of the Conflict model. Clearly, one is not more valid than the other. In this country, many of the analysts of Japan, Inc., or the gurus of excellence point to the benefits to be derived from viewing the marketplace (and certainly the enterprise) as a vast, interconnected whole in which

conflict avoidance and mutual advantage are the guiding principles for behavior.

However, most of us still work in business settings in which the Conflict model is the norm. Therefore, analyzing its key beliefs in more detail is an essential starting point for our discussion of business relationships.

THE CONFLICT MODEL

Two of the most fundamental principles of organizational behavior arising from the Conflict model are:

1. The Balance of Power (BOP).
2. The Iron Law of Oligarchy (ILAW).

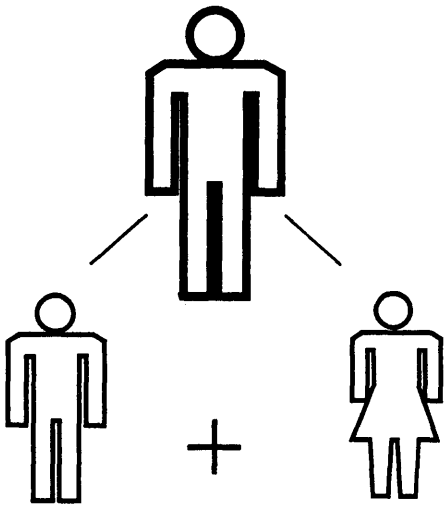
THE BALANCE OF POWER

The Balance of Power (BOP) concept states that we all live in a world of scarcity--that there are never enough resources, goods, wealth or prestige available to satisfy everyone. Therefore, conflicts will arise over who should control these scarce commodities. The degree of control an individual, group or national entity exercises over these commodities is a direct reflection of that entity's power.

In the BOP concept, such issues as friendship or morality should have nothing to do with the contest between entities. Rather, each entity is motivated to act on the basis of its perceived interests. It is not wrong or immoral to seek to strengthen one's position of power; it is the natural way of things. We should not be surprised by tactics of aggrandizement; rather, we should expect them and be able to counter them to our own advantage. An "enemy" is simply an entity who is seeking to acquire commodities to our disadvantage. A "friend" is another entity who is as interested as we are in stopping (or at least minimizing) that effort.

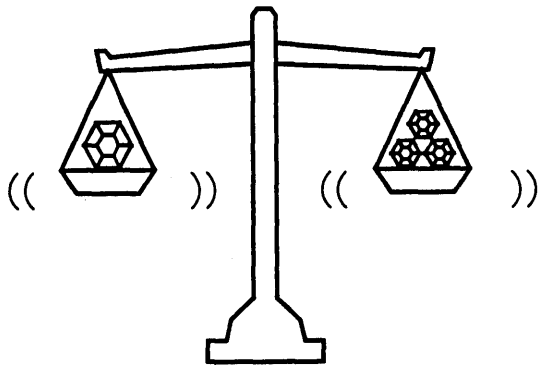
This is the basis of strategic alliances. Two entities who might have nothing much in common can join together to counter the moves of a third party. This alliance is made purely on the basis of mutual interests. We do not have to like or approve of our alliance partner. Indeed, we both recognize that, given the shifting nature of events, we will probably find ourselves on opposite sides in the next controversy.

FIGURE 2: STRATEGIC ALLIANCE



This is where the concept of "balance" comes in. BOP sees the world as a multi-armed scale, with one set of entities and the commodities they control balanced against the other sets. When one entity upsets the balance, all rational participants seek to reconfigure themselves in such a way as to restore the balance. This can mean seizing or neutralizing the rogue entity's resources, undermining its strategic alliances or presenting a show of force.

FIGURE 3: MAINTAINING THE BALANCE



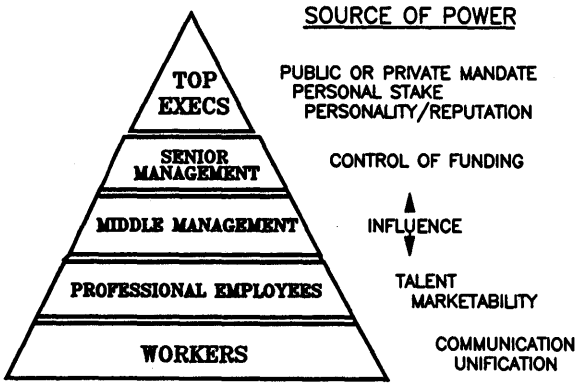
Lest this sound like a totally bloodthirsty approach, consider that BOP always prefers negotiation to war. Wars have a terrible effect on the balance of things and they destroy scarce commodities. Victories can be Pyrrhic; the long-term consequences of war are hard to predict. Negotiations are much more controlled and almost always lead to outcomes that restore the BOP and order.

Consider too, that although BOP denies that morality should be the basis of interaction (because morality is subjective), it also denies that prejudice should play a role. Thus, anyone who can influence the BOP should be a part of the negotiation, however humble they might be. BOP also seeks to preserve all the players in the game, because power vacuums are dangerous. The successful player recognizes these basic rules and uses them to full advantage in negotiation.

IRON LAW OF OLIGARCHY

Iron Law of Oligarchy (ILAW) finds that, in any organization, a power structure exists. At the tip of the power structure is an elite, and it is the elite which actually rules. This is as true for democracies as the most rigid totalitarian state; as true for "matrix organizations" as the conventional corporate hierarchy. Any mass organization will, over time, come to be ruled by a small elite or oligarchy.

FIGURE 4: THE POWER STRUCTURE

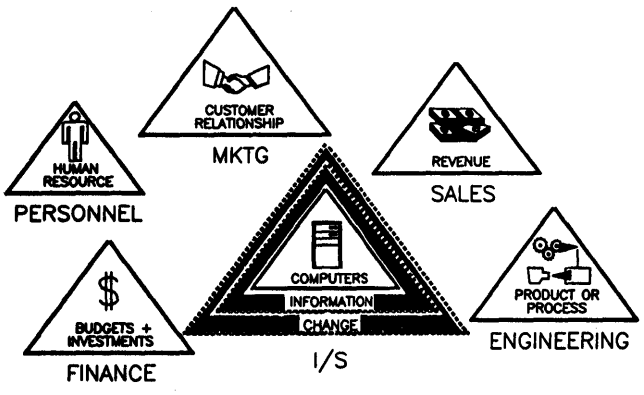


Now, organizations differ considerably on how they select these elite few, and what kind of constrictions are placed on them once they are in power. In more democratic organizations, the masses are formally elect representatives which have been carefully preselected by the elite from among their own ranks. In other organizations, different groups within the elite battle for positions of preeminence. Some rulers are explicitly recognized as such, others are "powers behind the throne." Yet, in no organization are the majority of decisions made by the masses.

This principle requires us to conclude that the average person has little to do with decision making. It can lead to cynicism and inaction. However, the positive side to this law is the fact that for any given decision, the number of decision makers involved is usually quite small. Certainly the numbers are small enough that we can identify the decision makers and seek to influence them. Thus, if we look at change as an incremental process, involving a slow series of small but significant decisions, it should be clear that we can position ourselves to be part of that decision-making process.

There are any number of ways of doing this. Some cultures admit members to the elite only by way of birth or sometimes marriage. Other cultures include or exclude members based on race, sex, religion, education, age or wealth. Most corporations are meritocracies, in which membership in the elite is a function of particular skills or talents, usually defined as the ability to make money for the enterprise. Most government agencies use longevity as the key criterion for entry into the elite.

FIGURE 5: POWER BASES



Corporate cultures differ as to the stress they put on certain skills or talents over time. Originally, the ability to engineer or manufacture products was the key skill. Nowadays, it is the ability to manage corporate finances which seems to be the key ingredient to the top. In the future, it may well be the ability to manage change.

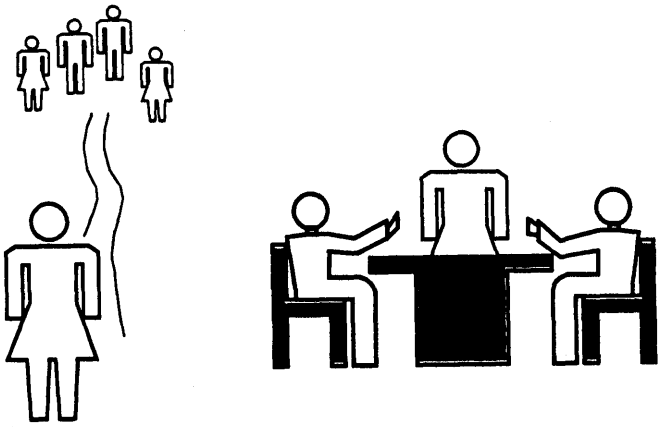
CAPACITY MANAGEMENT

Capacity management professionals can use these organizational principles in a number of constructive ways. First, they should be able to identify I/S's base of power and how that power base affects its role in the organization. They can realize that the source of conflict between their own department and other areas of the company has much less to do with technology than with the desire to control scarce and valuable resources. Technology is never neutral--it changes the way people are organized, the way they work, the way they make decisions. Other departments naturally see this as a threat to their own position within the power structure.

On the positive side, CM's should use BOP to analyze the operational departments more carefully, identifying opponents and potential allies. They should see that given the issue at hand, the roster of allies versus enemies can shift. Therefore, a fair amount of constraint and demonstrations of goodwill are called for, so as not to irrevocably antagonize any entity. Most good or universal truth will do little to marshal support for their plans, but that appealing to mutual interests is far likelier to ensure success.

CM's have two ways of responding to ILAW. They can seek to become part of the decision-making elite by demonstrating their business acumen, or they can maximize their specialist talent and become a trusted advisor to that elite. Both paths have advantages and disadvantages. But the choice always begins with understanding the organization's culture, identifying the oligarchy, and acting in such a way as to support the oligarchy's visions and goals.

FIGURE 6: MEMBER OR ADVISOR?



Obviously, I/S is not alone in seeking to enter or influence the oligarchy. Most savvy employees are attempting to gain the elite's recognition and approval. This usually takes the form of successfully developing and implementing programs and projects. This requires resources. Thus, there is always a contest for power in organizations, usually involving the acquisition and control of resources. Resolving these power conflicts is the function of managers through a process of negotiation.

NEGOTIATION

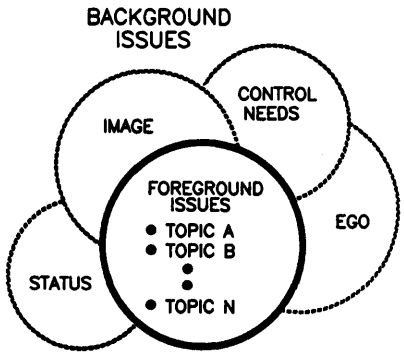
BASIC PRINCIPLES

We are constantly involved in negotiations of one kind of another, whether in our personal or professional lives. Yet, it is curious how seldom we take a rigorous approach to the subject. Somehow, being a good negotiator is viewed in a negative light, as if only slippery characters or Machiavellian mentalities were truly good at it. But negotiation, like so much else, is a learned skill. Moreover, it is the essential skill of management.

How can we improve our odds in any negotiation? There are two key principles to apply. The first is to understand that any negotiation is a joint enterprise, not a solo effect. The very heart of negotiation is a give and take between two or more parties. Thus, preparation for the negotiation must focus on not only one's own requirements and aspirations, but those of the other party as well.

In this process, it is important to distinguish between tangible and intangible outcomes. That is, a negotiation may have specific points or topics that need to be resolved. These are the foreground issues--"What should response time be?" "What specific performance issues will be included in the system requirements document?" "What factors will be included in the CPU purchase agreement?"

FIGURE 7: TANGIBLE AND INTANGIBLE OUTCOMES



The intangible outcomes revolve around the ego or psychological needs of the participants. These background issues include, "How will I look to my peers or my boss??" "How important is it to appear to be in control of the situation?" "How necessary is it to have decisions appear as if they came from the other side?" A truly successful negotiator spends as much time worrying about perception as about reality.

Inattention to this principle has resulted in many people coming away from a negotiation with a sense of victory only to find that their presumed adversary is actively taking steps to negate the outcome. In this case, the win has been strictly on the tangible side. The opponent's commitment to the solution has not been achieved. The performance analyst does not want to negotiate such tough requirements that the applications designer will use this as an excuse for project delays. The planner should not impose such penalties on users in a Service Level Agreement (SLA) negotiation that they feel abused and free to denigrate the department.

The second basic principle to remember is that real life rarely affords a demonstration of a WIN/LOOSE scenario. Almost all outcomes are compromises. Again, compromise may be viewed in a negative light. but the alternative to compromise is statis, a condition of complete immobility. WIN/LOSE games are tantalizing but they are rarely the means to long-term success.

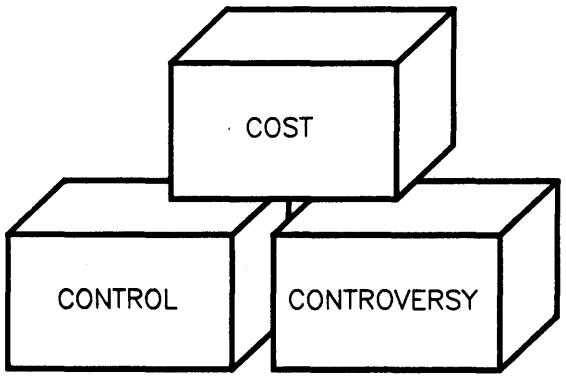
A METHODOLOGY

There are a number of specific steps that can be taken to encourage more successful outcomes using these two principles. Step One is to establish the true topic of the negotiation. That is often not as easy as it sounds. What appears to be a simple agreement on IMS response time and availability might actually be the first step toward a chargeback system. The negotiation may involve obtaining support and concurrence on the new policy. The user representative may be apprehensive about the long-term consequences of this change, and may feel that concessions made now will set unwelcome precedents.

The best negotiations are straight forward and focused. It may be necessary to explicitly state that each negotiation is a separate deal and that any agreement made now will not be used in future agreements. This should increase the flexibility on both sides.

Step Two is to identify all the necessary parties to the negotiation, that is, anyone who has a vested interest in the outcome. Not including participants means running the risk of having the outcome overruled. For our IMS SLA, users or project managers may seek to sell their viewpoint to higher ups and undermine the CM. Rather than gnashing teeth over the underhandedness of this approach, one should adopt it. An understanding of both the formal and informal corporate structure should include knowing who will ultimately commit to the agreement and what is likely to influence the decision.

FIGURE 8: THE THREE Cs'



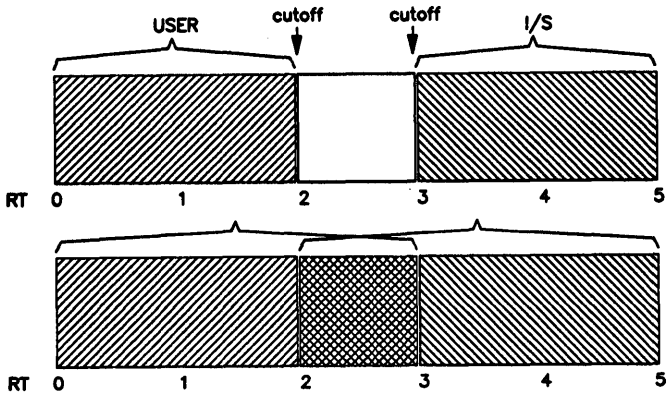
Typically, decision makers are concerned about the three "C's", Cost, Control and Controversy. A given project or program should meet certain cost/benefit criteria as established by the enterprise. For instance, the SLA should provide tangible benefits in the form of better workload forecasts to assist in planning upgrades, or more reliable response times to allow the users to manage their workflow. The project proposal should include sufficient mechanisms and controls to ensure that management has a reasonable chance of achieving a desirable outcome. Essential controls in an SLA include the ability to identify and explain noncompliance with the service level objectives.

Finally, the project should not create undue controversy--it should not seriously threaten organizational efficiency, effectiveness or public image. I/S management must be convinced that the SLA will smooth or regulate relations with the users and will allow the department to improve its image. User management must believe that the SLA opens a communications channel to I/S to allow their particular needs to be satisfied.

Having identified the participants, it is necessary to establish and rank their tangible and intangible objectives. Clearly, the greater the knowledge of the other side, the easier this will be. Sometimes some informal fact finding with colleagues or associates in other companies is appropriate. It is extremely difficult to negotiate with strangers. For the SLA, some research into the personalities involved, their "hot buttons", particular strengths and weaknesses and special situations would be recommended.

Once the issue lists are completed, the Fourth Step is to draw a line at each side's cutoff point. This is the place beyond which one could not compromise, the true bottom line for any negotiation. If the bottom lines are mutually exclusive, serious negotiation at this stage is probably a waste of time. It will then be necessary to go back to management to authorize changes in terms.

FIGURE 9: CUTOFF POINTS

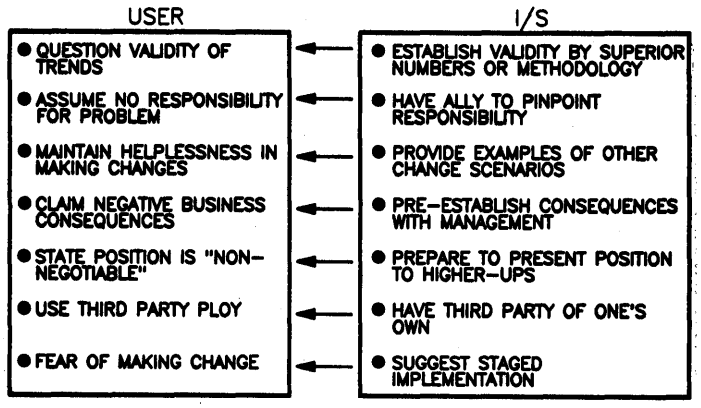


For instance, the user department might have made commitments to external customers which require two seconds or less response time for 90% of all transactions during peak periods. The CM knows this goal cannot be achieved without upgrading the CPU, an option which his/her management has absolutely rejected during this fiscal year. The negotiating positions are mutually exclusive. I/S and user management must create some flexibility in their own positions for the negotiation to work.

If there is still room for maneuvering, an assessment of strength should be prepared. This denotes what forces each side can bring to bear to win the issue. This might include such things as budget, personnel, time, management commitment, support from third parties, better information or more experience. In an SLA, I/S brings knowledge of the capabilities of the hardware and software management commitment and trained personnel. The user might bring support from third parties and budget clout.

The final preparatory step is to prepare a list of tactics. For instance, "How do I intend to establish certain facts or support my demands?", "How can I defuse the negative aspects of this position?", "How can I effectively play off one side against the other?" An equivalent list of tactics should be made for the other side, along with notations on how each of his tactics will be countered.

FIGURE 10: TACTICS AND COUNTERS

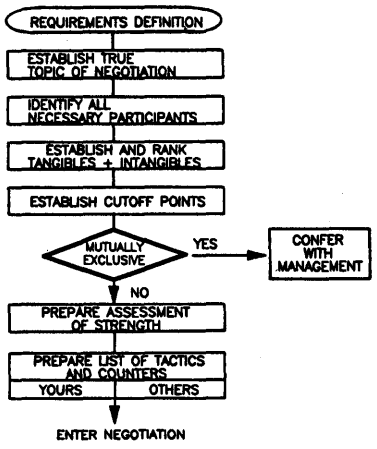


USER
I/S
● QUESTION VALIDITY OF TRENDS
● ESTABLISH VALIDITY BY SUPERIOR NUMBERS OR METHODOLOGY
● ASSUME NO RESPONSIBILITY FOR PROBLEM
● HAVE ALLY TO PINPOINT RESPONSIBILITY
● MAINTAIN HELPLESSNESS IN MAKING CHANGES
● PROVIDE EXAMPLES OF OTHER CHANGE SCENARIOS
● CLAIM NEGATIVE BUSINESS CONSEQUENCES
● PRE-ESTABLISH CONSEQUENCES WITH MANAGEMENT
● STATE POSITION IS "NON-NEGOTIABLE"
● PREPARE TO PRESENT POSITION TO HIGHER-UPS
● USE THIRD PARTY PLOY
● HAVE THIRD PARTY OF ONE'S OWN
● FEAR OF MAKING CHANGE
● SUGGEST STAGED IMPLEMENTATION

For example, the user might charge that response time has traditionally been bad and is getting worse, causing projects to slip. The CM should know the performance history of the application and be able to challenge the validity of this claim and point to other possible causes. The users might maintain that they have no control over when work is submitted to the computer. I/S should investigate the work processes in that department to determine whether control is impossible or just untried. Here the CM might offer to negotiate with a third party for assistance.

In this way, it is possible to rehearse the process in advance and the surprise factor is minimized. This will allow greater control of the situation, which means better odds of achieving goals. Even if all the goals are not achieved, the other side is likely to be impressed by the CM's thoroughness and coolness under pressure.

FIGURE 11: NEGOTIATION STRATEGY



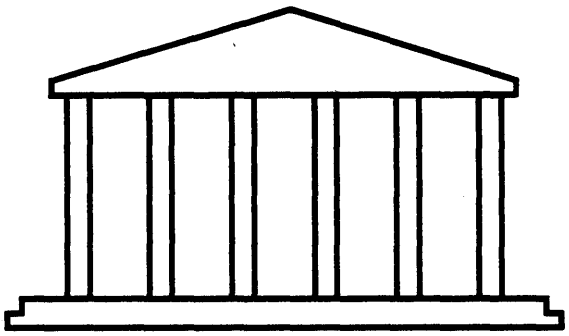
BUSINESS RELATIONSHIPS

Clearly, negotiating is a learned skill. These preparations can be complicated and time consuming the first time through. But with time they can become almost unconscious. The key to success is

understanding that opposition to one's plans and ideas is not the result of malice or stupidity. It is a natural consequence of a world view that sees conflict as the basic mode of human interaction.

The message of this paper is that this model, and the organizational principles that flow from it can be used in a positive way to build effective business relationships with our colleagues. The key is successful negotiation where conflicts are resolved in a mutually satisfactory way. Justice Louis Brandeis has observed,

"Harmony in...life is a resultant of the struggle between contending forces. In frank expression of conflicting opinion lies the greatest promise of wisdom."



"Harmony in...life is a resultant of the struggle between contending forces. In frank expression of conflicting opinion lies the greatest promise of wisdom."

– Justice Louis Brandeis

A SYSTEMS ENGINEERING LOOK AT SAA

James R. Cook, Managing Partner

Data Strategies, Systems Management Consultants

ABSTRACT

Most experienced I/S planners pay considerable attention to vendors' statements of direction. Architecture statements, which are much rarer, are even more valuable as planning guides, because they represent a technical plan as opposed to a marketing plan. If history is any guide, many of us will find IBM's Systems Applications Architecture occupying much of our professional lives for the next several decades, just as our counterparts of fifteen years ago became obsessed (or possessed) by SNA.

Recognizing that many of the implications of SNA could have been predicted from the original descriptions of the architecture, I have applied the techniques I generally use to assess competing products for vendors to the limited information currently available on SAA. Based on this analysis, I have developed some startling (and surely controversial) predictions, among them:

- The end of the System/370 architecture,
- The obsolescense of 3270-type terminals, and
- The "demise" of CICS!

I hope the readers find the conclusions as thought-provoking as I do.

1. INTRODUCTION

"...the SAA announcement was by far...IBM's most important statement in a decade....More than any new product, SAA defines the future for IBM and its customers."

David Kull, *Computer and Communications Decisions*

Most experienced I/S planners pay considerable attention to vendors' statements of direction. Of course, it makes good sense to pay attention when vendors tell you what they plan to do in the future. Architecture statements, which are much rarer, are even more valuable as planning guides because they represent a technical plan as opposed to a marketing plan.

In recent history, IBM has only made two major architecture statements: SNA in 1974 and this year's System Application Architecture announcement. Various industry analysts have claimed that SAA is everything from marketing hype to an attractive but unlikely pipe dream.

I see SAA as more than any of these things. Beyond the narrow limits of the announcement, I see a reflection of irrefutable technological and economic forces which will significantly change mainframe computing as we know it. I believe that the support for my beliefs has been made numerous time, in print, by various IBM developers. I have attempted to bring these statements together within the framework of the SAA announcement and to that end have extensively quoted a number of articles and authors.

I expect my comments to be controversial; after all, they imply the obsolescence of many vendor products (both IBM's and others). Since no ones crystal ball is perfectly clear, I recommend that you read my analyses and draw your own conclusions. But I remind those who discount SAA as a major force that, when originally announced, IBM's System Network Architecture was only supported by the DOS/VS operating system and the only SNA terminals were on the 3600 Finance Communication System.

2. WHAT IS SAA?

"Systems Application Architecture is a collection of selected software interfaces, conventions, and protocols....[It] will be the framework for development of consistent applications across...future offerings..."

Systems Applications Architecture An Overview

Opinions differ as to just what SAA is. There is the established viewpoint of industry analysts, and there is a considerably broader view (held by myself) which is outlined in the following section. Of course, neither of these viewpoints is important. The important view is held by IBM and that will not be revealed until it makes good marketing sense.

2.1. THE COMPONENTS OF SAA

Like most architectures (e.g. SNA), SAA is most easily described as a series of related layers which will be implemented across each of the applicable operating environments. These layers are:

- The Common Programming Interface
- The Common User Interface
- The Common Communications Support
- The Common Applications Library

The contents of and relationships between these layers are shown in Figure 1.

2.1.1. SAA's OPERATING ENVIRONMENTS. SAA is specifically directed toward "...the three major IBM computing environments..."[1] which are defined as:

- o System/370
  - TSO/E under MVS/XA
  - CMS under VM
- o System 3X
- o Personal Computer
  - Operating System/2

I prefer to think of these environments as: mainframe systems, departmental (small-work-group) systems, and individual systems because the functional requirements at each level are more indicative of the nature of operation than are the operating systems. For example, a 9370 has more in common functionally with a System 38 than with a 3090 in spite of the fact that they may both run MVS.

2.1.2. THE COMMON PROGRAMMING INTERFACE The components of The Common Programming Interface fall into two categories: common languages and common services. SAA will contain specifications for each component and applications which conform to these specifications will operate consistently under any of the three environments.

The currently supported languages are: C, COBOL, and FORTRAN supplemented by an Application Generator based on Cross System Product and a Procedures Language based on REXX.

The Services consist of Structured Query Language (SQL) for database access, a dialog interface based on the current implementation of the EZ-VU product for the PC, presentation services which are based on S/370 GDDM but clearly borrow heavily from Microsoft Windows, and a report generator based on S/370 Query Management Facility (QMF).

2.1.3. THE COMMON USER INTERFACE The user interface specification will provide commonality in three categories physical, syntactical, and semantic. Physical consistency will ensure that the user interface hardware (e.g. keyboards, displays, etc.) will have the same physical layout. In other words, you can expect your PC to have a keyboard suited to a mainframe for the foreseeable future.

Syntatical consistency will ensure that the location and sequence of presentation of information on displays will be the same across systems and applications. It will also "force" keystroke sequences controlling generic functions to be identical. The current implementation of PF5/6 for Page-Up and Page-Down when using the PS/2 configurator, as opposed to PF7/8 as implemented by ISPF, or PgUp/PgDn as labeled on the keyboard, is an example of lack of syntactical consistency.

Semantic consistency means simply that commands which have the same name will produce the same effect when executed regardless of the operating environment.

2.1.4. THE COMMON COMMUNICATIONS SUPPORT SAA's communications support is its most fully defined element probably because the prior existence of SNA enforced a greater level of consistency among the communications products and implementations. In fact, there are multiple implementations corresponding to most of SNA's several functional layers. Figure 2 lists these implementations, the SAA functional category in which they are grouped and the corresponding SNA transmission layer to which they apply.

2.1.5. THE COMMON APPLICATIONS LIBRARY Common Applications refer not to a product or facility but rather a commitment from IBM that it will develop some applications which conform to the SAA specifications. "These will be key applications that satisfy a significant customer need for use *across the three Systems Application Architecture environments* (emphasis added)."[2]

Allowing for the fact that a list of "key applications" that span all three environments is clearly limited, the Common Applications are currently the most insubstantial portion of the SAA specification.

2.2 WILL SAA CHANGE COMPUTING?

"The announcement is as significant for what it doesn't say as for what it does"

Philip B. Ross, V.P. Research,
Management Science America

"...prominent products...that did not make the SAA list may face tenuous existences"

David Kull, *Computer and Communications Decisions*

"...IBM plans to continue to support the execution of existing applications, thus conserving customers' current investments"

Systems Applications Architecture An Overview

While SAA is obviously still in the early stages of definition, it is equally clear that a siginificant effort has been made to "map" the existing IBM product base into the framework defined by SAA. As a result, some relatively obscure products (e.g. REXX, EZ-VU) are included in the specification while some prominent products are not.

2.2.1. THE COMMON PROGRAMMING INTERFACE. The initial emphasis of the SAA architecture is clearly programming. Since languages are of utmost importance to programmers, it is interesting to analyze the languages that SAA will support in contrast to the ones that have been omitted. COBOL, FORTRAN, and C are all relatively obvious choices for support. COBOL was mandatory because of its prominence as a business applications development language. FORTRAN support was required by engineers who account for a significant percentage of the usage of the installed base of minicomputers. Since portability was central to the SAA "theme", C, liberally supported by compilers for processors of all sizes could not be ignored.

In fact, all three high-level languages have been implemented on a variety of different machines with widely varying architectures. If a common element exists between the three, it is that none of them depend on specific architectural designs or implementations. Notably absent in the SAA specification are otherwise obvious language choices such as IBM's own Assembler and PL/I. These, I contend, were not included in the specification specifically because it is SAA's long-term intent to eliminate architectural dependencies across IBM's entire product line.

The specification of VM's REXX as the basis for the SAA procedures language is probably due to the additional capabilities it offers over MVS' CLIST language and the ISPF Dialogue Manager.

2. *Ibid.* p 16.

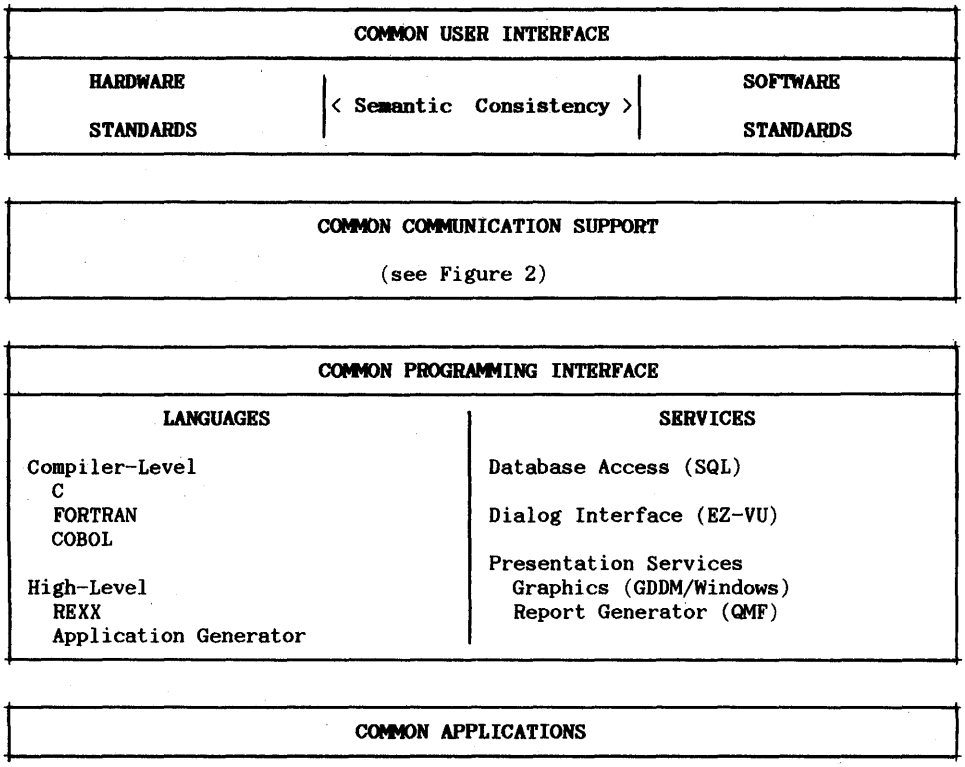

Figure 1. The Components of SAA

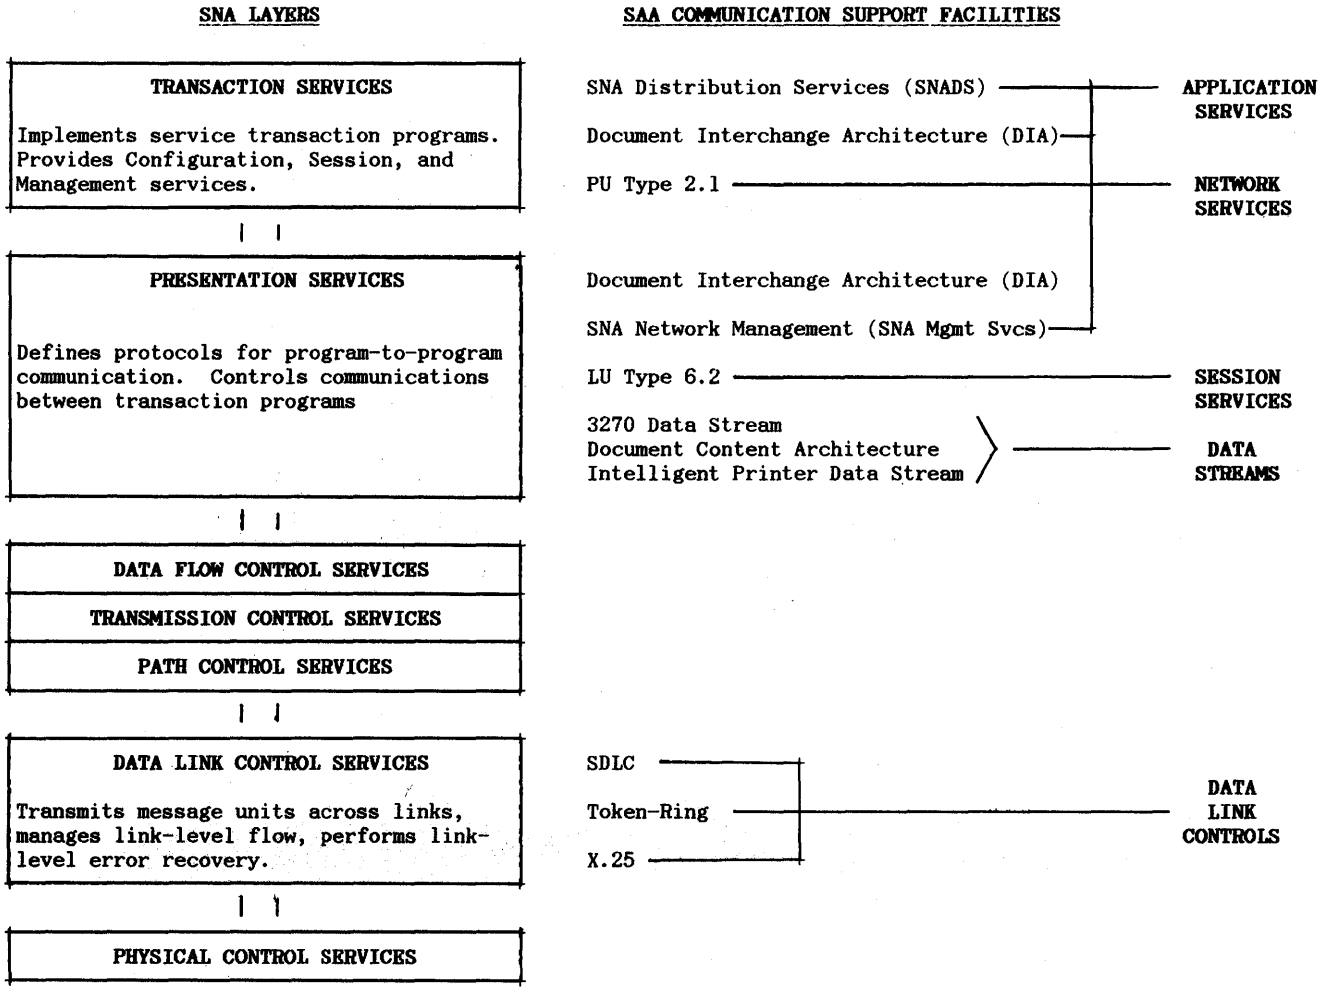

Figure 2. The Relationship of SNA Layers to SAA Communications Support

The Application Generator is the least-defined element in the current specification. While many industry analysts have made much of Cross-System Product being a weak offering, it does indicate that IBM intends to support a split-function generator implementation (i.e. separating the development and execution portions).

Ultimately, these language specifications will impact both in-house developers and vendors. For instance, any shop contemplating starting a major development effort, which might take four years to bring to production and three years of operation to amortize the initial development cost, would have to seriously consider committing to the PL/I language. Similarly, long term commitments to vendor products written in PL/I or Assembler will have to be reevaluated. How soon the SAA "blackball" will begin to be felt remains to be seen. I suspect that it will "trickle up" from the PC world to the mainframe and predict that in another year "SAA Compatability" will be a selling point for some major PC products.

2.2.2. THE COMMON COMMUNICATIONS SUPPORT. The communications suport focuses on program-to-program communication and low-level (PU 2.1) networking. These elements are key to integrating intelligent devices into SNA networks but their potential, if realized, would significantly overshadow existing forms of data communication. In short, as the following statements show, 3270-type terminals are becoming obsolete.

"The high bandwidth of the processor-to-keyboard/display of such systems as the IBM PC cannot be provided with a terminal such as the 327X."

G. Glenn Henry, Manager of Hardware and Software System Development for the IBM PC/RT

"...SNA will continue to exploit advances in technology as they appear. Here, a known requirement is to extend the peer-to-peer operation in SNA. This need follows from developments both in processor design--especially in small systems--and in transmission technology....

Robert J. Sundstrom, Phd. IBM's Manager of Communication Systems Architecture

"OS/2 is going to be...the terminal of choice in host attachments...."

James B. Archer, IBM Systems Manager, Operating Systems and Extensions

More importantly, the applications subsystems designed to support them, specifically CICS and IMS/DC, will also be obsoleted by LU 6.2 functionality. What user would willingly lock himself into a CICS application if he could have windows, pop-up menus, multiple session, graphics, etc., and probably faster response to boot?

3. WHAT WILL THE SAA ENVIRONMENT LOOK LIKE?

"In some years we may think of all of the computing power at a single...site of business activity...as effectively a single node, regardless of its physical disbursement...and...number of 'local operating systems'"

Harold Lorin, Consulting Faculty Member, IBM Systems Research Institute

Most analysts see SAA as an attempt to provide continuity between IBM's many diverse mid-range architectures and its mainframe and microcomputer environments. They imply that such diversity is at best a liability and, at worst, a potentially disabling strategic and tactical blunder.

However, IBM maintains that it:

> ...offers systems based on several different hardware architectures and control programs....[in order] to provide products with outstanding price/performance ratios across an ever-broadening spectrum of customer requirements....[which spans] a nearly thousand-fold capacity range....[3]

This approach makes good sense if these "non-compatible" systems are used in a stand-alone manner or only in concert with each other. And there is reasonable evidence to indicate that this has been the case in the past. No definitive figures are available on the percentage of "departmental-class" minicomputers installed which are attached, in some way, to a mainframe computer, but it is widely reported that IBM expects only 10 to 15 percent of the 9370s to be. Industry analyst Rick Martin of Sanford C. Bernstein & Co., member of the New York Stock Exchange, says "Only about one percent of Digital's installed base communicates with IBM mainframes...."[4]

3.1. DRIVING FORCES

If IBM has found it previously uneconomic to engineer compatability across its product lines, it seems only reasonable that some change has encouraged the SAA effort now. In fact, these "driving forces" have been discussed in several articles in the *IBM Systems Journal.*

Dr. Alan Scherr, an IBM fellow, claims there are strong technical reasons for a tiered approach to information processing. Dr. Scherr sees departmental computing as a logical extension of the distributed computing concepts of the mid-to-late 1970s[5]. He notes that historical trends in configuring systems in networks have resulted from trade-offs based on two factors:

- o the largest systems had the best price/performance ratios
- o the cost of computing was relatively high compared to the cost of communications

This has resulted in four basic configurations of networks being used, all of which are asymetric (i.e. computer-to-terminal) in nature. These configurations are shown in Figure 5.

Price considerations are transitory in nature, changing from one class of machine to another with technological innovation and maturity. However, Scherr claims, there are currently "underlying technology-based pressures that...motivate the design of complex networks of systems."[6] These are:

- o A larger range of available capacity with greater overlap between size-classes
- o No discernable economies of scale between size-classes
- o Communications costs greater relative to computing costs

---

3. IBM Corporation, *Systems Application Architecture An Overview,* GC-26-4341-0, May 26, 1987.

4. Freedman, David H., "digital vs. IBM", *Infosystems,* May, 1987 p. 46.

5. Scherr, A.L.,"Structures for Networks of Systems", *IBM Systems Journal,* Vol. 26, No. 1, 1987, p. 4.

6. *Ibid.*

The range of available capacity gives greater freedom in the selection of a class of machine to address a requirement. Where certain types of database applications might have required a mainframe computer a decade ago, today this requirement might easily be filled by a mini or even a large microcomputer. This cpapcity range applies not only to processor power (MIPS), but to memory and disk storage as well. Inexpensive microcomputers are now available with four megabytes of memory and over two hundred megabytes of disk storage.

End-users tend to think of computing economy in terms of price/performance ratios. This is too simplistic a criteria for assessing the departmental or personal environments. Productivity is a function of the amount of work done versus the total cost to perform the work. Large machines have an advantage when the workloads are large because of their richer hardware and software architectures and because of their typically greater duty cycle. In contrast, smaller machines benefit from reduced costs due to lower software overhead and a simpler structure. Scherr estimates that these factors are roughly equal given today's technology, thus the cost per MIP is approximately equal across mainframe, minicomputers and microcomputers.

Communications costs will not decrease (at least for the foreseeable future) as rapidly as computing costs. Also, sustaining communications absorbs a significant amount of computer power. Scherr estimates that the number of instructions required to retrieve a disk record across a communications link is five times that required to access a local disk. Therefore, placing computing capacity where it avoids communications is an increasingly attractive trade-off.

3.2. LOCATION OF FUNCTION IN A PROCESSOR NETWORK

The location of function in a processor network results from resolving a number of trade-off decisions which may be different for each installation and application. These trade-offs generally involve compromises between ease of use, performance, data access and availablilty. Location has generally implied a class/size of processor, i.e. centralized computing is usually done on a mainframe; however, this is not strictly a requirement. Therefore, this paper will refer to the "direction" of function placement, with *upstream* meaning more centralized and *downstream* meaning more distributed.

3.2.1. EASE OF USE. Small systems have typically offered a richer user interface than large systems. This originally resulted from the requirement for these systems to be useable by a single-user, which implied a consistent, easily learned and understood, "total system" interface supporting installation, operation, programming, and maintenance. The implementation of this interface was made feasible by a high-bandwidth path between the processor and the "console". Such interfaces have set a standard for user interfaces (e.g. windowing, keystroke-by-keystroke responses, and graphics) which are impractical to implement in a terminal (e.g. 327X) environment. Therefore, the optimal place to implement the interface is within the workstation itself.

3.2.2. PERFORMANCE. Performance, except in the case of extremely computation-dependent processes, is largely maximized by minimizing communications requirements. To the greatest extent possible, data should be stored in the node where the application program using it will be executed, thus reducing communication delay.

In addition, the effect of advanced technology is to make incremental increases in "raw" processor power relatively cheaper in small machines. As G. Glenn Henry points out[7]:

> [The] influence of VLSI is a reduction in the fraction of the cost of a computer that is represented by the cost of its logic components....[As a result] the cost of small systems [is] rapidly approaching an asymptote formed by the cost of their frames, covers, power supplies, and manufacturing costs...."

In other words, small systems can utilize extremely advanced logic design as long as they can be physically packaged in relatively small units. Prime examples of this effect are the PC/RT and PS/2 systems which are cheaper than their predecessors in spite of their more elaborate logic designs. As a result, technology has begun to favor smaller rather than larger machines for simply computational workloads.

3.2.3. DATA ACCESS AND MANAGEMENT. Unfortunately, it is frequently not possible to minimize communications simply by placing sufficient processor power locally. Few "front office" applications are isolated to an individual small work-group. Even applications which are highly localized (e.g. branch-office banking, retailing, etc.) require remote access to data to support the "foreign" customer. This implies that either peer-to-peer access to information stored on separate distributed nodes is supported or that a centralized "master file" is maintained.

Data management (synchronization, security and integrity) requirements are independent of data location (upstream or downstream). However, data control is more expensive the smaller the volume of data managed becomes. Thus the liability of less rigorous data managment (or the additional data management cost) resulting from moving data downstream must be weighed against increased communications costs.

3.2.4. AVAILABILITY. Availability is also a major consideration in locating function. From an overall enterprise standpoint, *horizontal distribution* (implementing the same functions in independent peer nodes) results in increased percentage availability[8]; however, the availability to any single workgroup remains the same. Therefore, functions requiring one hundred percent availability may be more effectively implemented upstream where expensive measures (e.g. redundant hardware, fault-tolerant processors, etc.) can be cost-effectively implemented. Note that as logic gets cheaper, it will become more feasible to implement hardware (tightly-coupled) fault-tolerance (a la System 88/Stratus) in smaller processors.

Practically, in current implementations, communications is much less reliable than computing and many more outages are caused by software failures than by hardware failures. Therefore, relatively stable downstream processors are likely to be more reliable than the more volatle upstream processors. On the other hand, upstream processors are more likely to have a larger support staff, thus reducing the mean-time-to-repair (MTTR) a failure.

3.2.5. ACCESS TO OUTPUT FACILITIES. As the user interface becomes more sophisticated, so does the requirement for improved hard-copy output. This creates a demand for expensive output devices such as: laser printers, plotters, slide-makers, etc. These devices

---

7. "IBM Small System Architecture and Design - Past, Present, and Future", *IBM Systems Journal,* Vol 25, Nos. 3/4 1986, p. 325.

8. Increasing the number of nodes decreases the probability that all nodes will be down, assuming the individual reliability of each node is the same. However, it also decreases the probability that all nodes will be up.

are too costly to be attached to an individual workstation, so an additional functional requirement, the ability to share output devices, is created.

3.3. STRUCTURE OF AN SAA COMPUTING ENVIRONMENT

The resolution of these trade-offs implies a four-tier hierarchy (which is totally compatible with the three SAA environments) based on isolation and distribution of data and function in such a way as to minimize the amount of data transfer required to process the majority of the workload. The four tiers:

- o Centralized
- o Enterprise (Site)
- o Departmental
- o Workstation (Private)

are shown in Figure 3.

The end-user accesses the processor network via a workstation which may be a "dumb" (e.g. 3270) terminal but is most likely a personal computer. The workstation stores individual data such as: draft documents, spreadsheets, individual telephone lists, "tickler files", personal schedules, etc. It also stores the programs required to manipulate that data and to support the interface(s) to upstream nodes in the network. These interfaces may be via LAN, APPC (LU6.2), 3270 protocol, DECNET, etc.

The small work-group or *departmental* processor is accessible to all workstations within the group and allows them to share data. This processor also provides communications to the other levels in the hierarchy. Applications related to the primary function of the work-group execute on this processor and data utilized by these applications are stored on this processor. Many of these functions involve external interfaces, such as: shipping, receiving, order entry, accounts payable, accounts receivable, etc. Also supported are generic functions such as: the department budget, document storage, time accounting, information logging, etc.

If no *departmental* applications are run by the work-group, this function can be supported by *servers* (typically a LAN) which provide storage and output device sharing. This is particularly significant (at least in the near term), because the majority of work-groups are not organized so as to minimize the sharing of data with other work-groups. Thus, the previously defined criteria encourages running applications upstream of the departmental level.

The departmental processors at a given site attach to an *establishment* processor. This may be one of the enterprise's "backbone" mainframes or may be another departmental-size processor. This node supports functions which are unique to the entire site such as communications concentration/gateway facilities to the enterprise's wide-area network.

At the upstream "end" of the network is the centralized processor. This is the traditional mainframe location and will typically support the back-office applications and enterprise-wide database support.

3.4. Future Evolution of SAA

The near-term evolution of SAA will certainly change the nature of IBM-compatibile computing. Instead of a highly centralized computing resource relying on large mainframes, the SAA environment might be called an *extended data center* in which processing is largely done remotely and mainframes are utilized for data management synchronization and backup, wide-area network management, and the support of highly centralized applications.

While many of the facilities required in the SAA environment are currently implemented in existing products, what is still lacking is adequate database support. SAA will require a distributed database architecture which can operate across multiple processors and processor architectures and still provide a single database image. This image would include file and record locking/update in a manner transparent to the user. Attaining these capabilities with sufficient performance may bring on SAA's second phase, the replacement of the System/370 architecture.

4. SAA, THE BROADER VIEW

"[A system's architecture is a hierarchy made up of levels. In] a perfectly encapsulated hierarchy...the nature of any level...would be of no concern [except to the level directly above it.] In contemporary systems structure, however, multiple lower levels are visible to a higher-level function."

"The full range of compatibility, portability, and cohabitability issues of current computing systems, hardware and software, derive from the multilayered views that are available to end users, application programs, subsystems, etc."

Harold Lorin, Consulting Faculty Member,
IBM Systems Research Institute

SAA's stated goal is to facilitate portability between dissimilar architectural environments. Few, if any, industry analysts have considered the ultimate implications of this effort. Once the SAA interfaces are in place and the Common Application Library has been populated, it will be possible to migrate mainframe computing beyond the constraints of the System/370 architecture.

Conceived in the late 50's and early 60's, the System/360 architecture preceeds most of the major forces in computing today, such as:

- o Virtual Storage
- o Microprocessors
- o Database Technology
- o Data Communications
- o High Software Cost versus Low Hardware Cost

While virtual storage was later implemented in the System/360 architecture (initially in the Model 67 and with caching in the Model 85), the major contribution of the System/370 evolution was to provide virtual storage as a standard feature of the product line. The recent XA extensions to the System/370 architecture were designed to relieve virtual storage constraints which had developed because of limitations in the original implementation. This section discusses some of the key architectural and design decisions which were made in the System/360 - System/370 implementations and how those decisions have begun to restrict mainframe computing capabilities. With that base, we will discuss various projects and products which foreshadow how future SAA-compatible processors will avoid these constraints.

4.1. THE SYSTEM/370 ARCHITECTURE

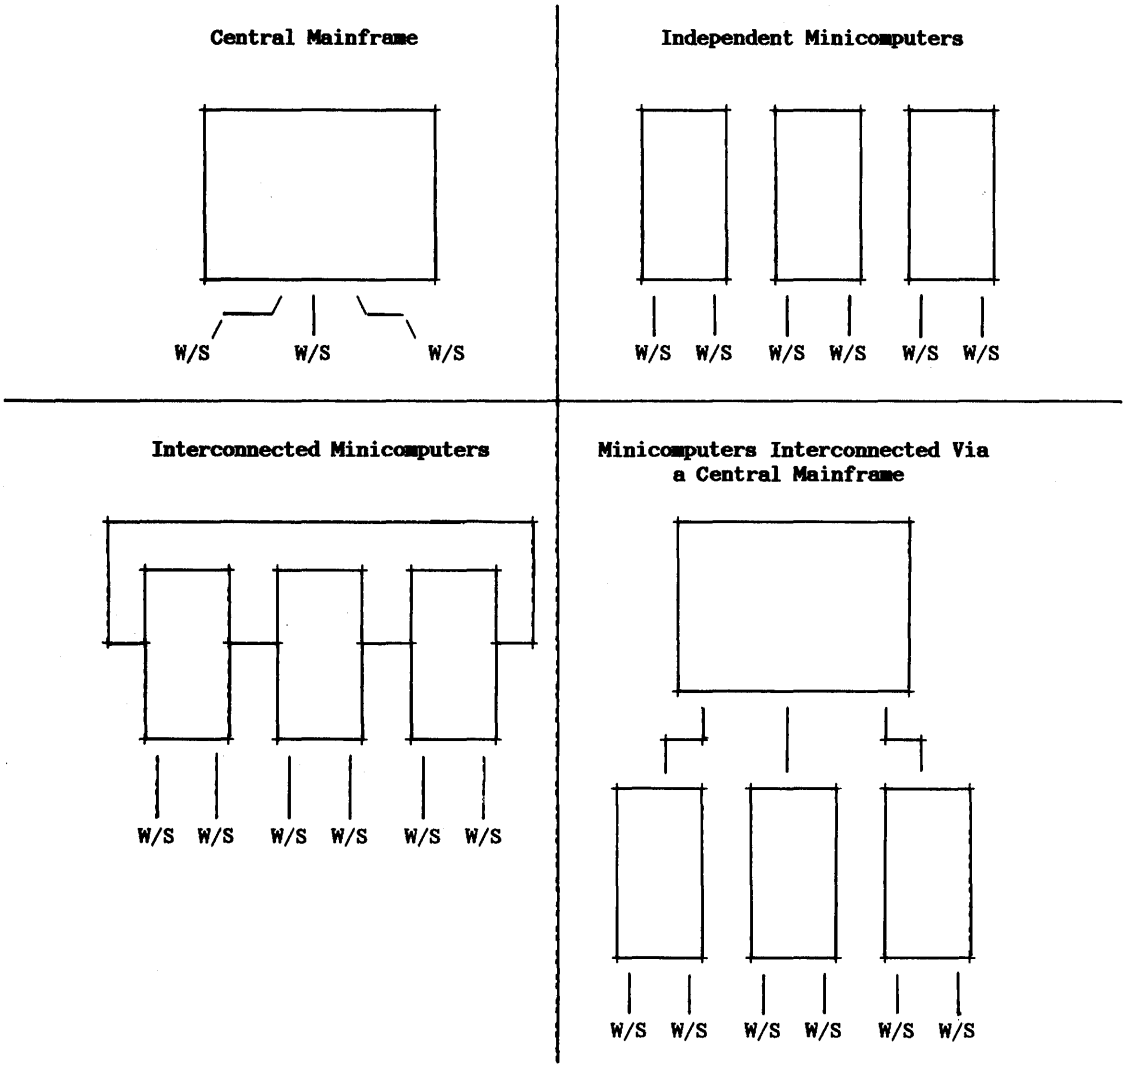

Figure 3. Pre-SAA Network Configurations

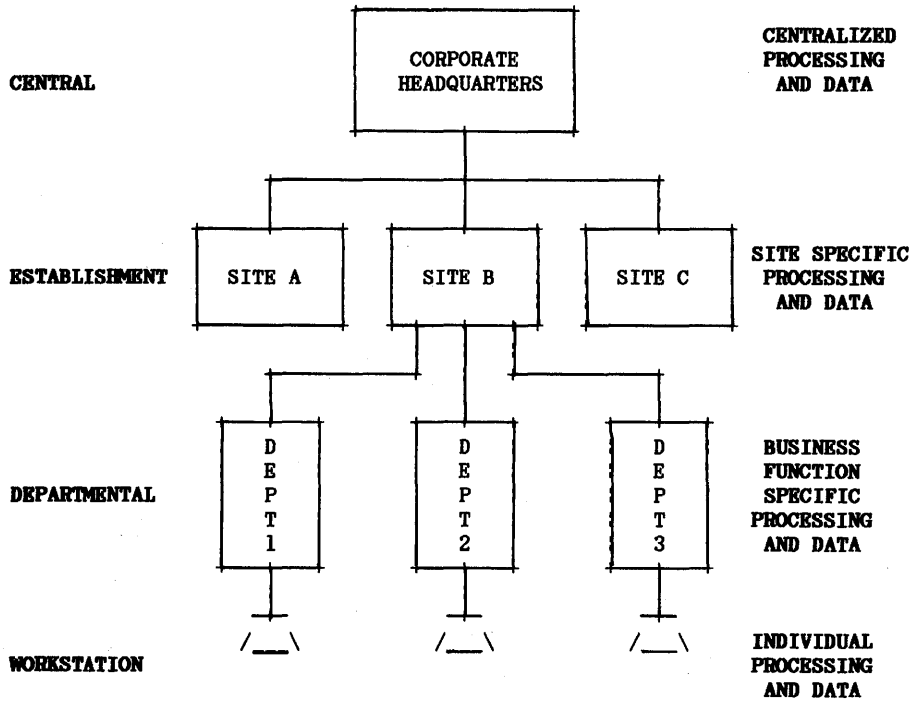

Figure 4. The SAA Computing Hierarchy

"Because they lacked clear criteria, computer architects between 1946 and 1975 tended to specify ever more complex systems....The computers acquired more instructions, more addressing modes, more data types, and more special features."

"The technology to implement a machine with many diverse instructions was provided [in the System/360] by very fast read-only storage that permitted the economical implementation of microcode. This ushered in a new era of machines with a great diversity of instructions."

Martin E. Hopkins, Manager of Compilers,
IBM Advanced Minicomputer Department

The major components of the System/360 implementation are: device-independent I/O and microcoded instructions. The device independent I/O channel architecture resulted from the recognition that I/O devices were proliferating and that supporting them had become a programming burden. The S/360 channel architecture isolated the details of specific devices from the CPU and thus from the programmer. The use of microcoded instructions allowed a large, complex instruction set to be implemented across a wide range of processor sizes; this instruction set contained many specialized instructions which were supposed to simplify programming in specific environments. Thus, the S/360 is very much a programmer's machine, specifically an Assembler-language programmer's machine.

The refinement introduced by the System/370 was cached virtual memory. Virtual memory reflected the programmer's need for larger address spaces because of the complexity of overlay coding. The cache was simply a way to increase the performance of virtual storage.

"In 1975...most System/370 machines were implemented with a cache and microstore....The cache had been introduced to provide faster access to main storage....The CPU fetched instructions from the cache and interpreted them on the basis of a microprogram in the microstore....Neither the cache nor the microstore is part of System/370 architecture."

Martin E. Hopkins, Manager of Compilers,
IBM Advanced Minicomputer Department

The System/370 hardware and operating system implementation is relatively tightly-coupled. A significant portion of the operating system code supports memory management and the implementation of that function is both pervasive and restrictive.

"In software architecture, the concepts of pages and segments as well as the use of segment and page tables for translation are so thoroughly entrenched that they are impossible to change. Early virtual memory designers decided to use tables for translation [because it was argued] that the use of software rather than strictly hardware to do the translation would not lock the architecture....In retrospect, there would be more flexibility in a hardware implementation. With the ever-increasing cost and complexity of system programming and the decreasing cost of VLSI, it is becoming more attractive in many cases to implement functions in hardware rather than software."

Richard E. Matick, Phd.,
Thomas J. Watson Research Center

Twenty-plus years of experience with the System/360 - System/370 architecture has made several things clear:

- o It is very difficult to identify instruction sets that are specific to a particular programming environment.
- o Implementations of functions in hardware may not be more restrictive than software implementations.
- o Tight coupling between the operating system and the underlying hardware tends to restrict the evolution of both.

Based on these observations, SAA can be viewed, in a larger sense, as an attempt to "decouple" various aspects of overall system architecture. We can expect this to be accomplished by more clearly defining the interfaces and separating functions. This effort, over time, will completely change mainframe design.

Key components of the new SAA-compatible architecture are already under development and, in some cases, are partially implemented in various products. The essentials of these efforts are discussed in the following sections.

4.2. PROCESSOR ARCHITECTURE

"A 'good architecture' (processor architecture) should be easily and efficiently represented in the technology, and should provide for simple, efficient compilation.

Harold Lorin, Consulting Faculty Member,
IBM Systems Research Institute

"In 1975 the 801 project was started at...IBM....to reexamine the trend toward complexity. The goal was to discover how to deliver the most computing power at the lowest cost in an environment geared to programmer productivity."

"This architectural point of view has become known as RISC....[which] nicely captures the spirit of research into the premise that less is better."

Martin E. Hopkins, Manager of Compilers,
IBM Advanced Minicomputer Department

Each successive new processor design introduced by IBM has offered increased CPU performance (MIPS) for the same price. Typically, the performance increase has been by approximately a factor of two. A doubling of processor speed has offered sufficient incentive for the installed base to upgrade without "over-powering" the marketplace to the point that future sales are endangered.

Traditionally, this increase in power has been arrived at in one of two ways:

- o The processor is implemented with faster logic
- o The design is made increasingly complex via increased use of pipelining, etc.

Recently, these techniques have been used alternately to increment processor speed. Thus 3033's were designed with elaborate pipelines but relatively slow logic, 3084's were much simpler in design but employed faster logic, and 3090's implement more sophisticated piplines without an increase in circuit speed over the 3084. Each approach involves a trade-off in the length of time required to "perfect" a design and its subsequent reliability in the field.

With the TCM package design (which is the basis for all the above-referenced processors) completed, it became fairly obvious that a maximum reasonable complexity level had been reached and that logic speeds could not be increased indefinitely. This prompted research into alternatives like the 801, RISC-architecture project.

The concept of a RISC (Reduced Instruction-Set Computer) processor is simple. Instruction traces originally performed as part of the research into the caching algorithm for the System/360 Model 85 had indicated that ten assembler instruction accounted for two-thirds of all instructions executed. A RISC machine is designed to optimize the most heavily used instructions and to eliminate from the instruction set those functions which can be accomplished by combinations of simpler instructions.

All instructions in the 801 instruction set can be executed in one cycle. Since the standard System/370 instruction requires eight cycles, this offers a basic increase of nearly an order of magnitude for those portions of the two instruction set which overlap.

Further refinements of the 801 design include thirty-two registers rather than the System/370's sixteen and the replacement of the S/370 microstore with an instruction cache separate from the data cache. More registers means potentially less overhead on branches and the instruction cache allows major routines to be executed at S/370 microcode speed. Thus, the 801 processor frequently offers a twenty-to-one improvement in execution speed over the S/370 with a penalty of an approximate twenty-percent increase in the number of instructions executed.

The advantage of processors based on the 801 concepts are the potential for three-to-four processor generations' "worth" of speed improvements realized without new circuit technology and with reduced complexity in the design.

It is significant to note, that the 801's processor design is near the complexity level of the current 3090 I-unit. This reduced complexity is extremely significant for new product development because it reduces development lead-time and cost. Both time and cost were critical considerations in the original design of the TCM and I suspect any significantly less-complex design which did not reduce performance would be seriously considered. For these reasons, I expect processor design for the SAA environment to borrow heavily from the 801 design.

4.3 OPERATING SYSTEMS DESIGN

"The designers [of the PC/RT]...wanted to achieve a higher degree of program isolation from the hardware...."

"[This is accomplished by using] a Virtual Resource Manager (VRM) to control the real hardware of the machine. The VRM presents operating systems with a Virtual Machine Interface (VMI) that not only conceals the complexities of [the design] but provides the guest operating system with a significantly more powerful set of functions than are available on the bare machine."

"[It is this] system architecture that permits accelerated adoption of new technological advances."

G. Glenn Henry, Manager of Hardware and Software System Development for the IBM PC/RT

"Shall we integrate new function into older operating systems, or should we begin to "hide" these older systems, to think of them only as components of a single operating system that contains all software elements and maintain them only so long as we maintain the architectures on which they run?"

Harold Lorin, Consulting Faculty Member, IBM Systems Research Institute

It has often been rumored, that MVS would become more VM-like (or even that some implementation of VM would replace MVS). Given that SAA implies "decoupling" of architectural components, I would expect that these rumors have a kernel (but only a small one) of truth.

If, indeed, an entirely new processor architecture is to be implemented, then MVS as we know it will be obsolete. Further, I would expect this new processor family to be designed so that it is relatively operating system independent. This could be accomplished by utilizing a facility analogous to the Virtual Resource Manager implemented in the current PC/RT.

The Virtual Resource Manager is essentially an emulator which provides the functions of a well-defined but physically nonexistant virtual machine. The operating system interfaces with this virtual machine rather than with the hardware itself. This design allows for multiple guest operating systems like VM does (which would be mandatory for transitions to a new operating system) but can be implemented without the VM performance penalty.

Use of a Virtual Machine Interface would free both the hardware and the operating system designers from dependence on one another. With the speed at which new hardware developments are being implemented, an implementation which does not provide this separation may well block the logical evolution of hardware (or software) design. In addition, this implementation is well suited to the support of special-purpose hardware such as: application specific processors, associative memory, etc., which would allow tailoring a system to an installation's needs at a much higher level than has been previously possible. For these reasons, I expect operating system design for the SAA environment to be implemented similar to the PC/RT's Virtual Resource Manager.

4.4. MEMORY MANAGEMENT

"...controlling and managing the virtual memory hierarchy is a pervasive task requiring substantial operating-system resources, as well as hardware and architectural assistance. If a very large, fast memory could be implemented to replace the memory hierarchy, substantial simplification in hardware and software could result.

Richard E. Matick, Phd.,
Thomas J. Watson Research Center

"In the future, the largest improvements in performance will probably come about through improving the memory hierarchy."

Martin E. Hopkins, Manager of Compilers,
IBM Advanced Minicomputer Department

"...a machine architecture with massive amounts of [non-volatile] memory...for use as an in-memory database....could do away with resource recovery in the database architecture....[and] provide extremely fast service....The implications of such an architecture are currently under study."

Patricia G. Sellinger, Phd.
Manager of IBM's Database Technology Institute

The design of the memory hierarchy in System/370 reflects a time when memory was relatively expensive. Since the quantity of real memory that could be installed was limited, virtual memory was implemented as a compromise to avoid constraining software development. Essentially, paging can be viewed as a way of standardizing and simplifying overlay coding. Thus, its goal was to reduce programmer effort.

Subsequent developments have dramatically reduced the price of memory and require the evaluation of new approaches to the management and usage of memory. Three trends seem evident:

- o Implementation of extremely large memories is feasible
- o Separation of memory function into instruction and data memory
- o Development of special-purpose memories with built-in associative search capabilities to support database requirements

The first two trends are currently being implemented in a rudimentary way within the existing System/370 architecture. The new 3990 DASD Subsystem supports cache sizes up to 256 megabytes. Even a moderately sized DASD pool implemented with these large cache sizes would constitute a very large "total system memory" which is optimized for data rather than instructions. If the path to these DASD caches had sufficient bandwidth, the distinction between DASD cache and main memory would be further blurred.

Further in the future, is associative memory. This special purpose memory would be capable of doing the compares required by database searches without using the CPU. This is an example of special-purpose hardware designed to support a specific (although pervasive) function.

Regardless of what specific facilities are implemented, we can expect the memory design for the SAA environment to be much less closely associated with the design of the processor. Certainly it will utilize very large memory sizes which may be segmented for specific purposes. Very likely, the control of memory will require a larger portion of the total system's logic than the CPU, just as it currently does in the PC/RT.

4.5. I/O DESIGN

"[The] speed differential between memory and input/output devices...has been the main factor influencing I/O architecture."

"A significant problem with large, fast computers is that of providing sufficient I/O bandwidth to keep the CPU busy....[As a result] each succeeding generation of computers has increasing numbers of channels and I/O devices....If the I/O devices ever become very much faster, many fewer will be required to keep the CPU busy."

Richard E. Matick, Phd.,
Thomas J. Watson Research Center

As processor speeds have increased, the requirement to supply them with data has increased. However, since device transfer rates have not kept pace, this requirement has been satisfied by adding more channels and devices. Clearly, this approach attacks the symptoms rather than the cause of the problem.

Two practical methods of addressing this problem are emerging: deep buffering at multiple levels within the I/O process (mentioned in the preceeding section) and more evenly splitting the I/O workload between the I/O subsystem and the CPU. It is only a small conceptual leap from the current channel architecture to one in which I/O requests are directed to an "I/O processor" which obtains the record and places it into main memory without further intervention from the CPU. This approach would build logically on the currently implemented large cache buffering approach.

4.6. LANGUAGES

"It should be kept clearly in mind that the term *software* really means the use of *general-purpose* hardware rather than special-purpose hardware."

Richard E. Matick, Phd.,
Thomas J. Watson Research Center

"Programming has long been recognized as a bottleneck....because today most programming is done in high-level language....the exact nature of the computer should concern only the compiler writers...."

Martin E. Hopkins, Manager of Compilers,
IBM Advanced Minicomputer Department

"The microcode approach arose in IBM because it seemed necessary to produce....a compatible family of machines with a wide range of cost, [utilizing] the same sort of instructions. Increased reliance on high-level language programming tended to undercut the argument for high-level operations based on ease of programming."

Martin E. Hopkins, Manager of Compilers,
IBM Advanced Minicomputer Department

If System/370 was the assembler programmer's architecture, then SAA will be the application programmer's architecture. The emphasis in SAA will be on languages which are not dependent on the underlying architecture of the processor. For this reason, an assembler for a "true" SAA processor may never be commercially released.

SAA processors will be optimized for compilers. In fact, one implication of the 801 implementation was that manually writing efficient code was non-productive because reordering, linkage conventions, etc., were simply too complex for human beings.

However, I doubt that SAA will endorse HLL (high-level language) implementations in the forseeable future simply because the advantages are too abstract to be measured. Therefore, I don't believe the professional programmer is jeopardized by SAA.

4.7. DATABASES

"The data base of an organization is one of its most significant assets....The existance of increasing amounts of parochially held data is a threat to the efficiency of the organization."

"...it will be necessary to devise ways of making the growing body of data held on small systems available to the remainder of the organization."

G. Glenn Henry, Manager of Hardware and Software
System Development for the IBM PC/RT

"...microprocessors [make] it economically feasible to have computer architectures with intelligent devices such as intelligent disk controllers, database search engines, and special-purpose dedicated machines, e.g., for message processing....One of the key problems is to invent a solution that will not prove obsolete as outboard microprocessors, memory devices, and communications become even faster and cheaper.

Patricia G. Sellinger, Phd.
Manager of IBM's Database Technology Institute

The management, coordination, access control, synchronization, etc., of multiple distributed databases in the SAA environment is going to be a significant task. If I were to guess at an area in which the SAA architecture was most likely to be ultimately self-limiting (as the 370 architecture has been in terms of virtual

storage management), this would be it.

Small systems (e.g. S/38) have recognized the need for an integrated database for some time. I anticipate that SAA will percolate this requirement up to the mainframe and that this database will enjoy significant design and implementation hardware assistance if not actual architectural assistance.

IBM has already stated that its direction lies with DB2. Effective hardware assistance could easily allow DB2 to surpass IMS' (or other hierarchical databases) performance level, especially since that hardware assistance could not be shared by IMS. For this reason, I expect functional enhancements to IMS to taper off in the near future.

4.8. DATA COMMUNICATIONS

"The underlying phenomena that motivates the need for more uniform software interfaces and for more function sharing across units on a network is the anticipation of dramatic improvement in interconnect facility. One provocative speculation comes from the convergence of I/O and local-area network technologies."

Harold Lorin, Consulting Faculty Member, IBM Systems Research Institute

"With the steadily decreasing cost of mini- and micro-processors and storage, more and more of the peripheral nodes are small *systems* such as personal computers, distributed processors, intelligent workstations, and office systems.

"A number of LU types are defined in SNA, with the earlier ones (LU types 1, 2, and 3) optimized for asymetric host-application-to-device communication."

Robert J. Sundstrom, Phd. IBM's Manager of Communication Systems Architecture

"The high bandwidth of the processor-to-keyboard/display of such systems as the IBM PC cannot be provided with a terminal such as the 327X."

G. Glenn Henry, Manager of Hardware and Software System Development for the IBM PC/RT

The requirements of the SAA environment are pushing SNA vigorously toward peer-to-peer communication. SAA will obsolete conventional, asymetric (host-to-terminal) communication simply because it cannot offer the level of features. Specifically, this means that new implementations based on IMS/DC, CICS, etc., are poor investments. More than any other aspect of SAA, this effect will sorely try vendors and end-users alike.

Longer term, SAA will blur the distinction between I/O and data communications. Given that an I/O processor design similar to that discussed previously is implemented and that wide-area networks can be implemented with very high bandwidths, what is the difference between a request for a record from a database on another processor and a "local" I/O?

5. MANAGING THE SAA ENVIRONMENT

Previously we have discussed the effects SAA's layered architecture and emphasis on applications programming will have on the design of various hardware and software components. In this section we will concentrate on the changes that SAA will have on the traditional IS management functions.

Managing the SAA environment presents significant additional challenges to the performance analyst, capacity planner, database administrator, space manager, operations manager, etc. Most of these problems are not actually unique to the SAA environment but are magnified by it either because the site of the problem is physically removed from the management group or because the number of sites in which the problem can occur has proliferated.

The functional effect of SAA's layered architecture is to move many key business processes outboard of the mainframe environment into departmental "servers" as shown in Figure 3. These "servers" may span a gamut of hardware environments, from LAN servers through supermicros to various sizes of minicomputers, and software environments, including MVS, VM, OS/2, non-IBM minicomputer operating systems, and eventually post-MVS mainframe operating systems.

Some analysts have implied that traditional I/S management disiplines such as: performance analysis, service level management, capacity planning, accounting and chargeback, etc., are not important in departmental computing environments because the installed hardware base is so much less expensive. However, an enterprise operating several hundred departmental computers in addition to the mainframes, may actually expend the majority of its total I/S dollars outside the central data center. The fact that those dollars come out of many different budgets and that the individual purchases are smaller does not diminish the total amount the enterprise has "at risk".

Except at the establishment and some mainframe site nodes, these processors will be locally supported by a far less technically capable staff than currently supports mainframe installations. This places considerable additional burden on the I/S technical management personnel. Some of these problem are outlined in the following sections.

5.1. PERFORMANCE ANALYSIS

Performance is a major consideration for adopting a departmental computing configuration. In general, this performance is obtained by minimizing the number of communication delays. In some cases, the performance analyst will be involved in database design decisions. To maximize cost/performance the optimum split between database content at the departmental level, the number of upstream accesses, and cost of synchronizing the establishment and site databases with the departmental database, will have to be weighed.

Accesses to upstream processors will also have to be optimized and subsequent upstream service tracked. This will typically require response time as seen by the downstream node by transaction type. Downstream response time measures will have to be integrated with upstream processor measures to determine the amount of time spent in the upstream processor versus the communication delay.

5.2. CAPACITY PLANNING

One of the significant advantages of a departmental computing implementation is the finer *granularity* of capacity increments available. Because capacity can be purchased, when required, in smaller units, the potential exists for the enterprise to operate with much less average excess capacity. This increases the cost effectiveness of I/S because more of the installed resources are actually being utilized.

Because the capacity increments will be less expensive, less effort will be required to cost justify them. As a result, a natural temptation will be to attack the majority of performance problems with additional capacity. This could result in a far greater percentage excess capacity being installed at departmental sites than would be tolerated in a mainframe installation, thus turning a cost saving opportunity into an increased

expenditure.

Each capacity upgrade will typically require an assessment of upcoming capacity requirements throughout the entire processor "network". In many cases, capacity upgrades will not be made by addition but by substitution. If the replaced processor is owned by the enterprise, a decision concerning its disposal will have to be made. If another node will soon require an upgrade and the previously replaced processor has sufficient capacity a second substitution might be made. This "ripple effect" would proceed throughout the "network" until the enterprise is left with the least expensive processor (smallest, slowest, oldest, etc.) to dispose of to an outside entity.

Given the potential proliferation of hardware and software architectures which could exist, some processors will be replaced by others of compatible, but entirely different design. Correctly sizing these dissimilar machines will require modeling and simulation tools which account for their architectural differences. Thus SAA demands a new, generic view of processor configurations as well as the conventional model-specific view.

5.3. RELIABILITY/AVAILABILITY MANAGEMENT

Enhanced reliability and availability is a further reason to adopt a departmental computing strategy. However, as was pointed out previously, multiple processors increase percentage availability without necessarily improving the reliability of the individual processor. Installations which distribute functions over many small processors can anticipate that one or more of them may be inoperable at any time.

Since few of these small-processor locations will have redundant hardware, potentially long outages will probably be addressed by moving the critical applications to the site's mainframe processor. This is approximately equivalent to offsite backup in today's more centralized environment.

Minimizing the effects of these outages will require extensive incident tracking and correlation of conditions related to outages. Changes which cause instability must be backed off of the hardware/software configurations which they compromise. Similarly, fixes and/or circumventions must be migrated onto these configurations as rapidly as possible.

5.4. INVENTORY/CONFIGURATION MANAGEMENT

Inventory and configuration management is closely related to the reliability/availability management problem. Currently, installations find it burdensome to maintain an accurate hardware inventory for medium-to-large networks. In the SAA environment, this inventory is further complicated by the addition of various processor types and multiple versions of operating system and application software at remote locations. Managing this complexity will require considerably more robust inventory management tools than exist today.

For example, a given departmental processor might support three "front-office" applications in addition to three office automation applications (e.g. word processing, electronic mail, personal calendar, etc.). Each of these applications might exist at one of three maintenance/enhancement levels, old version, current version, or new version. In addition, these applications might be supported under three different operating systems: MVS/IS, VM/IS, and a non-IBM operating system such as VMS. Each operating system environment might be supported on two different processor models and at three different release levels analogous to the application levels. This results in potentially 189 distinct software environments. If the enterprise operates 100 departmental installations, each of which have different hardware configurations, the overall installation complexity is dramatically increased.

5.5. DATA MANAGEMENT

Data management in the SAA environment is similar to software management and places additional loads on the configuration database. Because the upstream mainframe processor will be required to backup its associated departmental processors, critical downstream databases will have to be replicated upstream. These databases will have to be synchronized at intervals depending on the downstream transaction volume. This technique may also be used to provide database backup and recovery similar to offsite vaulting.

Performing the functions listed above represent a complex and pervasive set of tasks. To accomplish them in a cost effective manner will require extensive support in the areas of data acquisition, data management, data analysis, and reporting. The next section describes some of the characteristics of a system to accomplish these tasks.

6. THE SAA MANAGEMENT SUPPORT SYSTEM

Managing the "array" of processors and operating systems that make up the SAA environment requires a mechanism for consolidating data across processor vendors, models and system software environments. Providing facilities to store this data, make inquiries upon it, ensure its availability (backup and recovery facilities), etc. We will define this system as the SAA Management Support System.

The development of comprehensive specifications for an SAA MSS are beyond the scope of this paper however, the following paragraphs describe a few of the functional characteristics it will require.

The key to the effective and efficient utilization of the information collected within the SAA environment is correctly organizing the data. This organization should enable analyses to be carried out across multiple processors and allow comparisons to be drawn between dissimilar processors. In addition, the summarization methodology should allow for the consolidation of data across multiple dissimilar operating environments while allowing for the retention of data elements which are unique to each processor/operating system implementation.

Various I/S management functions will be controlled from various levels within the total organization. Few operational decisions will be made at the departmental level itself. However, many will be coordinated separately by each individual site. Some of these activities will be localized, but others will have to be reported to and coordinated with other sites throughout the organization. Thus a requirement is created for a comprehensive status reporting mechanism.

At a minimum, information related to the basic I/S management categories listed below will have to be collected.

- Configuration
- Workload
- Performance
- Availability
- Capacity

- o Reliability
- o Financial/Accounting

This information will have to be logged independently at the departmental, site, and establishment levels of the SAA hierarchy. However, the majority of its archival and processing will be carried out on the site and establishment mainframe processors. As a result, the system which manages and maintains this information will have to fulfill five key roles:

- o Data Management
- o Data Transmission
- o Data Consolidation
- o Data Storage
- o Data Presentation

Subsets of these functions will be performed at various locations both upstream and downstream. Figure 4 shows the relationship between these functions which are, themselves, described in detail below.

6.1. DATA COLLECTION

Data will be collected by monitor products which are unique to each operating system environment. The collectors will log data to files resident on the departmental processor for later transmission upstream through the network.

6.2. DOWNSTREAM DATA MANAGEMENT

The function of the Downstream Data Manager is to manage the collection and transmission of monitor log data. This includes switching the monitor log files and staging data for transmission to an upstream node. The Downstream Data Manager will ensure that no data is lost in the event of a communications outage or failure. In addition, it will reduce to a minimum the amount of manual intervention required at the departmental level.

6.3. DATA TRANSMISSION

Data logged at the departmental processor will be transmitted to the establishment processor via a process equivalent to a POS "pull". That is, the establishment processor will query the departmental processor for the available data which it will then transmit. The transmission will be accomplished by the Upstream and Downstream Transporters utilizing an LU6.2 session.

The Upstream Data Manager will cause the Upstream Transporter to initiate a request for data from a Downstream Transporter. The Downstream Transporter will send the data that the Downstream Data Manager has staged. Successful transmission will be verified by both transporters. The Upstream Transporter will notify the Upstream Data Manager of successful receipt of data and that node will be marked complete in the "pull" list. Upon verification of successful transmission, the Downstream Transporter will notify the Downstream Data Manager which will mark the dataset as sent. When all datasets have been successfully transmitted, the Downstream Data Manager will "clean-up" the staged datasets based on user-defined retention schedules.

6.4. UPSTREAM DATA MANAGEMENT

The Upstream Data Manager schedules and controls the data "pull" from the departmental nodes. It maintains a list of nodes and the associated times at which to "pull" them. It maintains a transmission log indicating which nodes were successfully "pulled" and which could not be contacted. The Upstream Data Manager can be parameterized to make multiple "pull" attempts if a node is not contacted.

6.5. DATA CONSOLIDATION

When the data "pull" is completed, the Upstream Data Manager will invoke the Upstream Consolidator to copy the "pulled" data into a single set of files for input to the Upstream Management Database. These files will be maintained as GDG's.

Using these facilities, an I/S management support database could be maintained at each site processor as well as at the establishment processor. A schematic representation of the relationships between the departmental processors and the site and establishment level management support databases is shown in Figure 5.

6.6. DATA PRESENTATION

The SAA Management Support System will have to present information in the appropriate format and at the appropriate scope and level of detail for each level of the SAA hierarchy. While the content of these information displays (tabular reports and graphics) will differ, their formats should be consistent. In general, these information displays will fall into one of six categories:

- o Management Alerts
- o Management Control Reports
- o Operational Exceptions
- o Operational Reports
- o Decision Support Analysis
- o Ad Hoc Inquiry

6.6.1. Management Alerts. are produced daily and monthly and identify variances from established management objectives.

6.6.2. Management Control Reports. summarize the activities of several functional units. They present status, planned-versus-actual and trend information.

6.6.3. Operational Exceptions. identify deviations from technical objectives to the operational support staff.

6.6.4. Operational Control Reports. provide status and performance information by technology group.

6.6.5. Decision Support Analysis. tools provide the facilities to manage I/S functions which cross operating unit boundaries or incorporate multiple I/S resources.

6.6.6. Ad Hoc Inquiries. are unscheduled and unstructured information requests. Because the inquiry process often involves several information extracts in which successive queries result from the real-time analysis of preceeding data, they place a premium on a flexible and responsive query facility.

7. SUMMARY

Twenty-four years ago, a major revolution occurred in the history of information systems, the announcement of the System/360. In light of the technological advances that have occurred since, in both hardware and software design, it is incredible that this basic architecture still supports the majority of commercial data processing worldwide.

As in most engineering endeavors, the compromises made in the 360 architecture reflected the economics of the

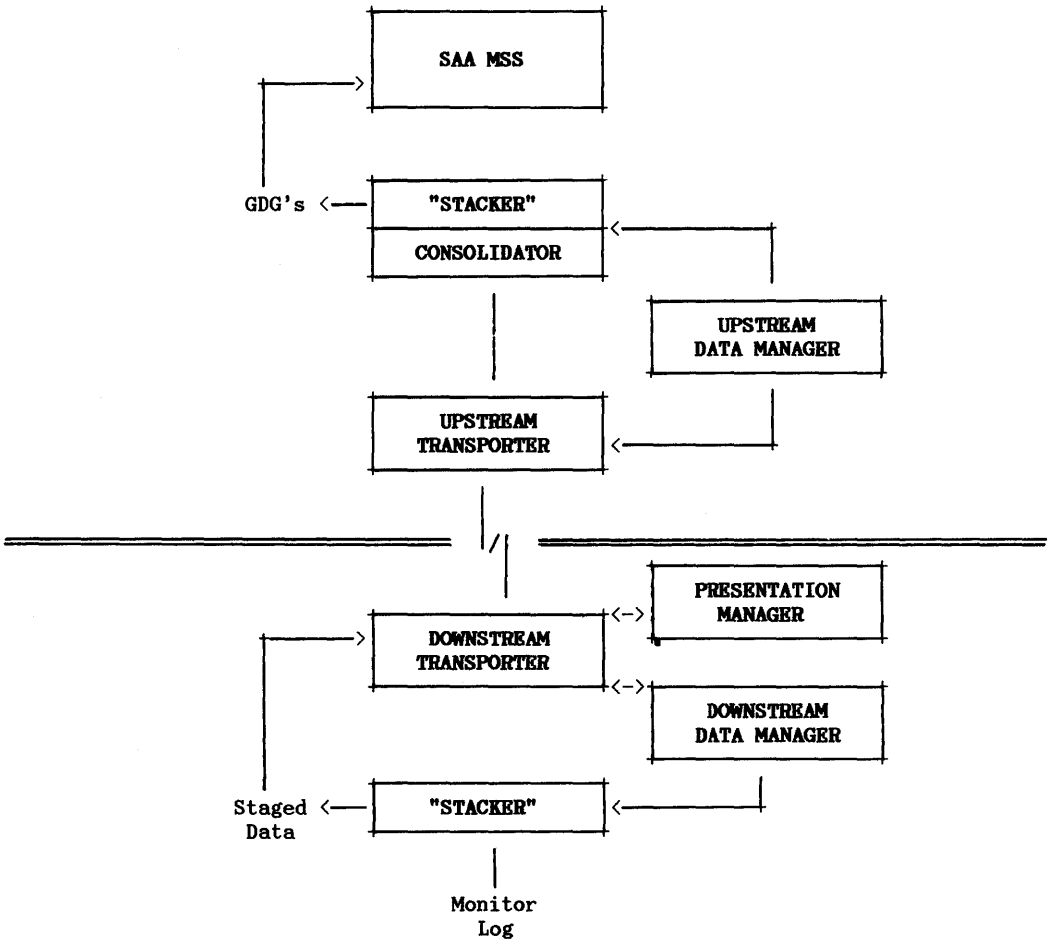

Figure 5. Functional Components of an SAA MSS

times. The advance of technology has shifted these price/performance boundaries. SAA is a reflection of these changing criteria. The implementation of SAA will, in some ways, be more painful than our predecessors' conversion to S/360 because we have so much more to convert. On the other hand, our experience, tools, and technology should help make it smoother and easier.

The decision to implement the SAA approach to I/S will not be an option for most enterprises. The direction of technological evolution coupled with the economic incentives will make this approach ever more competitively advantageous as time progresses. Therefore, I/S organizations need to provide now for managing these environments.

In the final analysis, most of us can only hope that SAA and the hardware and software designs it spawns will be as robust as the System/360 - 370 architecture it replaces. That way, it will probably be the only such conversion we ever have to make.

DASD MANAGEMENT: LET'S TALK MONEY

Greg H. Parker
Mountain Bell Telephone

ABSTRACT

Because disk related hardware represents a significant investment to the data center, the prevailing DASD management philosophy should be sensitive to business costs and corporate strategies. By successfully balancing the relationship of storage capacities, workload service, and configuration cost effectiveness; performance and capacity management activities can be performed within budget and still compliment company plans and objectives. Identifying the cost and expense associated with a given level of service is a key function in this type of DASD management program. Because costs play such an important role in the ability of the data center to provide the necessary service and data space capacity of it's major workloads, business cases are oftentimes required for resolving future needs. This paper addresses how costs and recurring expenses can be extracted and utilized to build a cost effective, yet service oriented DASD configuration.

1. INTRODUCTION

The term "DASD management" takes on a special meaning to different people. However, most would agree that in terms of cost and performance, the potential impacts of DASD makes managing this resource an extremely important function in the data center.

Many of todays data centers maintain comfortable levels of spare storage for reasons relative to performance, hardware failures, and anticipated application growth--while other centers operate at near capacity. Department budgets, company politics, and personal bias' are all controlling factors of how disk space is utilized.

With regard to performance, it is important to realize that the amount of data online contributes to device performance. We have to ask, "how much data can be placed on a device and maintain good performance?"[1] Furthermore, "how can the activity be spread over the configuration in order to provide priority workloads with the service required?" Some industry observers estimate that in a typical installation, about a third of IBM 3380 drive space is unused because of I/O performance considerations.[2]

Hardware failures are costly in terms of service and availability commitments. Experience seems to prove that a small percentage of empty spare volumes are essential for timely data recoveries in critical, high availability online environments. The choice of how many volumes depends on the configuration size, mix of device types, and nature of the workloads. Whereas, a minimum of four and a maximum of sixteen may seem reasonable, can the cost of this empty space be justified in terms of insurance?

Forecasting the storage requirements of future workloads is oftentimes frustrating. For example, a dependence on multiple application groups for anticipated growth projections, increases the uncertainty of space reserve requirements. Working within too strict of a DASD procurement policy, gives the appearance of being unsympathetic to user needs. However, a relaxed and over-obliging attitude lends itself to waste and inefficiency.

While the extreme in maintaining comfort zones of empty space for whatever reason can be a blatant misuse of company money, the result of exploiting every available byte of disk storage leads to the negligence of I/O performance. Thus, the DASD management process should be sensitive to costs while addressing the various functions of performance and capacity management. In this context, the overall goal is directed at building a cost effective, yet service oriented DASD configuration.

2. PRORATING DATA OCCUPANCY COSTS

The first objective is to identify in terms of capacity, the cost distribution of the DASD configuration. In other words, how much of the available DASD space is being utilized; what amount remains unused; and what is the cost of this condition? Additionally, we want to know what workloads are responsible for the resident data.

The approach used to break-out a workload's DASD costs begins with a baseline value consistent to both capacity and performance. This value is derived from the cost of all DASD channels, control units, cache, and disk devices in the system's hardware configuration. It should also be noted that the baseline value will be used for DASD management purposes--not for user billing. This value is referred throughout the remainder of this paper as the "baseline-cost."

Other recurring costs that can generally be found in department records are relative to vendor maintenance. These expenses can be tracked as a separate baseline value. Therefore, a workload can be held accountable for it's share of intermittent expenses in addition to the cost of the space consumed during peak DASD I/O activity. The term "baseline-expense" will be associated with this value.

Unlike a DASD billing product, where data residency time lengths are critical for effective charge-back, a peak period "snap shot" view of space utilization is used as input. High I/O activity time frames are used because of the response time effects of peaks to online systems.[3]

2.1. DATA COLLECTION

One or more local DASD management reports may be required to extract the necessary data. Volume information is needed in addition to measurements of data set utilization. Separate data bases can be easily created and later used for growth and trend reporting. The minimum variables required are:

VOLUME

- Unit Address
- Volser
- Byte Capacity
- Bytes Allocated
- Mount Attribute
- Date & Time

DATA SET

- Data Set Name
- Bytes Allocated
- Bytes Used
- Date & Time

2.2. COST-PER-BYTE

A cost-per-byte of DASD storage is derived from the earlier calculated baseline-cost and the byte capacity of the disk configuration. Each available byte of storage can then be expressed in terms of cost. Using the other baseline for expense, a byte level value can be generated that indicates the data centers on-going commitment for providing the existing space. To determine a cost-per-byte of DASD storage:

. Total the byte capacity of all DASD devices.

. Divide the baseline-cost by the total capacity.

The end result is fractional dollar amount for one byte of storage. Repeat the calculation using the baseline-expense value to determine an expense-per-byte of storage.

Since the scope of our analysis encompasses the entire DASD configuration, there is an assumption that resources are distributed in a priority fashion that provides each workload with it's required level of service. Therefore the assignment of resources and relationship between workloads is according to some master plan. This assumption precludes having to break down costs by device type even though there may be performance differences.

2.3. WORKLOAD IDENTIFICATION

In order to determine what workloads, or major applications are responsible for the allocated DASD space, it is necessary to find a common variable for grouping. Automated routines prove extremely helpful when processing large amounts of data.

Where data set naming standards are used, one method is to look at one or more levels of the name. Then a series of "if" statements can be used to assign an owner to the data set. For example, the following SAS statements can be used to extract the high level node of a data set name and assign it to a major workload:

```
DSNODE = SCAN(DSN,1,'.')  ;
IF DSNODE =  'WKL' OR
   DSNODE =  'WKLB'
         THEN WORKLOAD =  'APPLICATION A'  ;
```

The "if" statements can be expanded to include all existing high level nodes and all workloads. In shops where entire volumes are used exclusively by a single workload, volume records can substitute for data set records.

2.4. SUMMARIZATIONS

To establish the relationship between the major workloads and the configuration's available capacity, total cost, and total expense, it is necessary to perform high level summaries. Once complete, the results will contain the essence as to how cost effective the DASD configuration was at the time of data collection.

Using the volume level information, we can determine the total available byte capacity of the devices. Furthermore, it is possible to subdivide the summary total by device type and mount attribute. The cost-per-byte and expense-per-byte values can then be multiplied by the allocated and device capacity totals to determine the cost and recurring expense of each summarized category.

With the data set information, we can perform a similar summary routine at a workload level. The cost-per byte values can be applied to the total allocated bytes for the purpose of determining what part of the total investment is being used by the different workloads. Figures 1 through 6 are examples of how costs and recurring expenses can be implemented into management reports.

A cost utilization measurement can also be established by looking at the used and unused capacity relationship. The ratio is determined by dividing the unused, or still available space value by the used, or allocated value.

For example, given a DASD configuration consisting of 120 gigabytes of capacity with 80 gigabytes allocated, the cost utilization ratio (40 GB / 80 GB) would be 1/2, or fifty percent. This is another way of saying that one out of every three bytes of storage is left unused. From a pure efficiency viewpoint, a smaller percentage indicates better use of company money.

Managing DASD space in terms of dollars instead of strictly tracks or cylinders is a worthwhile endeaver. It not only captures one's attention but develops an appreciation and awareness for business costs. However, the cost of capacity is more tangible and easily understood by management than is the cost of performance. Establishing the price of good service is further compounded by factors such as inaccurate workload characterizations and the lack of specific service agreements.

3. PRIORITY WORKLOADS

A performance problem exists when response time commitments to resident workloads are not being met. Typically these commitments are in the form of service level agreements. Furthermore, the relative importance among applications is determined by the resource, service, and availability requirements agreed to by the data center's management.

An installations' priority workloads will typically be given preferential treatment in terms of faster I/O and minimum contention. These are the applications that tend to utilize solid state devices, cache, short strings, and partially allocated volumes. Therefore, when an important workload requires a specified level of DASD service, what becomes the most cost effective means for providing the expected response time?

Like any other system resource, increased demand for DASD can be satisfied three ways:[4]

. Buy it.

. Tune for it.

. Steal it from another workload.

However, each method has it's own associated cost. The reference of stealing resources from other workloads is a case of robbing the poor to give to the rich. Hence the cost is in terms of less resources and decreased service to the victim workloads.

Tuning is costly with regard to the time and energy of the people involved. This method attempts to utilize an existing configuration more efficiently and more effectively. Although time consuming, successful tuning efforts can provide significant hardware savings to the data center.

	TOTAL DASD INVENTORY VALUE	TOTAL DASD RECURRING EXPENSE	ALLOCATED DASD SPACE VALUE	ALLOCATED DASD SPACE EXPENSE	UNUSED DASD SPACE VALUE	UNUSED DASD SPACE EXPENSE	
	$2,150,402.00	$8,025.00	$1,686,756.00	$6,467.00	$463,646.00	$1,558.00

FIGURE 6. CUMULATIVE DATA SET NODE SUMMARY

once tuning and stealing for additional DASD resources have been fully exploited, buying more is the next alternative. Depending on the nature of the situation, procurement alternatives may include both hardware and software. For example, the reduction of physical DASD I/O provided by expanded storage, cache, and virtual fetch products may prove more advantageous than new hardware. Traditional hardware procurement solutions can overlook the benefits available with other viable alternatives.

3.1. BUSINESS CASE

Because of the expense associated with cache and semiconductor disks for example, justifying the cost may not be easy because it means assigning a dollar value to a soft benefit--better response times.[2] Most likely, before management will accept and approve the procurement of "performance boosters," a specific business case will need to be developed.

The document should include information on the configurations current performance and cost utilization. Furthermore, a specific tuning agenda containing the projected results will probably be required. Additionally and most important, is the presence of alternative solutions to a performance problem--each in relationship to workload service and cost to the company.

4. SUMMARY

The data center's DASD management philosophy should be concerned with storage capacities, workload service, and configuration cost effectiveness. Furthermore, performance and capacity management efforts work best if all possible solutions are investigated. As each alternative is reviewed, the preferential choice will be the one that meets the service level requirements and provide the most benefit to current and future business plans--with the least cost.

A DASD configuration's cost and recurring expense are important baseline, or index values for managing disk space. Whereas dollar values command greater attention than traditional measurements of tracks and cylinders, it also places management reports at a level more appropriate for business planning. Additionally, a sense of cost effectiveness can be developed based on how well existing resources meet organizational objectives.

The overall goal of DASD management should be to provide a cost effective, yet service oriented disk configuration that compliments company business plans and philosophies. Because the data center's disk investment deserves the same attention and financial care as other major corporate assets, an awareness of costs and expenses is essential.

WORKLOAD CHARACTERIZATION AND FORECASTING FOR A LARGE COMMERCIAL ENVIRONMENT

George W. (Bill) Miller
American Airlines

ABSTRACT

This paper suggests an approach for characterizing the activity of a large data processing environment into discrete workloads which are consistent, measurable, and recognizable. Some practical techniques are suggested for predicting the growth of these workloads using a combination of historical trending and the identification of major future influences. The discussion is conceptual in nature and no detailed technical expertise is required other than a general understanding of the nature of a computer center.

INTRODUCTION

It can be truthfully said that all forecasts are wrong. The challenge is to reduce the margin of error down to an acceptable level. The approach used will depend on the size and complexity of the installation, the nature of the business, and the historical information available. In simplest terms, workload characterization is a way of describing the DP activity occurring in an installation. Forecasting involves determining what has happened in the past and predicting how the future is expected to differ from that.

WORKLOAD CHARACTERIZATION

OBJECTIVES

The computer workload of a large data center is most likely to be both varied and complex. In all probability there are both batch and interactive environments coexisting in some fashion. There will be hundreds or thousands of different jobs and transactions running at all hours of the day and night, doing very different things, and having very different resource requirements. In order to be able to describe all of this we must develop some means of grouping all of this activity into a manageable number of pieces.

The object of any workload characterization technique is to group elements of the workload that collectively represent some consistent resource characteristics, are distinctly visible to the observer, and which ideally have some intuitive meaning to the observer.

Consistent. The characterization must display consistent resource characteristics from one observation to another. One would expect to talk in terms of resources for a given volume of activity. The individual elements which have been grouped together may or may not have similar characteristics; the group as a whole must have.

Measureable. It must be possible to discreetly identify and measure the elements which make up the characterization. They must be distinguishable from other elements of the workload with no overlap or missing pieces. This implies that appropriate accounting information is in place and routinely available and that the necessary software is in place to process and retain this information. Many authors have detailed the possible sources of accounting information and explained in detail the techniques for processing this information. A lengthly discussion of SMF data, RMF data, IMS log files, etc., will not be repeated. Suffice it to say, however, that the existence of dependable historical performance data is the stuff of life here.

Recognizable. If the pieces into which the workload has been grouped are not intuitively recognizable to the rank and file within the installation, then discussion of present and future activity in terms of these pieces does not necessarily accomplish good communication. Management is better able to discuss and understand the need to accommodate growth of a particular workload if it represents something whose function and purpose is understood.

UNITS

For purposes of discussion it seems useful to identify three kinds of units:

Computer Resource Units (CRUs) are the basic units representing computer hardware activity. Examples would be CPU time, various I/O counts, tape mounts, DASD storage, etc. Service Units (SUs) are weighted composites of several CRUs and are used to describe the overall hardware resource associated with some activity.

Computer Workload Units (CWUs) are the basic workload elements within the computing environment. Examples are batch jobs and interactive transactions. The resource characteristics of CWUs are described in terms of CRUs, i.e., we describe the activity of a batch job in terms of the volume of CPU time and I/O counts.

Business Work Units (BWUs) are the business related activities that are the purpose of all this computer activity. Examples are bank deposits, claims received, units manufactured, or passengers boarded. Until we look at the work done in terms of BWUs, we have difficulty in distinguishing the computer installation of a bank from that of an insurance company or a manufacturing company or an airline. These BWUs will require a number of jobs and transactions (CWUs) for their completion and will ultimately be equated to typical requirements for resources (CRUs). Note that what is being called a Business Work Unit here is the same thing that other authors have referred to as a Natural Forecast Unit (NFU).

GROUP WORKLOAD ELEMENTS

In most cases workload characterization is simply a technique for grouping Computer Workload Units. Each of these techniques has both advantages and disadvantages.

Clustering. Techniques can be used to identify elements of the workload with like or similar resource characteristics. One example might be that set of batch jobs which typically account for less than 10 seconds of CPU time, no tape mounts, and produce less than 50 pages of printed output. Another might be an IMS transaction with less than 2 seconds of program execution time and less than 25 DBD calls, or whatever. This results in a characterization with very consistent CRUs. The problem with using clustering to characterize the workload for purposes of workload forecasting is that the resulting groups may be intuitively meaningful to no one except the performance

analyst. Clustering is a technique particularly useful for benchmarking and modeling.

Major Application. By "application" is meant a functionally related set of work elements such as the jobs and transactions making up a payroll system. Although the elements being grouped together are likely to vary considerably in their individual resource characteristics, the typical CRUs for the total application may be quite consistent. If so, then this has the advantage that the application represents a piece of work which has a recognizable identity to individuals within the organization. It may be possible to utilize survey or interview techniques to discuss the expected growth of an application. It may also be that the application is utilized by a number of organizations in several locations making such discussion more challenging. In a large installation there may be so many hundreds of major applications that the process becomes somewhat difficult to manage. Some additional higher level summarization may be necessary. This also implies that some accounting conventions or naming standards exist which will allow this activity to be properly identified from SMF or other accounting or log files.

Organization or Location. If considering the workload by application describes what the installation is doing, considering the workload by organization or location describes for whom it is being done. Again, the accounting information must exist to determine the who and where. If a chargeback system is already in place, this type of accounting should be straightforward. As before, there must be some consistency of overall volume and resource units, and there are apt to be problems with exceptions. There is also the problem of the work which does not fall neatly into a particular slot, for example development work, or system support. However, this characterization might be particularly useful in considering growth resulting from organizational or geographical expansion.

Major Subsystem. Not uncommonly, the workload is characterized by major subsystems such as batch, TSO, IMS, etc. This is perhaps the simplest characterization in terms of data collection. The organization of SMF and RFM data lends itself to a simple summary of subsystem activity without regard for who or where. This is also probably the most common way of characterizing the installation workload. These are the major pieces of work in an installation, and in a multiple CPU environment they will be placed so as to minimize conflict. Often the large interactive environments are kept to a single processer, and it is the projected growth of one of these to above a threshold level that signals the required upgrade of a mainframe.

Installation. Equally simple is the compilation of total resource for the installation as a whole. This yields the grossest characterization of them all, the total shop. This is in fact the bottom line. Developing history and an overall growth trend of total installation gives one a target or check for the process of adding up the pieces. If the sum of the pieces does not fall near the trend line, it would be interesting to know why not.

Business Work Units. Ultimately one would prefer to use Business Work Units to characterize the workload. This will serve to tie the data processing forecast to the business forecast and makes the DP forecast much easier for corporate management to understand. The problem with BWUs is that there are often large segments of the installation workload that do not tie neatly to fluctuations in these BWUs. The alternatives are to show these activities separately as "overhead" or "installation support" or to prorate them somehow over those activities that do relate to BWUs. If the resources associated with the activities in question are considerable, neither of these alternatives are apt to be entirely satisfactory.

USERS/CUSTOMERS

A typical large computer installation is putting out an impressive amount of DP resource to somebody. It would be useful to know who that somebody is. While it is relatively easy to know what the impact of the major workloads is, it is not as commonly known just who is responsible for all that activity.

If you are in the business of selling computer service to outside customers then you will have developed some means for determining the cost of the service provided to each customer and the means for billing them for it. If not, then your career as a service bureau is likely to be somewhat short lived. Even if the DP center provides service only to itself, or to the larger organization of which it is a part, there is a requirement to define and quantify the cost of services to each user or customer. Any DP organization worth its salt will have some kind of a process for doing just this, be it called chargeback, cost allocation, transfer pricing, or whatever. But what if such a system is not present? How might reporting of resource by customer be developed for management control?

*BRIDGES

Most installations have developed the means for doing some kind of workload summarization for management reporting purposes. What is required is a relationship or "bridge" between the activity described in the basic accounting log record (SMF or IMS log, etc.) and the identity of the group (the particular workloads, applications, organizations, locations, customers, etc.) to which this activity is to be related.

Stated very simply, the process consists of three steps. First develop the means for obtaining the basic accounting information which describes detailed computer activity. Second, describe the "buckets" into which you want this detail accumulated. Third, build a bridge of relationships which will tell you into which bucket to pitch this detail.

If these source records contain good accounting codes which have been well thought out, enforced, and maintained, then you should be home free. A chargeback or cost allocation system essentially solves the problem. If you are one of the multitudes of shops whose accounting codes are a series of poorly maintained good intentions, then you have a challenge. Even so, the lack of a convenient mechanism for doing something does not remove the need or benefit of doing it. Nor will it necessarily get you off the hook.

If a proper and convenient bridge does not exist, then one must develop what the military calls a field expedient. The use of battlefield terminology is not completely inappropriate here. To group activity by application, first go talk to your scheduling people. They have to know what jobs go together. The data base administration people can do the same for IMS, CICS, etc. It may be necessary to build tables of job names or transaction names to application systems. It may also be that someone has already worked out such a relationship and even maintains it. It is likely that several relationships will have to be tied together to eventually get from the accounting source to the proper bucket.

To relate activity to organization or geographic

location, again consult the good people in operations. They have to send all the computer paper to somebody. The people responsible for the interactive systems should know who and where the users are. The source records will likely contain some sort of user ID required for logon or for data security. Either the system support or data security people can no doubt relate these user IDs to a name and or an employee number, etc. From here the personnel or payroll people can point to organization and/or location. Try the people who maintain the organization phone book for a relationship between names and places. the idea is that relationships will exist or can be created which can be pieced together to build a bridge from the source data to the desired grouping. Once the relationships have been established the intermediate steps can be eliminated.

Resourcefulness and creativity are an asset here. It is also very helpful to ignore the advice of knowledgeable and well-meaning individuals who counsel that this sort of thing will not work, and continue to snoop about.

REALITY

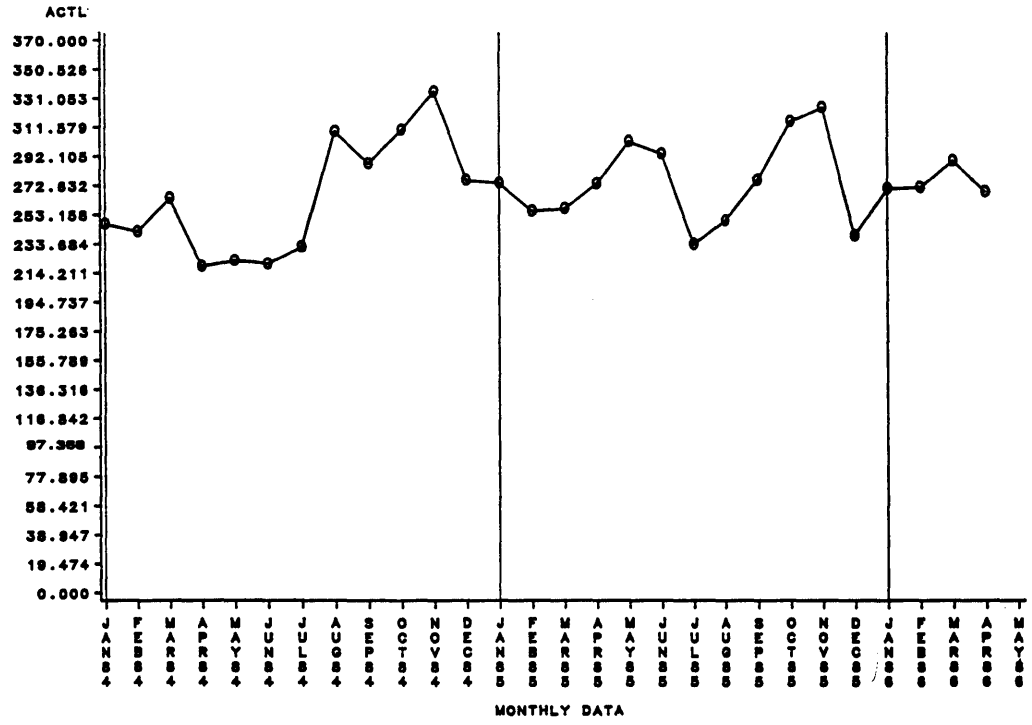
Having set out a nice neat list of schemes for characterizing the computer workload, it is only fair to admit that none of them is really completely adequate. The complexities of our environments prevent any one approach from fitting all the odd cases without a good bit of stretching and hand-waving. They serve different purposes and answer different questions. To develop a forecast whose probable margin of error is within an acceptable comfort range, one must characterize and forecast the workload in several different ways. What emerges is a final result which hopefully is both reasonably accurate and intuitively sensible.

BUILDING THE FORECAST

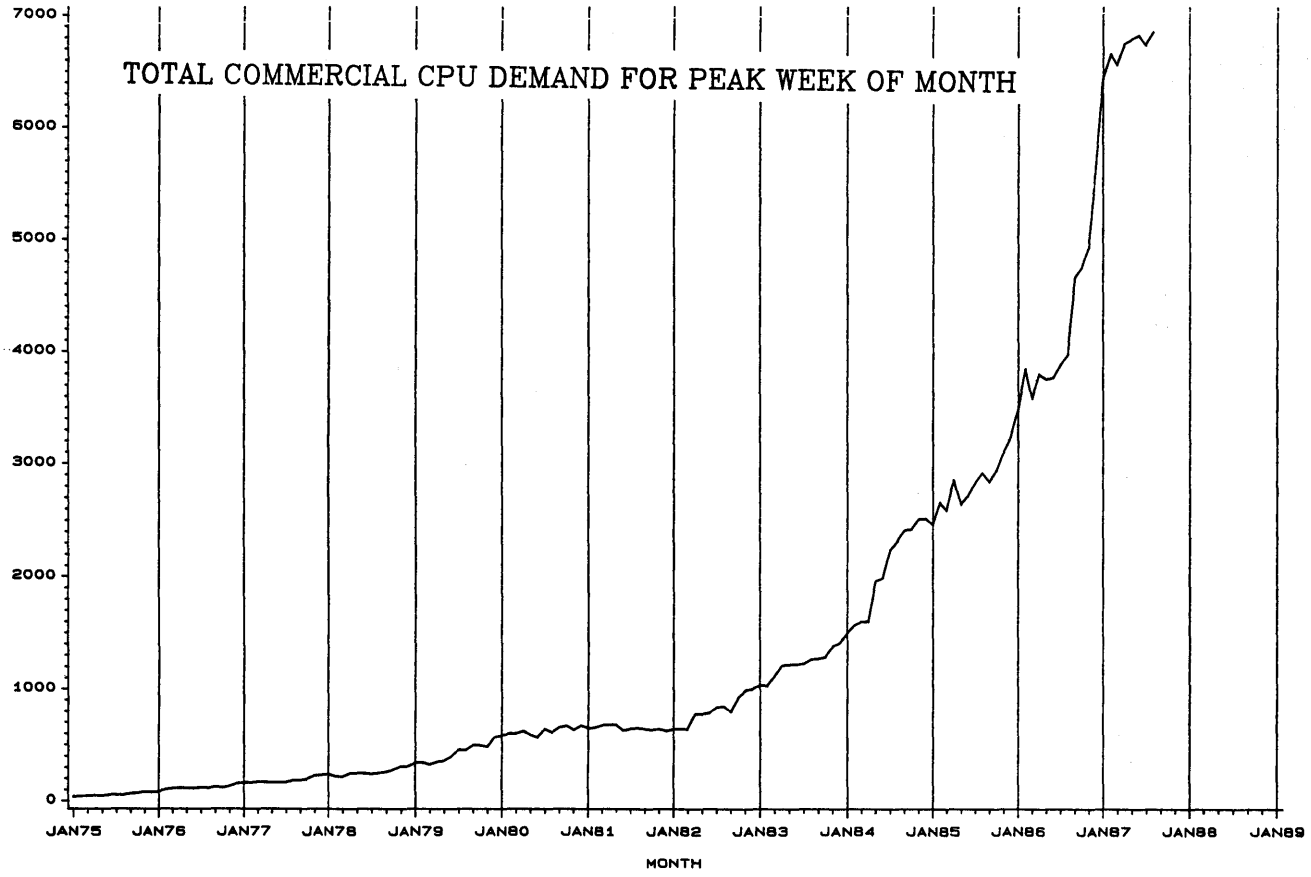
Let us now investigate the black art of computer forecasting. The simplest but not necessarily most cost effective way of forecasting is to call in your friendly neighborhood hardware vendor and ask for a recommendation. This will be almost guaranteed to solve your capacity problems. Just in case this is not what you want to do, we will explore some other options.

MACRO FORECASTING - The Big Picture Approach

History. The first step would seem to be to get an overall understanding of the historical growth patterns for the installation. It would be helpful to identify the total size of the installation in terms of MIPS or equivalent CPU numbers of some kind for as far back as feasible. The previous two years is minimal, the previous five is much better. The appropriate unit is anything that indicates the total shop across various mainframes. If continuous data is not available then interpolate between known points. Use graphs and charts profusely. Try to get an understanding of what the activity of the installation looks like. One may look at individual workloads (figure 1), or at the installation as a whole (figure 2). Actually, it is useful to do both.

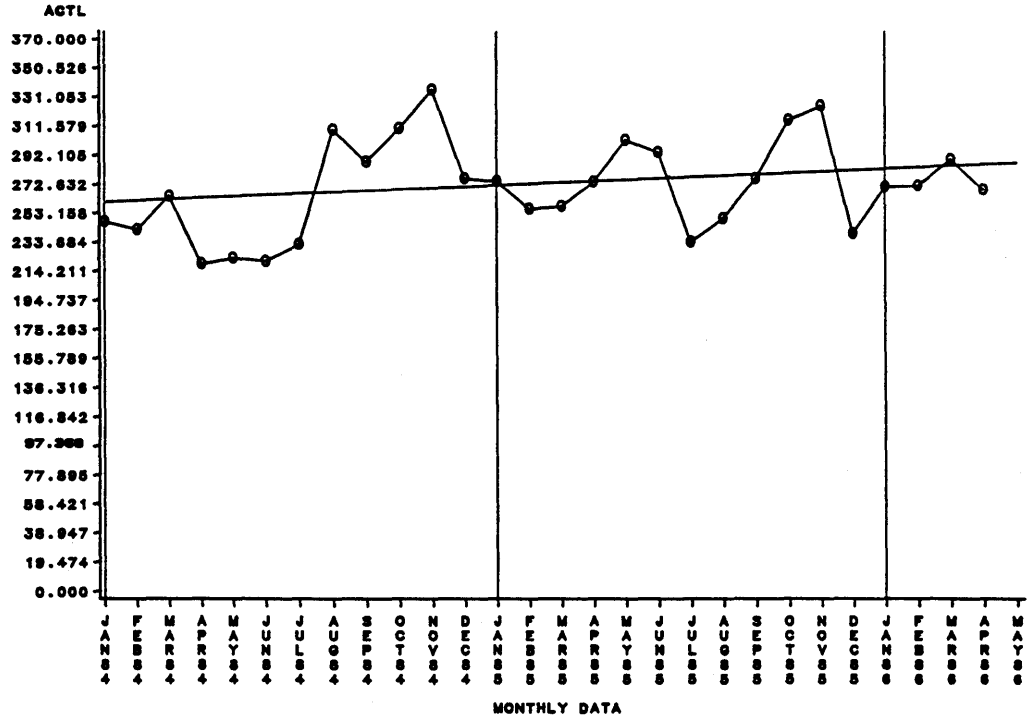


GROWTH OF WORKLOAD A
figure 1.



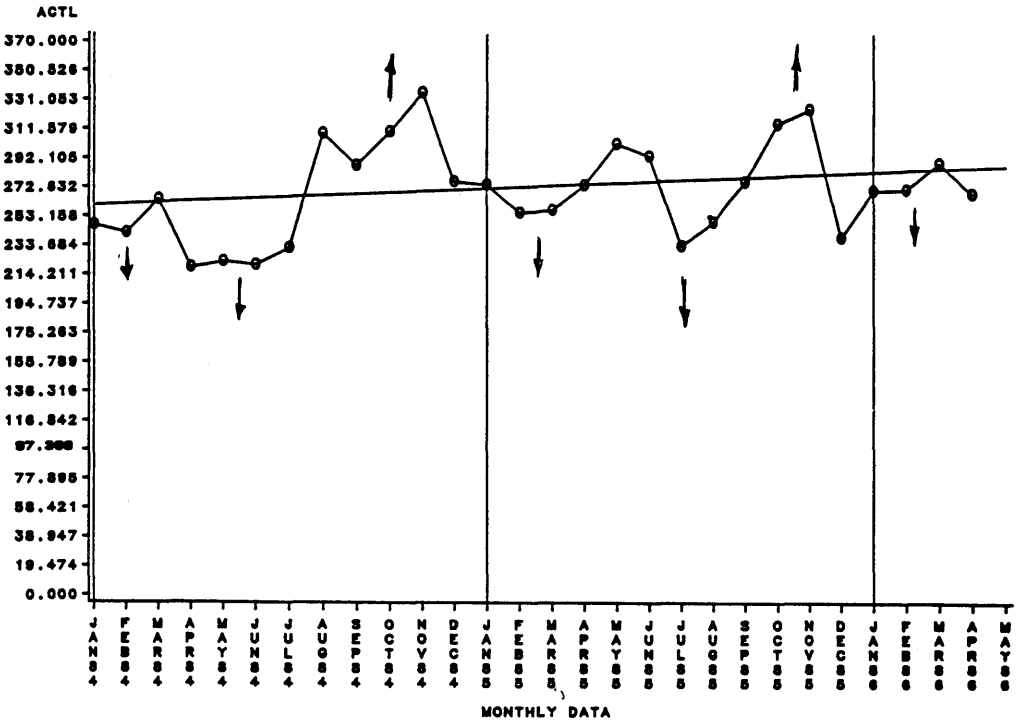
TOTAL INSTALLATION GROWTH
figure 2.

Trends. Develop some simple trends based on this historical information, then graph it and look at it. The typical reaction is to be somewhat frightened by the prospect of continuing to grow at the present rate. Remind yourself that the average large installation is growing at an annual rate of somewhere around 40%. Try to relax. So as not to frighten the reader, we have elected to look at Workload A (figure 3) rather than the total installation. Besides, Workload A is quite cyclic and makes a good example.



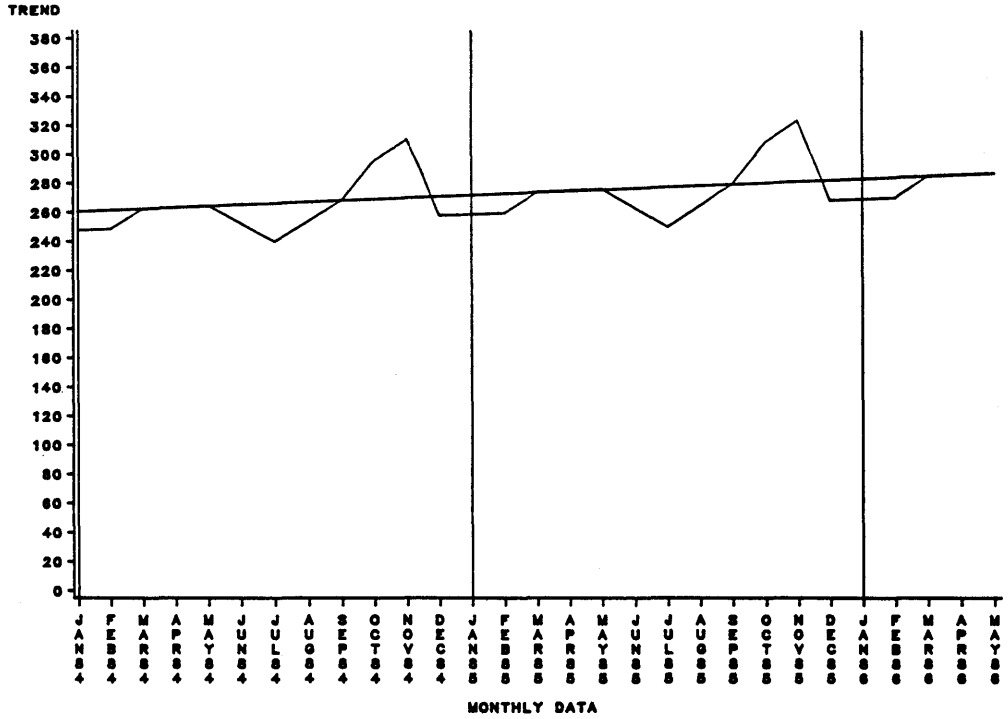
TREND OF WORKLOAD A
figure 3.

Variations. Over long periods of time, workloads tend to rise. From month to month, they tend to rise and fall, and viewed from week to week or day to day, they tend to go all over the place. Note periods of rise and decline and make a sincere attempt to be able to explain why they occurred in terms of hardware modification, major changes in the workload, and cyclic phenomenon (figure 4). Consider the relationship to business or budget cycles, seasonality influences, employee holiday periods, etc. If possible develop the same information for the total volume of batch and interactive workloads. The idea here is to develop a relatively simple model which will allow us to restate the past in somewhat abstract terms.



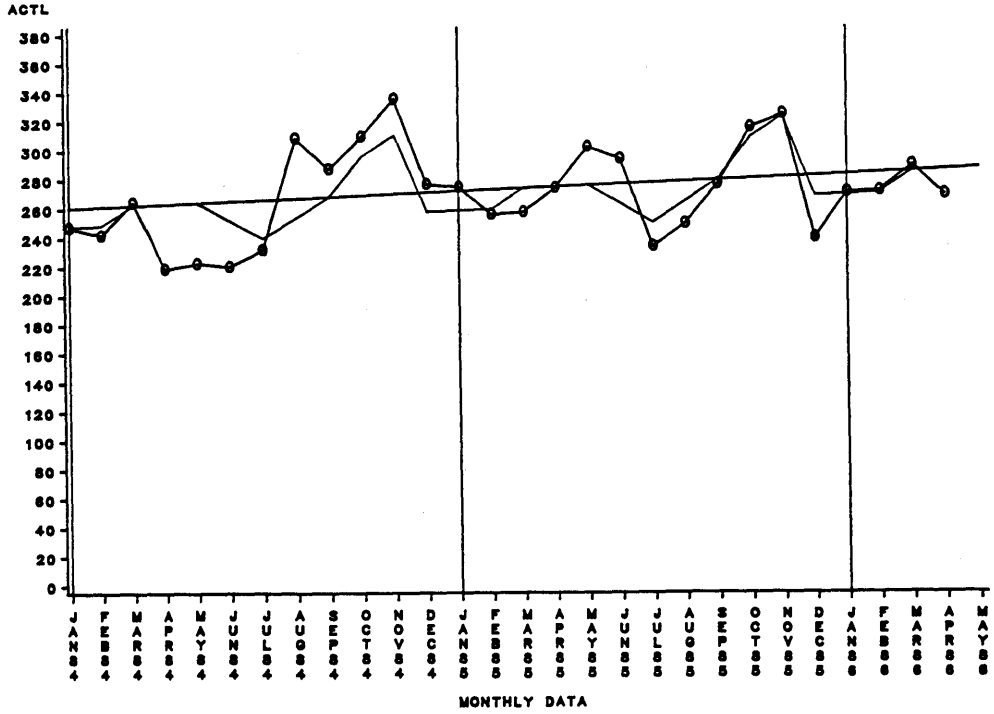
CYCLIC VARIATIONS IN WORKLOAD A

Adjusted Trend. Determine which of the variations are likely to continue to occur in the future, and apply them to a projection of the trend line (figure 5). If nothing is going to change and the future is expected to look like the past, then this adjusted trend line might serve as a forecast. It can be fairly noted that the future generally brings a few changes.



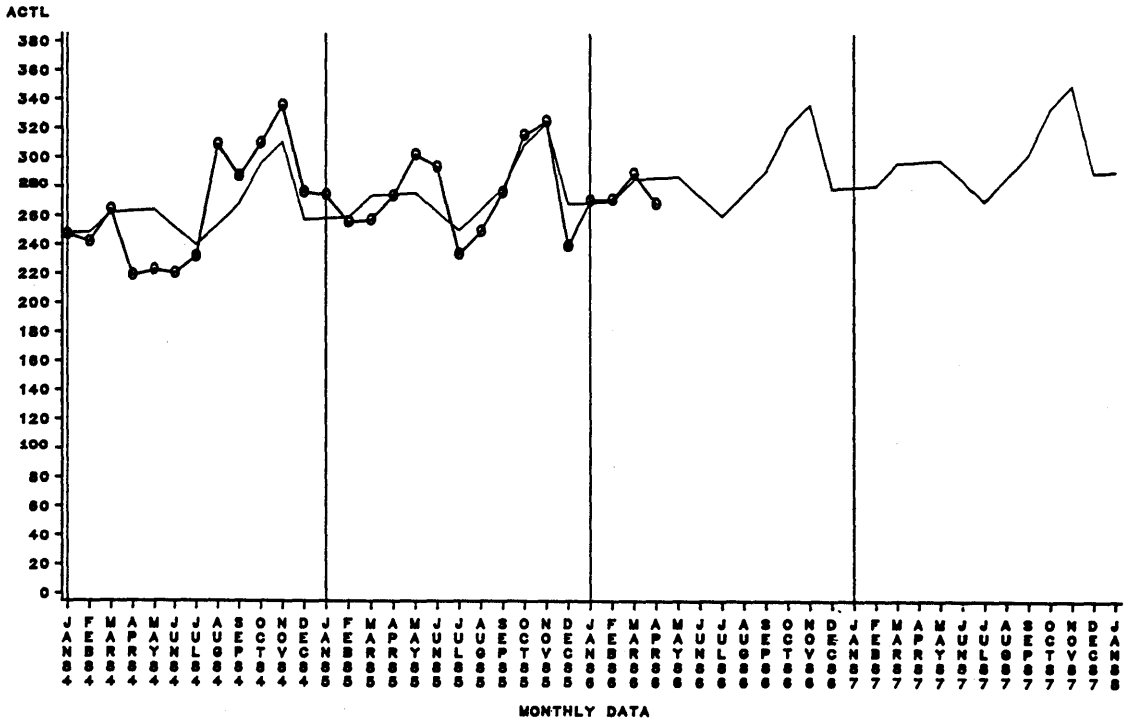
ADJUSTED TREND OF WORKLOAD A
figure 5.

Restate the past. If we have done this correctly, we will have constructed a graphic model which has approximately restated the past (figure 6). If the model will not restate the past, it will surely not predict the future. Furthermore, this model, while mathematically very simple, is intuitively quite satisfying.



SIMPLE MODEL OF WORKLOAD A
figure 6.

Major Changes. Review the business plan and interview the necessary people to determine the major changes in the environment which will occur over the next two to five years. You have determined what the past looks like. Now you are trying to get a general idea of the major ways in which the future will differ from the past. Estimate as best as possible the effect that these changes will have on the trend line. Again, graph and review, adjust and repeat. As this adjusted trend line is extended out into the future, it is a forecast with which we may have some relative degree of comfort (figure 7).



FORECAST OF WORKLOAD A
figure 7.

Projected Total Growth. The idea of this process is to gain a clear understanding of the nature of the growth of the installation and a general idea of where it is going. If this were to be used as the forecast, it shouldn't really be that far off. At least it should be close enough to define the ballpark. Further efforts to characterize and forecast the workload should not vary wildly from this ballpark without raising serious questions.

This might actually provide us with a forecast that we could live with if the resulting accuracy proved decent. In a large stable environment is can actually result in a forecast which is quite good. the problem with this is that it is simply not defensible. It has been developed from a somewhat lofty vantage point and is not based on detailed analysis of the many individual elements which make up the workload. It is based only on a knowledge of the past and the insight of a few well-informed people. Not bad, perhaps, but risky.

MICRO FORECASTING - Adding Up the Pieces

Knowledge of future activity can be obtained in a number of ways. Basically the challenge is to ask the right people the right questions at the right times. If we manage to get the right answers, forecasting is a simple matter of adding up the pieces to determine future requirements. This turns out to be simpler in concept than in execution.

Asking The Right People. Really, what we are trying to do is to identify those things that change. If nothing changes, then next year will look pretty familiar. The right people to ask are those who are in the position to discuss changes in the workloads. Obviously these people and their positions in the organizational structure will vary from place to place, but we can consider some examples.

The users/customers of the DP service can describe their plans for changes in the way they do their business. They may foresee increases or declines in certain areas or changes in the way they plan to utilize the services of the DP center in the future.

Most organizations have a group of marketing people who are aggressively trying to sell the services of the business, or of the data center directly. These people are paid to sell, not to minimize DP headaches, and at least occasionally can be counted on to make promises first and check on capabilities later. They often have several possibilities going concurrently and frankly are not always in the position to predict just how things will work out. It is also true that these people are generally difficult to gain access to and may be less than enthusiastic about discussing the possible outcome of some delicate negotiations. Nevertheless, these activities can have a profound effect on the DP workload and their information is of great value.

In many organizations the applications development people reside at the neck of the funnel between the customers and the operation of the data center. Applications development has the challenge of translating the requirements of the customer into an orderly subset of the workload which is compatible with the operation of the data center. For this reason, they can often provide excellent information on the characteristics of new applications and changes to existing applications.

Long range plans are probably best defined by data center or corporate management of director level or above. These are the big picture people who influence the emphasis of one particular environment or another, and who are privy to corporate strategy. Their time is valuable and so is the information and insight they can give. It is very important that these people understand the importance of your requirement for this information. The reason we need this information is to allow the forecasting and planning to be done which will provide them and their people with the computer resources required to do their jobs. The understanding and cooperation of these people is vital. Remember that the rest of the people we need to talk to report to them.

It also needs to be recalled that it sometimes pays to have friends in low places too. As time goes by, it will become apparent that there are certain individuals within the organization who are well placed to identify what is going on and what is likely to happen. These are apt to be very skilled technical people who may or may not have any managerial responsibility, but whose insight and perspective is invaluable. These are the people who can shed light on reality in a very helpful way. Cultivate their friendship. Buy them coffee. They can save lives.

Asking the right questions. What questions we ask depends on who we are asking. Asking customers what they are going to do assumes that they are in the position to know. It is possible that the activity of some customers will be driven by events beyond their control or current knowledge. It is not reasonable to ask a customer of DP services how much CPU time, or how many DASD EXCPs, or how many tape mounts are going to be required to support the customer's workload. It is reasonable to ask how much work is expected to occur in terms of Computer Workload Units or Business Workload Units, but translation of these requirement into equivalent resources is and should be the job of the performance analyst.

Personal interviews are perhaps the best means of obtaining information from marketing people and from upper management. The absence of an obvious written document should not indicate the lack of a specific agenda. Gather as much information as possible about new applications, expected changes to existing applications, expansions in business, new locations, increases in numbers of people having access to systems, etc. Remember that this is the ultimate opportunity to sell the individual on the importance of providing the best information possible. The better the information, the higher the probability of a smooth transition into the future.

The lack of hard information may cause an individual to hesitate to respond. The inability to predict the future with absolute certainty does not relieve the necessity of producing a forecast. If a considered best guess is all that is available, then that is what must be obtained. A best guess is almost certainly of greater value than no information at all. The alternative is terminal paralysis.

A periodic survey document may be used to obtain information from the users or customers of the DP services. Survey documents can be used to ask users about changes in their expected demand. Asking people what will be happening in the future assumes that they know what is happening now. It is not reasonable to ask what future activity will look like without providing information regarding the current level of activity and how that activity has varied over some period of recent history. The more information that is made available to the respondent, the better the information that can be provided by the respondent. If the base is properly established, response can be stated simply as a percent change. A good example of such a document can be found in reference [6]. it will not uncommonly be useful to follow up the survey with

an interview if the information warrants further investigation.

Resource Impact Forms can be developed and required as part of the development cycle of new project by the applications development people. Since the development people have the unique position between the customer and DP operations, they are often able to describe the characteristics of future changes to the workloads. If a completion of a comprehensive set of documents is made a part of the development cycle, much valuable information can be obtained. An example of such a document is referenced as attachment A.

The Right Time. The best time for obtaining forecast information is any time it is available. Resource impact forms established as part of the development cycle will likely be filtering in on a constant basis. Marketing and management interviews and surveys of the customer base might best precede the forecast cycle. It is necessary to constantly keep an ear to the ground to listen for distant rumblings. Keep the faith. There will come a time when the organization's DP community will understand the importance of this information in assuring that their own DP needs will be met, and will seek us out to see if we want some information that they think we may find useful. At that point we will know that we are getting somewhere.

Locating All The Pieces. At this point we have asked all the right people all the right questions, and have left no stones unturned. Now what do we have? Determining the total workload requirements by adding up all the pieces assumes that it is going to be possible to identify all the pieces. While we may be able to obtain a fair estimate of the expected workload activity for as much as 6 to 12 months into the future, between 12 months and 2 years things get pretty thin, and beyond 2 years falls into the realm of pure speculation. It is entirely possible that after taking all the surveys and adding up the pieces, the result indicates a declining total. Such a result should be viewed with a certain amount of suspicion. Again, it is most important that the estimates be based on knowledge of the existing workload. Careful consideration must be given to the growth of program development, system support, and installation management requirements. Some means must be devised for migrating into that hazy area of 12 months or more into the future. Those organizations that rely heavily on this approach tend to do a good bit of quiet gap filling.

A COMBINED APPROACH

The exclusive use of trending, and the attempt to identify and add up all the pieces form the extreme ends of a continuum. Obviously, what works is somewhere in between. It would seem sensible to define some middle ground where the strengths of each approach are combined. Actual experience has indicated that overall validity of the forecast has improved as we have shifted more towards a macro forecast. While we conscientiously gather detail on new activity from a variety of sources, we tend to apply that information only as it will pull the workload out of the "normal" range. Let us review how one might actually go about doing all this.

RESTATE THE PAST

Characterize The Workload. Decide on the workload characterization that best meets the needs and realities of your installation. This characterization should be consistent, measurable and recognizable, and some history should be available in these terms.

Create A Baseline. In any case it is advisable to first create our macro forecast. When considering the period from two years out, this would seem to be the best available. Even for the short term, the vagueries of the micro approach make the creation of this baseline necessary to define our ballpark.

Normal Growth. The trended value includes normal growth. This means that just as new applications were developed and implemented, and existing systems expanded and grew, the trend reflects the expectation that new applications will continue to be developed and existing systems will continue to expand at this same rate. This is "normal" growth. This reassures us that it is not necessary to identify every little piece of future work.

Predictable Cycles. Develop adjustments to the trend line based on those phenomenon which tend to push demand up or down at the same time each year. We are now able to restate the events of the past with a reasonable degree of accuracy. If no big changes to the workload or environment occur, this will also project the future.

IDENTIFY FUTURE CHANGES

Gather Information. Utilize the techniques of the micro approach to forecasting to gather as much information as possible about the ways in which the future will differ from the past. A variety of sources can be employed to gather revelant information. Survey documents can be used to ask customers about changes in their expected demand. Resource Impact Forms can be developed and required as part of the documentation of new projects. Key people both in high and low places should be periodically interviewed. Good 'ol boy networks should be cultivated. Experience is essential and an element of espionage may be helpful. Remember that people must be aware of their current level of activity before they can be expected to be able to describe their estimate of future activity. The means must be developed to relate these changes to workload and resource demand.

Publish Assumptions. Compile the significant results of the information gathering process into an assumptions document that basically indicates what changes are going to be considered in the next iteration of the forecast. Publish this document to a wide audience and wait for people to tell you why it is incorrect. Thank them.

Significant Changes. We must be careful to survey the right people with the right questions, but now we can recall with some comfort Pareto's 80/20 rule and concern ourselves most with those elements or combination of elements which will take us outside the "normal" range. Recall that "normal" growth has been accounted for in our trend development process. In fact, we may be tempted to deviate from our baseline forecast only when we are able to identify specific reasons for doing so. When we identify activity that will cause workload demand to fall outside trended values, we will indicate a step in the trend line.

What this amounts to is an admission that we are willing to go to a great deal of trouble to gather a volume of information that will largely be ignored. By doing this however, we have significantly reduced the possibility that a major impact on the accuracy of our forecast has slipped by undetected.

The Result. Now we have a forecast which is firmly based on reality. It is historically sound. It has identified and considered the best available information regarding changes to the environment and

the corporate business plan. It is an accurate as possible, and it is defensible. The ability to defend or explain a forecast in terms that are intuitively sound is obviously of great benefit. Ask anyone who had to renegotiate an ever-expanding DP budget with cost conscious management. Now we take a big deep breath and publish our forecast to the world, or at least to the same audience as we asked to review our assumptions. Don't forget computer operations and the people responsible for doing the hardware plan. They have a vested interest.

The final forecast document might look something like figure 8.

DAILY VOLUME PER WEEKDAY PRIME SHIFT

SAMPLE FORECAST
figure 8.

Track And Report. It is essential that the actual workload is tracked and reported routinely (figure 9). If the process is to improve, it must be generally understood. The better the parties involved understand the process, the better the quality of information for the next iteration. Don't be afraid to publish your batting average. It is probably better than anyone would have expected, and is sure to improve.

MONTHLY COMMERCIAL PERFORMANCE SUMMARY

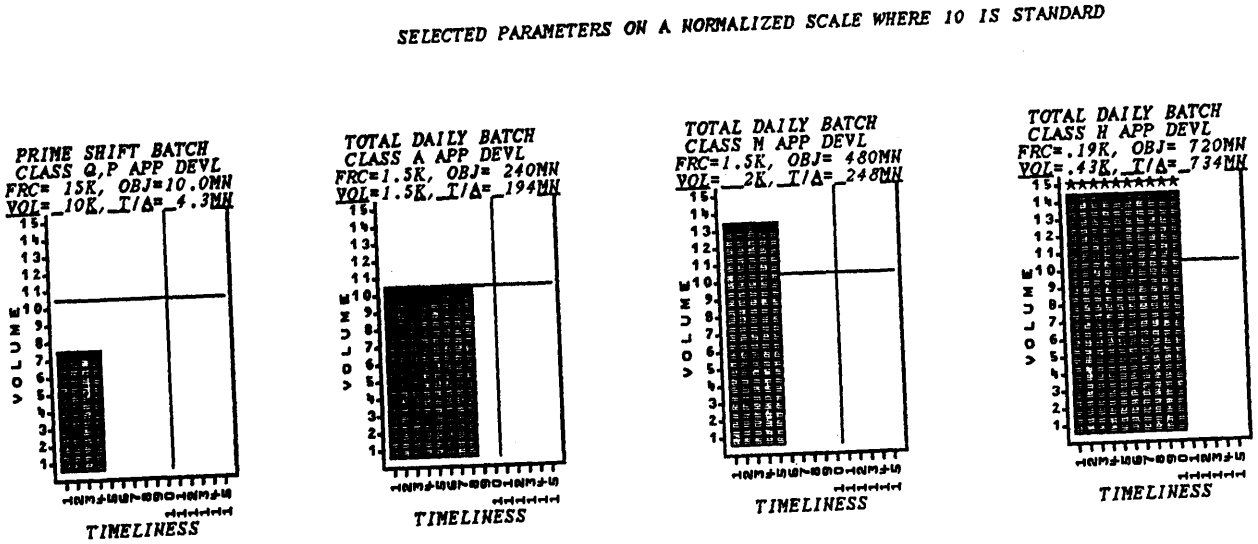
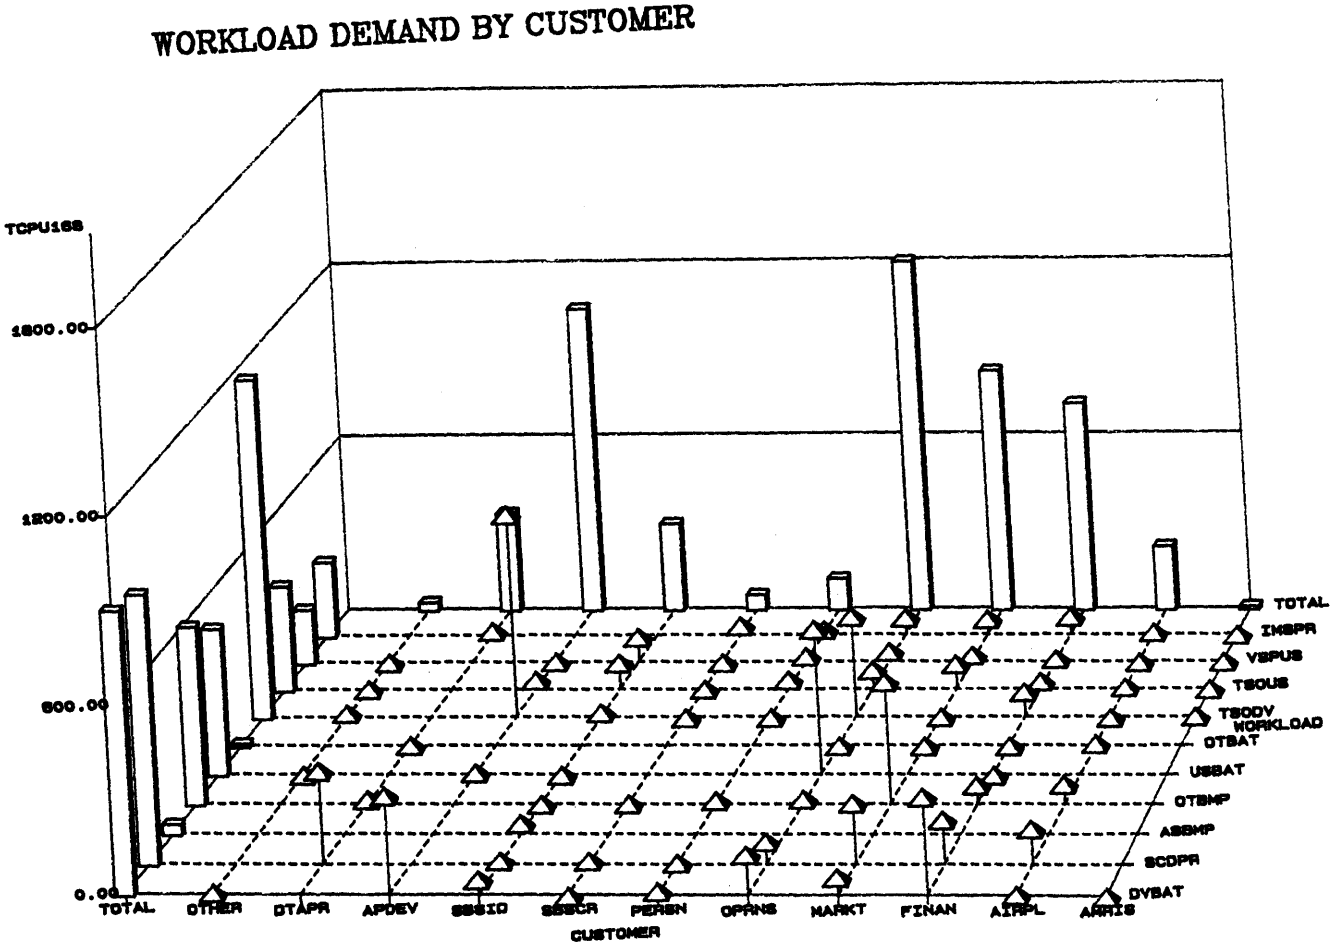
WEEKLY/MONTHLY ACTUAL VS FORECAST REPORT
figure 9.

The use of graphics helps the reader conceptualize information quickly. Figure 10 is a graphic (locally called a "Millergram") that normalizes both the forecasted volume and timeliness standard on a scale of 1 to 10 and allows a quick look at "how are we doing?"



COMPARE ACTUAL VS FORECAST WITH MILLERGRAMS
figure 10.

High level summarization of both workload and customer information can be displayed by SAS Proc G3D to give an insightive look at "who is doing what?" In figure 11, note that the vertical axis is in CPU units and the totals for each workload and customer are projected against the walls.



SHOW WORKLOAD DEMAND BY CUSTOMER WITH SAS PROC G3D
figure 11.

A FINAL WORD

This discussion here revolves around forecasting the workload. We are talking about the work to be done, not about the means for doing it. The discussion of a hardware/software environment to accommodate this workload and the costs of that environment are rightly the subject of a separate discussion. When both the work to be done and the cost of doing that work is made available to corporate management then the approval of the DP budget becomes a business decision. This is what we are here for.

Obviously, this brief paper does not comprise a "cookbook" for workload characterization and forecasting. It has simply attempted to suggest some approaches to this complex and challenging problem. There are a number of articles which provide more detail on specific aspects of the problem. A few are referenced here as a starting point.

APPENDIX A

RESOURCE IMPACT FORMS

The Commercial Resource Impact Forms are required to be completed as part of the feasibility study for a new application, and again as part of the detailed system design. They are intended to serve two purposes.

First they will be used to derive estimates of the cost of providing the application's resource requirements once implemented. Second, they will supply valuable advance information for the Commercial Demand Forecast used to support hardware planning.

These forms are intended to provide a convenient means of recording this information. Where possible, the questions are of the yes/no or fill in the blanks variety. If you have any difficulty with the question and require additional definitions or assistance, please referance the related pages which follow. If all else fails, call the Resource Measurement and Forecasting Group at 832-4631 or 832-4986 for assistance.

Some of the questions may be difficult to answer at feasibility time, although in all cases we would appreciate your best estimates. Questions which are optional at feasibility time are marked with an asterisk. By design time, most of the requested information should be available. Once provided, the information contained in these documents remains available to you for your examination and correction.

Once you have become familiar with these documents, it is hoped that you will not have any particular difficulty in using them. As you see ways in which they might be improved, please give us the benefit of your suggestions.

Good Luck!

HELP/Definitions for page 1

PR/SR #: Project Request Number or Service Request Number. This procedure may be used for either.

DATE: Today's Date.

SYSTEM/APPLICATION NAME: Title or name by which this activity is commonly known.

DESCRIPTION: Brief narrative description of what is to be accomplished by this activity.

MANAGER: Name of the Applications Development and Programming Manager with primary responsibility for this activity.

PHONE: Business telephone number. MD: Mail drop or business address.

PROG/ANALYST: Name of the individual supplying this resource impact information (you).

CUSTOMER/USER CONTACT: Name of a customer or user contact for whom this activity is being accomplished.

CUSTOMER/USER LOCATION: Physical location of customer/user; city, state, and country. May reference existing generic locations such as reservations, airports, subscribers, etc.

New Application: This activity will create a new application.

Provide the name ....: To assist in the estimation of resource requirements for this activity, it would be helpful to relate it to an existing activity whose resource requirements can be determined. For example, "similar in function to XYZ, but one-half the size."

Modification to ....: This activity changes an existing application.

Indicate the change ....: Estimate the relative size of the application after the modifications are completed. For example, "will expand XYZ by 25%."

Production Batch: Batch jobs to be submitted by computer operations.

IMS/BMP: Batch Message Processing jobs run as batch jobs to access online IMS databases.

Production IMS: Utilizes interactive Message Processing Programs (MPP's) to access online IMS databases.

IMS/DB2: Utilizes DB2 to access online IMS or DB2 databases.

TERADATA: A Decision Enabling Technology application utilizing TERADATA equipment.

TSOE/APL: APL activity under the TSOE environment.

TSOE/DB2: A DB2 application under the TSOE environment.

Other: A host environment or combination of environments not specified above.

PLANNED IMPLEMENTATION DATE: Estimated date at which this activity will be implemented into a production status.

PLANNED DESIGN REVIEW DATE: Estimated date at which the next scheduled design review will take place.

NEW BATCH/BMP APPLICATIONS (If the answer to any of these questions is yes, go to page 3.)

1 YES NO Will this activity require IMS BMP batch jobs?

2 YES NO Will this activity require other batch jobs?

3 YES NO Will job submission be controlled by the user/customer?

4 YES NO Will more than 5 jobs be submitted per week?

5 YES NO Will job submission and processing normally need to occur during prime shift (6am to 6pm workdays)?

NEW INTERACTIVE APPLICATIONS (If the answer to any of these questions is yes, go to page 4.)

6 YES NO Will this application add new users to the system?

7 YES NO Will this application require the creation of any new transactions?

8 YES NO Will this application result in more than 100 transaction entries per day?

9 YES NO Will this application require the creation of new data bases?

PERIPHERAL REQUIREMENTS (If the answer to any of these questions is yes, go to page 5.)

10 YES NO Will this application require more than 5 tape mounts per week?

11 YES NO Will this application require the allocation of more than 200 megabytes (millions of bytes) of permanent DASD?

12 YES NO Will this application require the allocation of more than 700 megabytes (millions of bytes) of temporary DASD?

13 YES NO Will this application produce paper output requiring distribution by Document Control?

14 YES NO Will this application create microfiche?

1: Batch Message Processing (BMP) jobs are batch jobs which access online IMS databases.

2: Any batch job other than an IMS BMP job.

3: YES if any jobs are submitted by the user/customer, NO if all jobs are submitted by computer operations.

4: YES if the total number of jobs submitted for the week is more than 5 jobs, NO if otherwise.

5: YES if jobs must be submitted during the prime daytime hours, NO if the jobs may be run during evenings and on weekends.

6: YES if new individuals, terminals, or locations will result from this activity, NO if otherwise.

7: A transaction is here defined to be an interactive cycle involving a program of instructions. This cycle may be initiated by a user at a terminal or by another program, and will result in the return of information to a terminal, or the interaction with a database of information, or both. YES if a new program cycle is to be developed, NO if otherwise.

8: A transaction entry is here defined to be the initiation of a transaction cycle either by a user making an entry from a terminal or by a message switch. YES if the volume of this activity will exceed more than 100 entries per day, NO if otherwise.

9: YES if a new database will be created or if new elements are to be added to an existing database, NO if no new databases or elements will be created.

10: YES if the total weekly activity of this application will require more than 5 reel or cartridges of magnetic tape to be mounted, NO if otherwise.

11: YES if permanent datasets will require the allocation of more than 200 megabytes of DASD, NO if less than 200 megabytes. This question is intended to determine if a threshold of 200 megabytes of permanent DASD is to be exceeded. If so, you will be asked in a later section to estimate the total permanent DASD requirements in megabytes.

12: YES if temporary datasets will require the allocation of more than 700 megabytes of DASD, NO if less than 700 megabytes. For additional help in estimating temporary DASD requirements, see page 2b.

13: YES if documents will be printed on a paper media for distribution, NO if otherwise.

14: YES if microfiche output will result from this application, NO if otherwise.

PERIPHERAL REQUIREMENTS

35* How many tape mounts will be required during the peak week? _____

36* What is the maximum number of concurrent tape drives allocated? _____

37 How many megabytes of new permanent DASD storage will be required? ___

38* How many megabytes of new temporary DASD storage will be required? ____

39* How many weekly lines of print will go to paper? _____

40* How many weekly microfiche masters will be produced? _____

Level 1 HELP/Definitions for Page 5

35: A mount occurs when a reel or cartridge of tape is loaded into a tape device. Estimate the total number of such mounts to be required by all jobs for the total week. If this may vary significantly over time, make estimates for a peak week. It may be useful to recall that a 3480 tape cartridge will contain approximately 200 megabytes of data.

36: The maximum number of physical tape devices which will be required at the same time. If this may vary over time, estimate a worst case.

37: The purpose of this question is to estimate the overall volume of permanent DASD which will be required by this application. While a more detailed breakout is not required, you may find it useful to detail your requirements to arrive at a total.

Data storage requiring the allocation of permanent DASD space are here defined as being one of three types: (Indicate space requirements in megabytes for each)

_____ Relational IMS or DB2 databases
_____ Generation Data Group (GDG) datasets
_____ Other non-relational non-GDG datasets (flat and VSAM files)

_____ Total for all Permanent DASD

It may be useful to recall that there are 630 megabytes of storage available on a single density 3380 device.

38: Temporary DASD space must be allocated for various work files and by sortout and sortwork requirements. Temporary space may be allocated and released at various times in the life of a job. It is of interest to know the largest concurrent requirement at any single time.

It may be useful to recall that there are 630 megabytes of storage available on a single density 3380 device.

39: The number of lines of print may be estimated as the number of pages for each report times the number of recipients times 50. If volumes may vary then estimate for a peak week.

40: A microfiche master is a sheet of microfiche film containing a maximum of 208 frames. A single document will require a microfiche master for each 208 pages of volume. Each single document will require at least one microfiche master even if its volume is as small as 1 page. Additional copies of such documents do not require additional masters. Estimate the number of microfiche masters to be produced. If volumes may vary then estimate for a peak week.

A STRATEGY FOR IMPROVING IO SUBSYSTEM DESIGN USING COST PER IO ANALYSIS

A. L. (Roy) Jones
Storage Technology Corporation

ABSTRACT

Traditional rules of thumb for IO subsystem design and maintenance are unsatisfactory. They often lead to the underutilization of very costly resources, less than desirable performance, and ever growing DP budgets. An alternative cost-effective approach is needed.

This paper outlines a strategy for improving the cost and performance of IO subsystems using a Cost-per-IO (CPIO) analysis methodology. By using the proper types of IO devices, empirically determined through CPIO analysis, most DP installations can both reduce costs and either increase workload throughput or decrease turnaround (response) time. CPIO analysis can easily be used to 1) evaluate current IO subsystem cost and performance, 2) assist data set assignment to an effective device, 3) assess the impact of alternative device assignments, and 4) estimate total system benefit if reconfigured. CPIO analysis will normally result in (suggest) a hierarchical IO subsystem design which places each individual data set on the storage device having the most appropriate related cost/performance characteristics. Thus, the cost and performance of the entire IO subsystem are improved. Operational and procedural benefits provide added value to most DP installations.

1.0 INTRODUCTION

In the current business world, Data Processing is often integral, if not critical, to the successful conduct of business by a corporation. Data Processing serves not only to enhance internal daily operations but also to provide timely and accurate support to valued corporate clients. Data Processing (DP) performance and related costs are becoming increasingly important to a modern corporation's bottom line profits.

Despite this, however, many DP installations today are faced with the somewhat unusual and highly undesirable situation of finding or being told that they cannot or should not fully utilize their DP hardware. For performance reasons, costly DASD storage devices are often only 50 to 70 percent utilized. Tape and DASD devices are often configured in "short" strings, thereby requiring a bloated number of even more costly device controllers. Recommended input/output (IO) channel utilization for the support of most device types is only 30 to 50 percent. Guidelines for maximum interval Central Processing Unit (CPU) utilization range from 70% to 90% with 70% the most commonly suggested for dynamic and highly visible online processing periods.

There are numerous studies available which employ queuing theory and industry findings to explain and justify limitations such as these. Hardware and software technology advances (e.g., dual-port or dynamic path reconnect) have been made over the years to relax restrictions but, despite these advances, the results are (or at least should be) unsatisfactory to a conscientious DP manager. Costly resources are underutilized and excess capacity must be provided to compensate.

1.1 COMMON PROBLEMS

Restrictive guidelines or rules of thumb may very well be valid for specific device types but, even when the common rules of thumb are followed, DP installations often experience slow batch job turnaround or extended periods of inadequate on-line system response. Problems which contribute to user dissatisfaction with DP service include:

- the low activity device syndrome
- high peak-to-average ratios
- workload and IO subsystem imbalance
- inability to fully utilize the CPU

The low activity device syndrome is characterized by the situation where low activity devices sharing a DASD string with high activity devices often suffer with degraded response time. Queuing theory explains this phenomenon: contention from the high activity device increases rotational miss probability for the low activity device and may therefore double or even triple the reconnect response time for an IO which is pending at the device. It may just be that the low activity IO is the real bottleneck or governing factor for online transaction response or batch job turnaround.

Interval peak-to-average ratios provide a well founded rationale for limiting overall average resource utilization to general guidelines during both online and batch processing periods, but they often do not fully account for the dynamic nature of the environment. In most cases, the guidelines are set at levels which will maintain resource availability for 85 to 95 percent of the processing period. It would be a rare DP environment, indeed, which would have a demand profile so consistent that 90 percent availability would also provide 99 to 100 percent availability. If resource demand significantly exceeds resource availability for only 5 minutes a day (approximately 1% of a prime shift), users can be severely impacted for 2 or 3 times as long while the demand backlog is worked off. It is during these times, however brief, that the phones of the Network Controller, Operations Manager, and even the Director of DP begin to ring with complaints from irate and frustrated users.

DP installations also tend to be characterized by workloads which shift their demand characteristics and resource requirements from period to period during the day, week, or month. Different types of IO devices are needed at different times. Once again, it would be an unusual DP shop which would have the luxury of a budget large enough to provide resources sufficient to meet all types of demand at all times. Resources are often shifted as needs and user pressures dictate, and inadequate "band-aid" measures are frequently used to provide adequate service for "special cases"; the end result is that some users are satisfied (more or less) at the expense of others.

The CPU is the most costly device in a DP installation but, even so, it often cannot be fully utilized. Peak-to-average ratios set guidelines for overall average CPU utilization at less than 100 percent. In addition, even when CPU demand is less than 100%, the demand cannot be fully serviced because the CPU must

wait for one or more IO operations to complete before proceeding (e.g., all tasks are waiting for data input). The latter condition is characterized on VMMAP or RMF reports by high queue lengths and the frequent occurrence of concurrent channel busy and CPU wait. The CPU has work pending but is waiting for IO.

The real problem which contributes to and actually aggravates the above problems, is the inability of the IO subsystem to respond to IO service requests in a timely fashion. More timely IO for both low activity devices and high activity data sets would permit the CPU to service processing demand more quickly. Speedier processing of individual tasks would reduce or eliminate demand backlog and tend to reduce the magnitude and volatility of peak-to-average ratios. Lower ratios would improve workload and IO subsystem imbalances. With faster IO, a CPU would experience less IO wait and could be more effectively and productively utilized during periods of peak processing demand.

1.2 SOLUTIONS: TRADITIONAL AND PROPOSED

Frequently suggested traditional solutions to DP performance problems include larger and faster CPUs, higher multiprogramming levels (MPLs), more main memory, more IO control units and/or storage devices, and more IO paths (or channels) to the IO devices [1]. All of these approaches involve the acquisition of more hardware resources at increasing cost and do little if anything to address the basic problems outlined above. With most of these solutions, device contention is aggravated and CPU demand is increased (to service the additional resources) while most job or transaction processing times are only slightly improved.

Traditional solutions tend to be implemented in piecemeal fashion when traditional rules of thumb indicate excessive utilization of (underutilized) devices. As such, these efforts tend to be preventative in nature (to prevent severe performance degradation) and do not offer significant performance improvement. All too often, the improvements which do occur are rather short lived.

The intent of this paper is to suggest an alternative way of thinking about IO subsystem design. The approach is designed to maximize or improve the utilization of current resources in a DP environment and to optimize the ratio of dollars spent to the amount of data processing work done. The hypothesis of this paper is as follows:

1) By making use of the proper set of IO devices, most DP installations can:

   - Improve device utilization
   - Reduce operating costs
     and
   - Improve performance
     (i.e., increase throughput
     and/or decrease turnaround)

2) The best device for any data set can be empirically determined through a process of Cost-Per-IO (i.e., CPIO) analysis

CPIO analysis offers the potential for an organization to improve DP performance while reducing related costs. CPIO analysis is based on a simple concept of producing the most work for the least cost through effective data storage device assignment and utilization. The proper application of CPIO analysis for IO subsystem design and maintenance will enable a DP organization to achieve what is, or at least should be, its primary objective --- improving the corporate return on dollars invested in Data Processing.

2.0 DEFINITIONS AND DEVICES

Before proceeding into development of the CPIO concept, the reader of this paper must understand the definition of certain terms used and the basic nature of the storage devices reviewed. The definitions establish a foundation and rationale for CPIO development. The IO devices are a tool and an end result of IO subsystem design; their fundamental characteristics establish guidelines for their effective utilization.

2.1 FUNDAMENTAL DEFINITIONS

Throughput is a measure of work units accomplished in a given time unit. Common DP measures of throughput include jobs per day, transactions per hour, and IOs per second. Turnaround is a measure of the time required to accomplish a unit of work. Common DP measures of turnaround include job run time, transaction response time, and device IO service time.

It is important to note that throughput and turnaround are not necessarily the inverse of each other --- the fact that an IO device provides an average service time of 20 milliseconds does not mean that the device can support 50 IOs per second. Path contention, queuing, and other factors come into play to prohibit linear inverse correlation of these measures.

While it is generally desirable to both increase throughput and decrease turnaround, the best overall measure of productivity in a DP shop is throughput. Simply put, this recognizes the fact that even though it may be desirable or even important to get work done in a timely fashion, it is even more important to just plain get the work done. Modern designs of Operating Systems, processing programs, and even computer hardware recognize this fact [2]; multi-tasking control programs and multi-processor CPUs all sacrifice turnaround (for the control of multiple operations) to achieve greater throughput.** Fortunately, greater throughput nearly always translates into a lower average turnaround over time and, hence, greater performance.

A work unit is a measure of work done. Common DP work units include jobs, jobsteps, transactions, and IO operations (IOs) to data storage devices. Among these, an IO is a basic building block; all of the other work units will invoke and require completion of a certain number of IOs on average. As such, improvements in IO processing will benefit the processing of all other common work units. For this reason, an IO is used as the basic work unit for development of the concept in this paper.

One additional definition is needed, not necessarily for development of the CPIO concept, but for clarification of what appears to be a common misconception in the DP industry. A megabyte (of storage device space) is a measure of space used, not work. A megabyte has occupancy or ownership cost only, relative to time. It is the use of (i.e., work done in) that time which establishes value. Work done to or from a storage device is an IO. A commonly heard statement that a certain storage device "should not be used because the cost per megabyte of storage is too high" is derived from misconception. Cost per megabyte (of storage space) on a device is not important; cost per IO (of throughput) on the device is.

** It is interesting to note that a rather loosely justified deviation from this philosophy is embodied in the introduction of synchronous expanded storage in the IBM 3090 series computer.

2.2 POTENTIAL DEVICES

Figure 1 presents a summary chart of commonly recognized current and pending technology storage device types. Nominal access time (order of magnitude) and the basic nature of data storage on the device are also depicted. It is beyond the scope of this paper to present a full discussion of each device, but certain characteristics are important to proper device selection [3,4] based upon (or in spite of) CPIO analysis results. The basic device considerations are described in the following paragraphs.

FIGURE 1

STORAGE HIERARCHY

Device Type	*Access Time*	*Nature*
CPU	nanoseconds	in-line
E/S	microseconds	on-line
SSD	milliseconds	on-line
CACHE	milliseconds	on-line
DASD	milliseconds	on-line
Optical Library	seconds	near-line
Cartridge Library	seconds	near-line
18-track tape, cartridge	minutes	off-line
9-track tape, buffered	minutes	off-line
Laser printer	-longer-	hardcopy
Impact printer	-longer yet-	hardcopy

The CPU (memory), while often not considered as such, is a storage device. Data accessed for manipulation by the CPU instruction processor is normally processed in chunks (words or frames) at CPU cycle time speeds. Even so, except in the very slowest processors, classical data records can be accessed in the nanosecond (billionth of a second) order of magnitude. CPU storage space is physically and logically (depending on the Operating System being used) very limited and therefore must be used very judiciously.

Expanded Storage (E/S), as currently implemented, requires an IBM 3090 CPU and extended architecture (XA). E/S currently supports paging only, so volatility (i.e., loss of data with loss of power) is not a significant issue. E/S cannot be shared between CPUs and plans for upgradeability (or transferability) to future generations of CPU can only be surmised; lack of upgradeability means that an investment in E/S must be written off over the life of the CPU to which it is attached. Access to E/S is by page frame synchronously (i.e., one page at a time without release of the central processor). IBM claims an access time of "about 75 microseconds" [5] but some industry measurements indicate that "the total time to resolve a page fault to expanded storage ---- is approximately 140 microseconds" [6].

Solid State Disk (SSD) offerings from several vendors, excluding IBM, include support for 2305, 3350, and 3380 device type interface. As such, SSD can be used on any CPU (and with any operating system) which supports one of these device types. SSD can be used for paging and non-paging applications, is sharable between different CPUs, and can be transferred from one CPU to another, even from multiple vendors. Access to SSD storage is asynchronous using 2 to 4 paths with an access time of 0.3 milliseconds (300 microseconds) plus channel transfer time for a usual total of 2-4 milliseconds. SSD storage is volatile but several technologies which eliminate or significantly reduce exposure to potential power loss are available in current offerings. These include battery backup, uninterruptible power supply (UPS), attached hard disk backup, and critical file duplexing via software. Volatility should certainly be considered for non-paging, non-temporary applications, but the issue should never preclude using an SSD if appropriate [7] for performance and cost improvements.

Cached DASD (CACHE) is simply rotating DASD such as 3350 or 3380 type devices enhanced by the inclusion of several megabytes of buffer storage (and the associated buffer management logic) within the rotating DASD control unit. The buffer does not represent permanent storage space; permanent storage continues to be the rotating DASD configuration. A cache control unit offers the potential for the significant improvement of access times to data stored on attached rotating DASD, but at significant additional cost for the acquisition and maintenance of the enhanced control unit. If properly [8] configured, a cache subsystem offers 6-10 millisecond service time and will permit significantly higher channel and device utilization than standard rotating DASD. A cache subsystem, however, is highly susceptible to misconfiguration; normally, data behind cache must exhibit a high (4+:1) read to write ratio and a suitable reference pattern in order to achieve cost effective beneficial results.

Rotating DASD is familiar to everyone. Rotating DASD potentially supports a wide range of IO per second with an equal or even larger range of IO service times. A nominally "good" service time can vary from 18 to 24 milliseconds. Device and operating system differences alter expected nominal results to some degree: dual port (or DLS) architecture increases supportable IO rate and/or decreases service time; dynamic path reconnect also helps. Data reference pattern has a noticeable impact on actual results with an individual DASD device. It is believed, however, that nominal results (or expectations) are valid for an entire DP installation. As a result, CPIO development uses a single value (from traditional guideline values) for rotating DASD of all types while recognizing that average values for any single environment might vary by 10 to 15 percent in either direction.

Automated optical or cartridge libraries are a device type which introduces a new concept of "near-line" storage. Data stored in such a library is not "on-line" with nearly instantaneous (millisecond) access but it is also not "off-line" with a manually initiated access which may take minutes or even longer. Mount times of 5 to 20 seconds are typical for library devices and may be very acceptable for many data sets currently maintained on relatively expensive rotating DASD. It may be time for DP installations to rethink archival policies in light of the potential offered by these devices. Users and programmers who keep large data files "on-line" simply to avoid the inconvenience of "off-line" storage may very well accept the minor delay associated with "near-line" storage, especially when the projected cost savings are substantial.

3.0 CPIO DEVELOPMENT

The basic objective of cost per IO analysis is to optimize (or improve) the overall cost and performance of data storage and retrieval subsystems within a Data Processing environment. The concept is based on the following tenets (developed and discussed at length in the preceding section):

1) Throughput is a better and more usable measure of overall DP productivity than turnaround. It is also more realistic for determining device and/or subsystem productivity.

2) A valid common measure of work done in a device, an IO subsystem, or a DP facility, is an IO operation. Average IO operations per second (IO/Sec) is the corresponding measure of throughput.

3) Improving the actual or potential throughput (IO/Sec) of an environment will improve the productivity of the environment. Improved productivity, with few exceptions, will result in improved turnaround (or performance).

4) Cost per IO (of throughput) is the ultimate measure of device or environment effectiveness. Improved effectiveness means:
   - lower cost with equal or greater productivity
   - higher productivity with equal or lower cost

5) Improving the effectiveness of the IO devices in an environment will improve the effectiveness of the total environment.

CPIO development is the process of deriving and understanding the cost per IO characteristics of various potential IO subsystem devices. Assumptions, results, and conclusions are presented in the following sections.

3.1 ASSUMPTIONS

In recognition of the myriad combinations of IO device variations, subsystem configurations, IO blocksizes, and IO device costs, several assumptions and scope limitations have been placed on this initial CPIO development. These limit the complexity of the development but provide a solid foundation for interpretation of the results and application of the concept.

To date, CPIO results have been developed for on-line devices only, in recognition of the fact that on-line IO subsystem effectiveness is usually the most important to a DP organization. Calculations and results have been developed for a representative "small" configuration and a representative "large" configuration of each "on-line" device type. Device throughput potentials (i.e., maximum IO per second) are based on a nominally "good" IO service time for the device when it is processing an average 4K to 6K average blocksize. The device characteristics used are summarized in Figure 2 and Figure 3. SPECIAL NOTE: CACHE configurations are simply a controller upgrade with an associated standard DASD configuration.

Cost calculations are based on list 5-year term lease payments (TLP) and maintenance from a standard vendor of the device type. It is fully recognized that some differences exist between vendors for the list price of equivalent configurations and that the list prices are usually discounted, but some basis for comparison must be used and this would seem to be as good as any. Costs associated with power, cooling, and floor space occupancy are excluded.

StorageTek Pricing Guide, April, 1987

The assumptions made for Expanded Storage deserve special comment. Access to E/S is synchronous (i.e., one page at a time without relinquishing the CPU). Access time reports vary from 75 to 140 microseconds. For simplicity, a value of 100 microseconds is used. At 100 microseconds per page (or IO), every 100 IOs per second consume 10 milliseconds (or one percent) of a processor per second (i.e., 100 IO/Sec = 1% of a 3090 processor). The author of this report is not aware of established or tested physical limits to E/S throughput but a practical limit of 1000 IO/Sec (10% of a processor) has been assumed; how much of the CPUs processing power should be realistically sacrificed in direct support of paging IO activity? It is also believed that CPU cost should be recognized and included as a factor (variable with IO rate) in the E/S cost per IO calculations, but, for simplicity and brevity, CPU costs associated with E/S block transfer activity have been excluded.

3.2 CALCULATIONS AND RESULTS

The calculation of cost per IO processed on a device involves the parameters of space, time, cost, and work. These parameters are variable by device type and by configuration size within device type. The basic CPIO analysis formula which incorporates each of these parameters is:

$$\frac{\text{COST}}{\text{IO}} \quad --- \quad \frac{\text{COST/SEC/MB}}{\text{IO/SEC/MB}}$$

COST/SEC/MB incorporates device configuration cost (COST) in relation to time (SEConds) and megabytes of storage space (MB); it is the occupancy cost for one megabyte of storage space in a device or IO subsystem configuration. IO/SEC/MB incorporates work done (IO) in relation to time (SEConds) and megabytes of storage space (MB); it is a measure of throughput per megabyte. COST/IO is the resulting measure of the effectiveness of a device or IO subsystem.

FIGURE 4

Cost Evaluation

Configuration Occupancy Cost($) : Cents

	$/Min	$/Sec/MB (x1000)
Small E/S	20.0	5.21
Large E/S	36.9	4.81
Small SSD	6.8	4.70
Large SSD	78.3	1.70
Sm. CACHE	11.9	.079
Lg. CACHE	44.9	.037
Sm. DASD	7.7	.051
Lg. DASD	25.6	.021

Figures 4 and 5 present initial development results for the reviewed device types and the assumed configuration sizes. Figure 4 develops occupancy costs and Figure 5 develops maximum utilization limits. The understanding and acceptance of these results is essential to the understanding and acceptance of the CPIO concept.

In Figure 4, $/Min represents the cost (presented in cents, or 0.01 dollars, for scaling reasons) of owning or having the corresponding configuration for one minute of time. It is simply the monthly cost of the device outlined in the preceding section divided by 720 hours and then divided by 60 minutes. For example:

Configuration: small DASD (2 directors + 4 3380-1x volumes)
Cost per month = 2841 (TLP) + 471 (maint.) = 3312 dollars
Cost per hour = cost per month / 720 = 4.60 dollars
Cost per minute = cost per hour / 60 = 0.0767 dollars
Cents($)/Minute = 7.7 (rounded)

$(cents)/minute results for the various configurations are highly variable. As might be expected, larger configurations of any device type cost more.

Also in Figure 4, $/Sec/MB represents the ownership or occupancy cost per second of one megabyte of storage space in the associated configuration. Once again, the results represent cents (0.01 dollars) and are multiplied by 1000; in other words, the results are really thousandths of a cent per second per megabyte (or they could alternatively be viewed as cents per second per gigabyte of storage space). For example:

Configuration: small DASD (2500 megabytes)
Cost per minute (from above) = 7.7 cents
Cost per second = cost per minute / 60 = 0.1283 cents
Cents/second/megabyte = cents per second / 2500 = 0.0000513
Cents($)/Sec/MB (x1000) = 0.051 (rounded)

$(cents)/Sec/MB has a definite decreasing trend as configuration size increases or the device type gets slower. This corresponds to the common (and frequently misapplied) recognition of this trend in relation to simple cost per megabyte of storage space.

In Figure 5, Maximum IO/Sec/MB is the computed maximum throughput capability per megabyte of each device configuration. It is simply the maximum throughput (IO/Sec) rate of the device (from Figure 3) divided by the total megabytes in the configuration (from Figure 2). For example:

Configuration: small DASD (2500 megabytes)
Maximum IO per second = 50 (from Fig. 3)
Maximum IO/Sec/MB = Max. IO per second / 2500 = 0.020

In reviewing Maximum IO/Sec/MB, it should be remembered that this value is not necessarily the absolute maximum rate supportable by the device; it is the maximum throughput rate which can be sustained on average while maintaining a nominally "good" average response time. As might be expected, the supportable IO/Sec/MB limit generally decreases as the devices get slower or the configurations get larger. One exception to the general trend is that a small SSD can support a greater throughput per megabyte than any size of Expanded Storage (mainly because E/S has a larger minimum size than SSD).

Minimum $/IO in Figure 5 essentially represents the maximum cost effectiveness for each configuration; therefore, the smaller the number, the better. Like

FIGURE 5

Cost Evaluation (cont.)

Maximum Utilization Limits
Cost($) : Cents

	Maximum IO/Sec/MB	Minimum $/IO(x1000)
Small E/S	15.6	.33
Large E/S	7.8	.62
Small SSD	25.0	.19
Large SSD	0.78	2.18
Sm. CACHE	0.08	.98
Lg. CACHE	0.01	3.70
Sm. DASD	0.020	2.55
Lg. DASD	0.0025	8.40

the other numbers above, this value is in cents (i.e., $ = cents) and is multiplied by 1000 for scaling purposes. This value is computed from the basic CPIO formula using the previously developed configuration residency cost and maximum throughput. For example:

Configuration: small DASD
$/Sec/MB (x1000) = 0.051 (from Figure 4)
IO/Sec/MB = 0.020 (from Figure 5)
$/IO (x1000) = 0.051 / 0.020 = 2.55 Cents per 1000 IOs

Because the maximum value is used for throughput (i.e., IO/Sec/MB), the result is the minimum cost per IO processed on the device if the configuration is used to its fullest potential. Cost per IO cannot be less without a an attendant degradation in average service time for the device.

3.3 INITIAL CONCLUSION AND EXTENDED RESULTS

The results presented above, particularly for minimum cost per IO, prove an important basic conclusion of CPIO development. Contrary to popular belief, fast devices such as CACHE and SSD, if properly utilized, can provide greater throughput at lower cost (per IO) than slower devices such as standard rotating DASD. Thus, effective use of faster devices offers the potential for a DP shop to improve performance and reduce cost of operation.

This conclusion, however, raises several attendant questions. How can effective use of a device be assured? What is the effect if the device is not used to its fullest potential? Can the best device for the placement of a data set be determined using CPIO results and, if so, can the financial and performance impact of placing the data set on an alternative device type be determined? Can the effectiveness of the current IO configurations at a DP installation be assessed? Can the potential for overall improvement to IO subsystem effectiveness be estimated?

In recognition of these questions, CPIO results have been extended to include an evaluation of cost per IO on the various device subsystems at throughput rates which are less than their maximum potential. Figure 5 gives a maximum throughput and a minimum CPIO for each evaluated configuration. When throughput is decreased from its maximum value for a specific configuration, the basic CPIO formula (i.e., Cost/IO = Cost/Sec/MB / IO/Sec/MB) produces an increasing CPIO.

Consider the following example of the impact of throughput variation:

Configuration: small DASD (2500 megabyte)
Max. throughput = 0.020 IO/Sec/MB
Min. cost per IO = 2.55 cents/IO (x1000)
Variable CPIO (x1000) = 0.051 / IO/Sec/MB

When this variable formula is used for a range of potential throughput rates, the results are:

Throughput(IO/Sec/MB)	CPIO(cents/IO x 1000)
0.020	2.55
0.010	5.10
0.001	51.00
0.0001	510.00
0.00001	5100.00

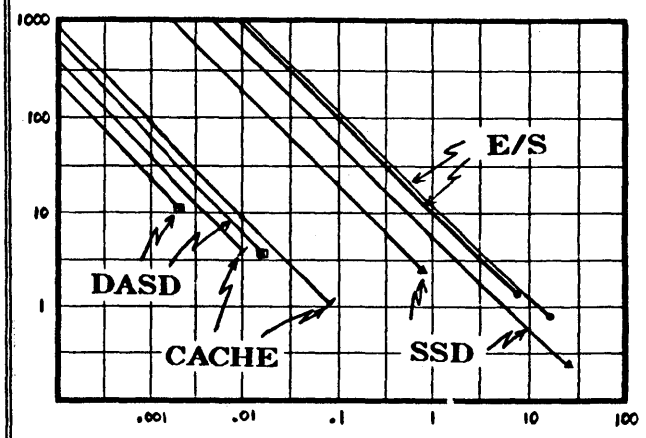
From these results, it can be seen quite readily that cost increases rapidly, in direct inverse proportion, as throughput decreases. It is also evident that any device which is significantly underutilized (e.g., a small DASD configuration processing less than 2.5 IO/second, or 0.001 IO/Sec/MB) can be very costly indeed.

Figure 6 presents variable CPIO results in graphic form for each device configuration within some reasonable parameter ranges.

FIGURE 6

Cost per IO Analysis Chart

Universal Scaling



Cost/IO vs. IO/Sec/MB by Device Type
X-axis: IO/Sec/MB (log scale)
Y-axis: Cents per 1000 IO Operations (log scale)

By using a logarithmic scale on each axis of the graph, the results for each configuration appear as a straight line. The delimiting point at the lower right end of each line is the maximum throughput, minimum CPIO value for the configuration. Each device type is represented by two lines; the rightmost line represents the small configuration for the device type and the leftmost line represents the large configuration. A large number of configuration sizes are available for each device type which would create lines (not depicted) at several points between and parallel to the extremes which are depicted. SPECIAL NOTE: the CACHE and DASD device configuration ranges overlap each other and create a special consideration which will be discussed later in this paper.

Since most of the potential cost values in Figure 6 are much higher than any reasonable or acceptable cost for a DP installation, Figure 7 is presented to put the CPIO values (Y-axis) into normal scale (i.e., not logarithmic). This presents a more usable form of the CPIO analysis data which will be referenced frequently from subsequent sections of this paper. It also accentuates the negative impact of inadequate throughput to a device and helps clarify lower limit throughput values for each configuration type.

The primary implication of this graph can be stated as follows:

> For each device type and configuration size, there is a limited range of throughput rates (IO/Sec/MB) which will provide an acceptable operating cost (i.e., cost per IO) and performance (i.e., IO service time).

For clarification of this basic CPIO concept, consider Figure 7 and a large DASD configuration (the leftmost curve). The results indicate that data placed on a large DASD configuration should exhibit an actual or demand average throughput rate between 0.0010 IO/Sec/MB (selected value) and 0.0025 IO/Sec/MB (max. limit from Figure 5).

Data operating at a rate less than 0.0010 IO/Sec/MB would have an undesirable operating cost (i.e., higher than 20 cents per 1000 IOs). Data operating at a rate greater than 0.0025 IO/Sec/MB would either exhibit subnormal performance (i.e., a service time longer than 22 milliseconds) or would require that compensating space on the device be excluded from effective utilization (e.g., 50 MB at 0.005 and 50 MB at 0.000 would maintain the supportable throughput level and the nominal service time).

If 20 cents per 1000 IOs is considered to be the maximum acceptable operating cost for an IO configuration, then desirable or target throughput rate ranges can be developed for each device type. The following table summarizes these results. The results are calculated but can be verified from Figure 7 (remember that the X-axis on the graph is logarithmic).

DEVICE TYPE	TARGET THROUGHPUT RATE (IO/Sec/MB) SMALL CONFIG.	LARGE CONFIG.	ALL CONFIG'S
DASD	0.0025-0.0200	0.0010-0.0025	0.001-0.020
CACHE	0.004-0.080	0.002-0.010	0.002-0.080
SSD	0.235-25.00	0.085-0.780	0.085-25.00
E/S	0.26-15.6	0.24-7.80	0.240-15.60

These target rates establish a clearly defined cost and performance effective throughput range for each on-line device type. They are an important and verifiable result of CPIO development and suggest a potential for improvement to IO subsystem design using CPIO analysis.

Y-axis: Cents per 1000 IO Operations

4.0 SUMMARY OBSERVATIONS

The CPIO development results presented above provide the foundation for several noteworthy observations. Items of interest include operating cost guidelines, device implications, and potential applications for the CPIO analysis concept.

4.1 COST GUIDELINES

A direct observation from the results is that the maximum utilization cost per IO for any on-line device type is less than 9 cents per 1000 IOs. If all devices in a DP shop are properly utilized at or near maximum IO rate and maximum space utilization, the DP shop should be able to operate at an average cost of 9 cents per 1000 IOs or less and maintain a nominally "good" average IO service time (e.g., 20-22 milliseconds for standard rotating DASD).

Many DP shops, however, cannot operate at maximum utilization levels on a constant basis. Because of workload fluctuations and the nonlinear degradation of device IO service times when recommended maximum throughput rates are exceeded, most shops must either maintain an average utilization less than maximum or suffer with less than desirable average IO service time. Operation at less than maximum utilization may be necessary but the reasons for doing so should be consciously recognized.

A nominal realistic operating cost target for any DP installation would appear to be 12 cents per 1000 IOs or less. If the most cost effective devices and configurations are properly employed in IO subsystem design, these results can be easily achieved even at 75% utilization or less.

4.2 DEVICE IMPLICATIONS

When the CPIO Analysis Chart for on-line device types (Figure 7) is studied, three gaps in the graph, relative to IO/Sec/MB, can be observed. An effective device type is not evident if the actual or demand throughput rate for data is:

- less than 0.001 IO/Sec/MB
- greater than 0.02 and less than about 0.10 (and the data is not cachable), or
- greater than 25 IO/Sec/MB

Gap 1 --- What should be done with data having a low throughput rate? Barring special circumstances such as a direct access file structure or a real need for immediate access, the traditional approach for low throughput data has been to place the data on tape. To put this in perspective, consider the following: a throughput rate of 0.001 IO/Sec/MB for a 200 MB data set equates to 17,280 IOs per day; this is equivalent to one pass of a 200 MB tape reel per day if the data is blocked at 12,000 bytes or only one pass every three days if the data is blocked at 4,000 bytes. Clearly, the data set is a classic candidate for placement on tape. CPIO results bear this out and indicate that cost per IO on disk would be at least 20 cents per 1000 IOs (unacceptable) and potentially much higher for a lower rate. The cost of maintaining the data set on disk would be at least $3.46 per day (i.e., 17,280 IO/day x $0.00020 $/IO) or over $100 per month; the cost for maintenance on tape would be the lower cost associated with 10 to 30 tape mounts per month.

Frequently, however, data sets with a throughput rate even lower than 0.001 IO/Sec/MB are (improperly) placed or left on DASD to avoid the inconvenience associated with manual tape mounts. This type of action is typically justified by placing the low activity data set on a volume with one or more very high activity data sets and claiming that the low activity data will simply utilize space left vacant and "wasted" for performance reasons. Thus, we have the crux of an important CPIO concept: CPIO analysis suggests that utilization of a DASD device to share both very high and very low activity data is normally an improper application of the DASD device on both counts. It is highly probable that the low activity data set would perform quite satisfactorily with lower cost on tape while the high activity data set(s) would perform much better and also with lower cost on a CACHE or SSD device. Recent developments with "near-line" storage devices would seem to make this even more attractive.

Gap 2 --- What should be done with data which has an intermediate throughput requirement (i.e., between 0.02 and 0.10 IO/Sec/MB) and is not cachable (i.e., will not provide assumed response time and throughput when cached)? Three current alternatives appear to be:

1) Relax cache requirements? This is a marginal possibility requiring individual case evaluation. Consideration of this possibility will reveal that doing so will only move the CACHE CPIO curves to the left and upward on Figure 7. As cache criteria are reduced, the CACHE curves will approach and actually rise above (i.e., become more costly than) the DASD curves; if improperly configured, CACHE could actually support less throughput [9] at greater cost than standard rotating DASD.

2) Place the data on standard DASD? This is always a potential course of action with recognition of higher (than CACHE) response time and the necessity to provide compensating "wasted" space on the receiving device or suffer with even worse than normal DASD response time.

3) Place the data on SSD? This can also be done. Response time would be better than for CACHE and much better than for DASD but the cost per IO would be significantly higher.

Each of these alternatives should be evaluated in light of the DP facility's objectives and priorities. If the data set is used primarily for batch processing, DASD may be the preferable option. It should be noted, however, that many installations today are being sold (improperly, we think) on the option to "relax cache requirements". If the data set is used primarily for on-line processing from terminals, the SSD option can do wonders for transaction response time and user good will, and may very well be worth the incremental cost.

A fourth possibility for the intermediate gap is that a new device type may be needed in the industry. Except for those relatively few data sets which are cachable, there is no effective device for the support of data sets in the intermediate throughput range. And many of these data sets are well known to DP shops; they tend to be those troublesome data sets which place the greatest stress on the total throughput capabilities of a standard DASD subsystem and which require constant and expensive tuning effort.

Gap 3 --- What about throughput demand greater than 25 IO/Sec/MB? Such demand is relatively rare but does exist. The most obvious device for placement of this data, at least while being used, is real CPU memory; operating systems and processing programs usually account for high usage and, by internal design (e.g., paging and buffering), provide for central processor residence of the highly active data. IO devices of the future may provide for extensions to this external device limit, but there are none in evidence today.

4.3 APPLICATION POTENTIALS

A final observation regarding the CPIO development results is that the concept offers significant potential for improving the effectiveness of IO subsystem design. The CPIO Analysis Chart (Figure 7), in particular, offers a simple framework which can easily be used to:

- evaluate current IO subsystem effectiveness
- assist identification of the best device for data set placement
- assess the impact of alternative device assignment, and/or
- estimate the cost and performance benefits offered by a suggested reconfiguration

The chart incorporates both cost and performance characteristics, permitting improvement of both. By assigning each data set to the device which is most appropriate to its throughput, usage characteristics, and importance, the overall effectiveness of an entire IO subsystem can be improved or optimized.

5.0 THE OPTIMIZATION PROCESS

IO subsystem design and maintenance is the process of assigning DP information files to IO devices, sizing and installing the appropriate equipment, and maintaining the resulting configuration. CPIO analysis offers the potential for a DP shop to truly "optimize" IO subsystem design if optimization is viewed as getting greater benefit for less expenditure.

In common practice today, files (or data sets) are assigned to data storage devices based on qualitative criteria (e.g., usage or file structure) rather than quantitative criteria (e.g., cost per IO). The number of device types employed tend to be rather limited. Standard configurations include devices for hardcopy,

off-line, and on-line data storage but there is often just one device type in each category. Multiple offerings within each category tend to be available only if prompted by sheer need (e.g., intolerable performance).

CPIO analysis provides a quantitative technique to assist the IO subsystem design process. CPIO development results indicate that several different types of devices are necessary to effectively support data sets with different throughput demands; CPIO analysis enables and enforces consideration of multiple device types.

Figure 8 lists the component steps of an IO subsystem reconfiguration effort. CPIO analysis will accomplish or augment the first five of these steps. While the concept can be used with exact configuration cost and throughput calculations for exact results, the CPIO Analysis Chart (Figure 7) can be easily used for working approximations and meaningful results. Applications of the chart are discussed below.

FIGURE 8

The Optimization Process

1. **Identify or verify need**
2. **Establish best device per data set**
3. **Evaluate data set placement(s)**
4. **Total system requirements by device and establish configuration levels**
5. **Project revised cost & service time**
6. **Review**
7. **Implement**
8. **Review**

SPECIAL NOTE: It is recommended that all data used for CPIO analysis (e.g., RMF, SMF, VMMAP, etc.) cover at least a representative 24-hour interval --- longer if possible.

5.1 STEP 1 - IDENTIFY OR VERIFY NEED

In the DP industry, hardware configuration changes are rarely scheduled or even contemplated without a present or imminently pending need. The need may be a simple application requirement for a new feature or more storage space, but more frequently it is a need growing out of performance concerns (e.g., complaints from users or measured deteriorating service levels). Performance and application needs will always occur (without respect to CPIO analysis).

CPIO analysis introduces the possibility for a new type of need, or measurable cause for concern --- namely, installation effectiveness. Quantifiable potential improvements to performance and cost imply a need (to improve operating effectiveness). Quantifiable shortcomings in either cost or performance with respect to other installations should also imply a need (to correct operating deficiencies).

CPIO analysis provides a method to measure current effectiveness and to assess the potential for improvement. The process of current installation assessment using CPIO analysis can be outlined as follows:

1) By device type or subsystem set (i.e., a configuration grouping within device type such as long strings versus short strings), determine:
   - total IO per second (average)
   - average configuration size
   - total megabytes in the set

2) For each set, compute the IO/Sec/MB; divide the total IO per second of the set by the total megabytes in the set.

3) On the graph in Figure 7, for each set:
   - move right on the X-axis the the computed IO/Sec/MB
   - move straight up from this point to intersect the curve which corresponds to the average configuration type and size established

4) The corresponding Y-axis value denotes the cost per IO for the device type or set; if more than one set is present at the installation, repeat steps 1 through 3 for each and compute a weighted average of the total environment CPIO.

5) Use standard RMF or VMMAP data (in DASD device activity reports) to determine weighted average IO service time for the installation.

Given the cost per IO and average IO service time, thus determined, we have a complete measure of current installation effectiveness. Each installation must be its own judge as to the need or desire for improvement (refer to Section 6 for comparative industry findings).

5.2 STEP 2 - OPTIMIZE DATA SET DEVICES

Once a need for reconfiguration is established, CPIO analysis can be used to easily identify the most cost effective potential devices for one or more data sets. The word "potential" is stressed because the the indicated device may not be functionally appropriate for the data set (see Step 3) or it may not be available (or provideable) in the required configuration size at the completion of configuration sizing (see Step 4). CPIO analysis is a design process which may involve reiteration between steps 2 and 4.

In step 2, the first activity is to determine the current or needed throughput (IO/Sec/MB) of the data set. Current throughput will produce acceptable results but consideration must be given to hidden or potential needs if the result is to be optimal. Consider the following:

- do multiple copies of the file exist?
- is there excess unused space in the allocated space?
- what will the throughput be if the data set is on a faster device?

With the established throughput, move across the CPIO Analysis Chart's X-axis to the determined rate and move vertically to the first curve line intersected. The line which is intersected is associated with the most appropriate and cost effective device with one possible exception --- if the line is the large CACHE line, either CACHE or an "intermediate" size DASD could be

considered. Step 3 will evaluate this situation; if the data set is cachable, then CACHE would be the device of choice because of the superior performance offered.

5.3 STEP 3 - EVALUATE DATA SET PLACEMENT

After the best potential device for a data set has been identified, the indicated placement must be evaluated with respect to proper compatibility of the device and the data set characteristics. For example, a data set which appears to be most appropriate for CACHE may not exhibit the read to write ratio and locality of reference necessary for the effective utilization of cache. If it does not, an alternative device assignment must be determined.

The CPIO Analysis Chart can be used to readily assess the impact of an alternative data set placement. The point of curve intersection established in Step 2 can be moved up to a new device-type curve with an increased performance and cost per IO or it can be moved to the left to the curve for a device offering less performance at equal or greater cost. The intersection point cannot logically be moved down or to the right: since the point was established by the first curve moving up, there is nothing lower; moving to the right would imply improved throughput, but maximum throughput demand has already (properly) been considered.

The relative cost and performance values for alternative devices, thus determined, can be subjectively evaluated to select a final recommended placement. Considerations of "cost vs. performance" have always existed but CPIO analysis puts the cost factor into meaningful quantitative terms.

5.4 STEP 4 - SUMMARIZE REQUIREMENTS

After all data sets have been assigned a "recommended" device type, appropriate device configuration sizes must be established. Thus far, we have a list of data sets, each requiring a certain number of megabytes of storage space and imposing a certain demand throughput on a set of recommended devices. The next step is to total (add up) the IO/Sec and the megabytes required for each device type; from these two values, the total IO/Sec/MB for the device type can be computed by simple division.

The total current throughput and space requirement, thus determined, provide a foundation for sizing an appropriate configuration of the suggested device. In addition to these current values, however, anticipated future growth, previous device assignment compromises, and the potential for revised utilization of the whole computer system (due to implied performance improvements), should now be considered.

The CPIO Analysis Chart can easily be used to facilitate this entire process. Cost per IO of the summarized configuration for each device type can be easily estimated. The potential impact of providing excess capacity for future growth can be assessed. The impact of possible changes to overall average throughput rates can be readily determined. The result of this process should be a complete, fully understood, and comfortable IO subsystem design which will probably incorporate several device types and configuration sizes in a clearly hierarchical structure.

5.5 STEP 5 - ESTIMATE BENEFITS

The last step is to estimate, in quantitative terms, the potential benefit of implementing the suggested IO configuration design. It is recognized that any change to a hardware configuration can be very traumatic for a DP installation, and a suggested reconfiguration which probably implies acquisition of new device types with some associated procedural changes can be even more frightening. The benefits which are offered must be clearly understood before a change will be warranted and approved.

The acquisition of new devices implies new expenses --- so where are the potential cost savings? This question pinpoints a basic and fundamental effect of using CPIO analysis for IO subsystem design and reconfiguration. By moving data sets with higher throughput demand to more appropriate (faster) devices, the space occupied by the data sets (and probably much more compensatory "wasted" space) is freed on the original device(s). If the impact of high throughput data sets is removed from low throughput devices, the low throughput devices can be utilized much more effectively (i.e., with a higher percentage of space allocation). The storage space, thusly reclaimed, has a definite monetary value which can be recovered by disposition (e.g., sale) of the vacated devices or recognition of the value in deferred future growth expense (i.e., the space can be reserved for future growth so that acquisition of new devices will not be required later). Performance improvement is a natural consequence of matching data set throughput demand with device throughput capability.

The CPIO Analysis Chart (Figure 7) provides a simple framework to estimate the new cost per IO on each recommended device type configuration. Device characteristics (Figure 3) provide the target estimated service time for each device type. For simplicity, the median value can be used. With these parameters for each device subsystem (designated by subscript $_n$), total system cost per IO and average IO service time can be estimated.

Total system cost per IO (X) can be computed as a weighted average using the following formulas:

$$A_n = (IO/Sec)_n * (Cost/IO)_n$$
$$B_n = (IO/Sec)_n$$
$$X = (A_1 + A_2 + ...) / (B_1 + B_2 + ...)$$

Total system average service time (Y) can be estimated with a similar weighted average development:

A_n = the average service time for device type $_n$
(E/S=0.1ms, SSD=3ms, CACHE=8ms, and DASD=20ms)

$$B_n = (IO/Sec)_n * A_n$$
$$C_n = (IO/Sec)_n$$
$$X = (B_1 + B_2 + ...) / (C_1 + C_2 + ...)$$

Thus, we have an estimate of the primary reconfiguration benefits. The cost per IO and average service time values provide a measure of revised installation effectiveness.

Figure 9 presents a list of somewhat intangible but meaningful added benefits. Several discussions presented above have laid a foundation for an understanding of the listed benefits so they will not be expanded in detail. It should be noted, however, that perhaps the most important added value benefit of a suggested reconfiguration is embodied in the higher throughput potential of the faster devices. The space on the faster devices (e.g., CACHE or SSD) may be fairly well utilized, but often, the throughput potential of the device will not be stressed. Available throughput headroom on the device will enable the device to easily respond to peak demand surges of short duration and provide the significant final benefit listed --- namely, improved overall response time consistency.

Needless to say, all of these benefits should be considered when the merits of a suggested device reconfiguration are under evaluation. The financial, operational, and procedural advantages are substantial.

FIGURE 9

Other Benefits

- Reduced floor space
- Reduced power & cooling cost
- Low activity IO much faster
- Less CPU with constant work
- Simplified cabling/operation
- Homogeneous DASD tuning
- Fewer channels required?
- Room for workload growth
- More consistent IO response

6.0 EXAMPLES AND SAMPLE INDUSTRY FINDINGS

Examples and industry findings which are presented in this section are based on and derived from actual Data Processing installations. Most of these installations are customers of Storage Technology Corporation (StorageTek) and utilize various types and sizes of StorageTek equipment. By and large, they did not make use of on-line device types other than standard rotating DASD at the time of initial CPIO analysis.

6.1 EXAMPLE 1 - PROVIDING FOR GROWTH

Figure 10 summarizes the environment, study findings, and primary results for a medium size (3081 class CPU) installation. The condition which prompted analysis of this installation was the pending implementation of new applications which forecast the need for 20 to 25 percent additional on-line storage space and a corresponding increase in total system IO activity.

Contemplated expansion, using traditional methods, implied the acquisition of 10 to 15 gigabytes of new DASD storage at considerable additional cost. The comparative value (i.e., list) cost of the current configuration was $37,980 per month with a potential addition of $6,470 to $8,767 per month for a DASD control unit and 2 or 3 3380-E class (i.e., double capacity) storage units. Cost per IO would initially increase but would return to approximately 16.7 cents per 1000 IOs after the addition of anticipated new activity.

CPIO analysis presented tne opportunity to actually lower the monthly cost to a comparative $33,369 while including preassigned space for the projected growth. The resulting average cost per IO would begin at 14.7 but would decline to approximately 12 cents per 1000 IOs as the new applications were added and the throughput increased.

6.2 EXAMPLE 2 - A CASE FOR COST REDUCTION

Figure 11 summarizes the environment, preliminary study findings, and estimated results for a fairly large

FIGURE 10

Example 1

Installation Overview

- DASD Environment and Device Configuration:
  - 80 8380-1x volumes (68.3% allocated)
  - all devices in 2x16 strings
  - 6 strings in total; 2 shared with VM & ACP
- IO activity:
  - 37.8 million IO's in 5 days (87.5 IO/second)
  - avg. blocksize = 5413; avg. response = 20.9 ms

Study Findings

- 11.9% of total system IO would fit in 48 MB of SSD storage (.20 IO/sec/MB)
- 16.0% of total system IO could be placed on four 8380-2x volumes behind 12 MB of cache and yield a modelled 5.9 ms host response (.0025 IO/sec/MB)
- Remaining data could be placed on 32 8380-2x volumes configured as two 2x16 strings with an estimated 19 ms IO response (.0014 IO/sec/MB)

Summary Results

- Pre-reconfiguration (little room for growth):
  - total cost/month = $37,980; cost/IO = 16.7
  - avg. IO service time = 20.9 ms
- Post-reconfiguration (room for 20-25% growth):
  - total cost/month = $33,369; cost/IO = 14.7 (12)
  - avg. IO service time = 15.0 ms

(multiple 3090 class CPUs) installation. This CPIO analysis was performed simply as a service adjunct to a customer requested tape subsystem analysis. The results, however, were quite surprising when put into the perspective of operating cost for the entire installation over a year's period.

The CPIO analysis was conducted for the DASD subpool and activity for one mainframe only. Whereas the results for Example 1 were based on extensive customer supplied data including SMF, RMF, VMMAP, and even GTF trace, these results are estimated and extrapolated from SMF data only. It has been repeatedly observed by this author that total DASD IO activity (including system data sets not reported by SMF) exceeds SMF reported activity by a factor of 10 to 15 percent. Adjustments for this additional throughput have been factored into the analysis results which are presented here.

The basic conclusion of CPIO analysis for this DP installation was that nearly $400,000 per year in comparative cost could potentially be saved for the on-line storage subpool of a single mainframe. The potential cost savings for this entire installation, even if the estimates are incorrect by quite a bit, could amount to one million dollars ($1,000,000) per year or more.

The major observation and point of this example is that while cost per IO differentials of a few cents per thousand IOs may seem insignificant, they can produce surprisingly large totals over a year. Savings of the magnitude indicated here should have a meaningful impact on any corporation's bottom line profits.

FIGURE 11

Example 2

Installation Overview

- DASD Environment and Device Configuration:
  - 140 3380-1x volumes (60% allocation (?))
  - two 2x16, four 2x12, three 2x8, and nine 2x4 (7.8 avg. string length) - 7 channels used
- IO activity:
  - 34.5 million IO's in 2 days (199.4 IO/second)
  - avg. blocksize = 4105; avg. response unknown

Preliminary Study Findings

- 10% of total system IO would fit in 12 MB of SSD storage (1.5 IO/sec/MB)
- A statistically estimated 27.5% of total system IO could be placed on 8 8380-2x volumes behind 18 MB of cache and yield an estimated 8 ms host response (.005 IO/sec/MB)
- Remaining data could be placed on 56 8380-2x volumes configured as two 2x16 strings and two 2x12 strings with an estimated 20 ms host response (.0016 IO/sec/MB)

Estimated Results

- Pre-reconfiguration:
  - equiv. cost/month = $83,892; avg. cost/IO = 16.2
  - avg. IO service time = ???
- Post-reconfiguration:
  - total cost/month = $50,684; avg. cost/IO = 9.8
  - avg. IO service time = 15 ms

6.3 SAMPLE INDUSTRY FINDINGS

Figure 12 presents a table of CPIO analysis findings for several existing DP installations (identified by letter only). Installation A is the same as that which was reviewed in Example 1; the others represent different environments which range in size from quite small (i.e., 4341 class CPU) to quite large (i.e., multiple 3090 class CPUs).

The data at the top of Figure 12 represents the results of initial CPIO installation assessments while the data at the bottom (i.e., below the horizontal separating line) represents the estimated results of several reconfigurations suggested by detail CPIO analysis. Reconfiguration estimates are not given for those installations which could not (or would not) provide adequate supporting data. An RMF or VMMAP report covering 24 hours or longer can be used for installation assessment; device assignment, however, requires detail information regarding individual data set size, throughput, and usage. A source for detail information (e.g., SMF or IO trace data) is not readily available in many DP shops.

Observations which can be extracted from an inspection of Figure 12 include the following:

1) As a general rule, the higher the cost per IO, the lower the average IO service time (i.e., milliseconds per IO); there are some obvious deviations from this trend, but it is beyond the scope of this paper to analyze the variations in detail

FIGURE 12

Sample Industry Findings

Installation	*Average Cost per IO*	*Average ms per IO*
A	16.7	20.9
B	15.8	23.6
C	14.4	26.7
D	12.6	26.8
E	11.3	36.0
F	9.7	24.0
G	9.6	35.7
-------- *With Reconfiguration* --------		
A	12.0	15.0
B	11.5	14.2
D	10.6	15.4
E	11.3	9.0
F	8.2	11.5

2) If initial cost per IO is relatively high, reconfiguration with CPIO analysis tends to offer significantly lower cost and moderately improved service time

3) If initial cost per IO is relatively low, reconfiguration with CPIO analysis tends to offer moderately lower cost and significantly improved service time

4) In all cases except one, CPIO analysis improves both cost per IO and average service time; for the exception, cost per IO remains the same but service time improves by 75 percent --- a seemingly worthwhile tradeoff

Figure 12 offers a gauge against which the results of any new CPIO installation assessment can be compared. The results in Figure 12, along with others which have been collected, suggest that there is a "normal" price/performance curve for traditional IO subsystem designs. New installation assessment values can be readily compared with the "normal" curve for the identification of significant deviations.

The results in Figure 12 also suggest a different curve for the price/performance of IO subsystems designed with CPIO analysis. The magnitude of potential movement from current values to the "CPIO" curve can be used to make a preliminary estimate (i.e., without detail CPIO analysis) of the benefit which might be derived from detail CPIO analysis.

7.0 SUMMARY AND CONCLUSION

The concept of CPIO analysis which is presented in this paper is suggested as a strategy for improving the IO subsystem design and maintenance process. It is not intended to replace traditional methods for assigning new application data sets to appropriate devices; in most cases, demand throughput needs are not well

understood prior to implementation of a new application or system, and traditional methods are quite adequate. It is proposed, however, to augment traditional methods and assist data set reassignment or system redesign when real throughput characteristics become known or change over time.

Despite the many potential benefits offered by CPIO analysis, it is not realistic to believe that many DP installations could immediately adopt a suggested reconfiguration. CPIO analysis offers quantifiable performance and financial improvements. It also offers a number of operational and procedural advantages to most installations. These should at least warrant recognition of the suggested reconfiguration and be used to establish guidelines for future equipment acquisition. Over time, the projected improvements to installation effectiveness (reduced cost and improved performance) would be achieved.

REPORT ON THE LARGE SYSTEMS STORAGE HEIRARCHY

Fred Moore and Jerry Percell
Storage Technology Corporation

ABSTRACT

Driven by conversions from batch processing to online systems and the quest for improved cost-effective storage solutions, the storage heirarchy has added several new levels in the 1980s. At the beginning of the decade, disk, tape and various mass storage devices were available. Today, through improvements in architecture and technology, these basic storage levels have expanded to include high-performance or solid-state disk, cache control units, automated cartridge systems and buffered tape controllers. This report will discuss the new storage heirarchy and explore likely future developments in each storage level.

INTRODUCTION

For years, data processing was perceived as a backroom activity within a company's finance organization. Today, data processing has changed significantly and become a major strategic asset of the enterprise. In fact, data processing has evolved into the critical role of information management. The degree of efficiency with which a company manages its information has a direct impact on the success of the business. During the 1980s, we have witnessed major conversions of batch applications to online systems required to implement the information management architecture of the enterprise. As more and more aspects of the business become automated, the corporate goals for productivity and efficiency become tied directly to the information management functions. The age of information is upon us. (See Figure 1)

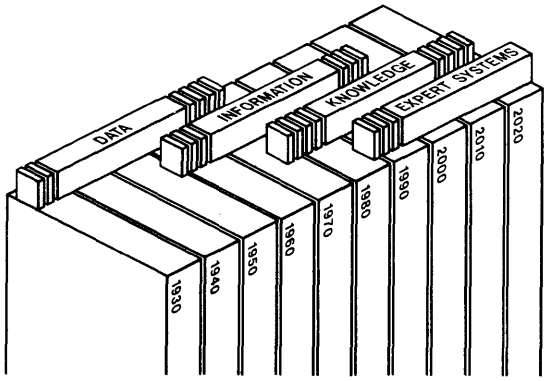

Figure 1. Data Processing Era

More specifically, in the IBM and compatible large systems environment, a primary concern of information management has become the issue of how to store and retrieve information cost effectively. In the 1980s, storage and retrieval systems have evolved from their 1970 counterparts to provide several potential solutions for information storage and retrieval. Those offerings may be depicted in five general levels of storage each having unique properties of performance, capacity and price to address storage. (See Figure 2)

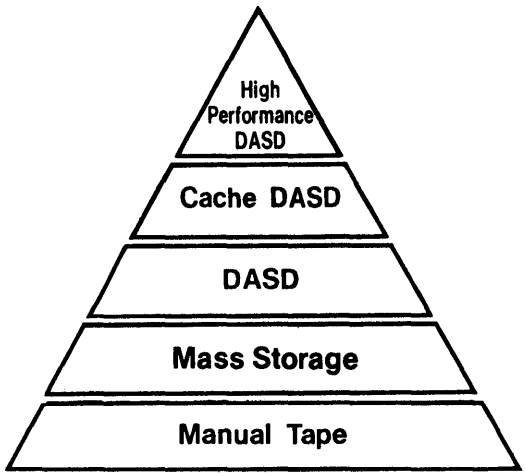

Figure 2. Information Storage Heirarchy

In particular, this report will discuss this new storage hierarchy describing architecture, performance, practical applications and future considerations for each storage level.

HIGH-PERFORMANCE DASD

ARCHITECTURE

During the early 1970s, paging operating systems were announced for use on computers implementing the virtual storage concept. In addition to processor and I/O constraints, these systems introduced a new bottleneck for performance analysts — paging. It was not until 1979 that the first high-performance (also called solid state) disk was delivered to address this problem. High-performance disk drives typically consist of one, two or four control modules, a variable amount of RAM (random access memory), and a variety of options to help address loss of power such as battery backup, internal hard disks and UPS (uninterruptible power supplies). The flexibility of microcode has permitted a high-performance disk to appear to the operating system as 3380 and 3350 disk images, and the 2305-2 fixed head drum. Several capacity and addressing options are available to permit configuration flexibility. Today, 3380 is the most common image used. Pathing options for high-performance disk provide one, two or four concurrent I/O operations per subsystem. (See Figure 3) From an architectural view, solid-state devices have relatively few mechanical components resulting in relatively high subsystem availability, a critical requirement for today's online response-oriented systems.

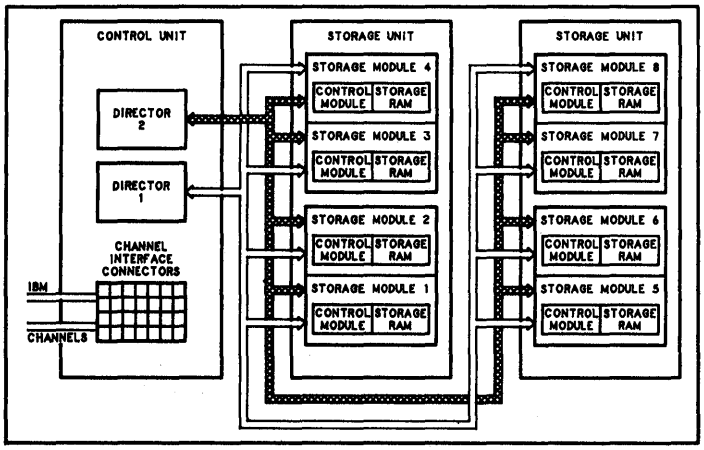

Figure 3. Configuration of SSD

Each storage module looks like an individual device to the host computer

Control Modules –
Provide control unit functions and channel interfaces sharable among CPUs.

RAM Storage –
High density RAM providing from 12 megabytes to two gigabytes of storage. Typically configured as several 3380 disk images.

Volatility Support –
Optional features to protect data in case of loss of power including batteries, UPS and small winchester disks.

PERFORMANCE

The use of RAM as the storage medium for high-performance disk provides just that — high performance. Access of data is provided typically of 0.3 milliseconds (ms) before data transfer begins. High-performance DASD sits atop the storage hierarchy because of its ability to provide consistent I/O response times. Unlike rotating DASD, these devices have no actuator arms to move (SEEK), no media to rotate (latency) and don't release the host channel to locate a record. This results in erratic response times for non-cache DASD. The 0.3 ms access time results in typical 2 to 4 ms I/O response times, depending on the blocksize, and between 300 and 400 I/O requests per second per I/O path are commonly attainable. In addition, the elimination of the RPS factor of rotating DASD and any data staging overhead of cached DASD provide for channel utilization to exceed 70 percent busy before any significant channel queuing occurs. Though not a requirement, high-performance disks usually reside on dedicated channels.

Performance Summary

- *0.3 ms access time*
- *Asynchronous I/O, 2 to 4 paths*
- *300 to 400 I/O requests per I/O path*
- *70 percent + channel utilization*
- *Sharable high-performance I/O between CPUs*
- *Eliminates RPS miss*

The initial and primary use of high-performance DASD was for the paging and swapping requirement of virtual operating systems such as MVS and VM. Until 1984 these devices were offered only as the 2305-2 fixed head drum with 11.25 megabytes (MB) of storage per 2305-2 image and only 90 MB capacity per storage subsystem. In 1984, the first 3380 device images were introduced and the era of non-paging applications officially had begun. These device images immediately addressed a broad range of response-time-starved applications for online information processing. The provision for device images that mirrored rotating DASD may have been the most significant enhancement for high-performance DASD. A new image facilitated the portability of data between real 3380-class DASD and high-performance 3380 without the need to convert blocksizes or change space allocations via JCL (job control language). This level of storage address applications requiring 100 percent consistent response, either random or sequential access modes and READ, WRITE or UPDATE processing modes. These include:

High-Performance DASD Applications

- *Response-critical load libraries*
- *High-performance data bases*
- *Work areas, storage pools, scratch pad areas*
- *JES2 checkpoint*
- *Catalogs*
- *Indices*
- *Security systems control data sets*
- *Enqueue/Dequeue files*
- *Sort work areas*
- *ACP/TPF Agent Assembly Area (AAA) files, file pool and fixed files*
- *Paging/swapping*

What about the initial use of high-performance DASD — paging and swapping? Page and swap are still the most common uses of these devices today though the growth of non-paging is accelerating quickly. The 31-bit addressing capability of MVS/XA architecture was a major extension from the 24-bit addressing capabilities of MVS/370. This 31-bit addressing permits an address space to be 128 times larger in MVS/XA than MVS/370. **(See Figure 4, Figure 5)**

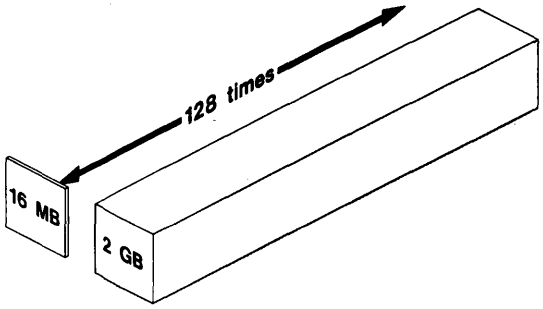

Figure 4. MVS/XA Virtual Address Space

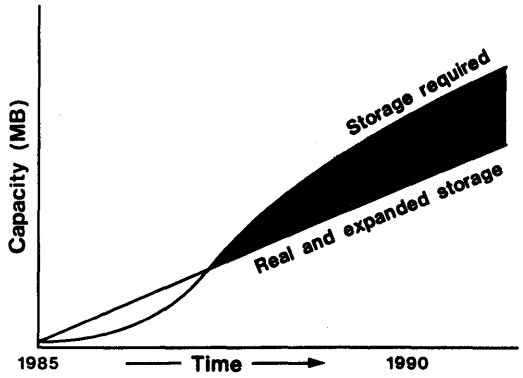

Figure 5. Virtual Storage Requirements

It is estimated that the 31-bit address space is being consumed at the rate of about one bit per year and that by 1992 the limits of this architecture will be pressed. It is also unlikely that real memory and expanded storage will be able to address this growth cost effectively, necessitating a continued requirement for paging. To support this view, IBM announced in October 1986, support for up to 256 page/swap data sets, up from a previous limit of 64, for MVS/XA 2.2.2. These data sets address a page/swap requirement above and beyond the capabilities of real and expanded storage. The additional page/swap data sets also may have uses yet to be announced such as for certain high-performance data files or dedicated functions belonging to specific address spaces.

FUTURES

High-performance DASD is emerging as a general purpose solution for response-critical requirements. By providing 100 percent space utilization and over 70 percent channel utilization, efficiency of architecture has become very appealing as a cost-effective benefit of this device. The issue of volatility has become better understood as users realize that any storage device has an exposure to data loss. For example, power outage can cause loss of data on high-performance DASD; head crashes or media damage can cause loss of data for rotating DASD; and edge, stretch, tear and humidity can cause magnetic tape data to be non-retrievable. Though battery backup, hard disks and UPS may *address* part of the volatile nature of these devices, the *solution* is to keep a secondary copy of any data on systems-accessible storage, i.e., accessible by a different channel path, control unit and device for maximum data availability. Advances in RAM technology permit a continued increase in device capacity. RAM has evolved from one kilobit chips in 1970 to one megabit chips in 1986 with continued development promising even higher capacity subsystems. Since the physical definitions of the device image are established by microcode, future changes in track size, cylinder size and device type can be changed relatively easily compared to other storage devices. Additional advances will permit higher availability and throughput with quad and octal porting capabilities exploiting the path connection limits of MVS/XA design. High-performance DASD also should provide an indicator of futuristic online storage devices by signaling an early beginning of the end of RPS based architectures. A summary of future advancements for high-performance DASD includes:

High-Performance DASD Futures

- *Improved connectivity and availability*
- *I/O channel utilizations 90 to 95 percent range*
- *Non-volatile storage*
- *Larger capacity*
- *Asynchronous I/O in conjunction with DASD*
- *Duplex capabilities*
- *Faster I/O channel transfer rates*

CACHE DASD

ARCHITECTURE

The use of cache DASD controllers has gained acceptance steadily throughout the 1980s. In the past few years there have been major advances in processor speed while the performance of rotating DASD has seen only small improvements. Cache controllers reduce I/O service times for many I/O requests, thus improving overall I/O subsystem performance. By storing data that is frequently accessed in the cache memory, the I/O request is satisfied by accessing data from the cache as opposed to rotating DASD. The cache then serves as a high-performance holding area for frequently referenced DASD data. The cache itself is RAM storage and represents an enhancement to the DASD control unit. Most cache designs today include two storage directors (control units), a variable amount cache, and microprocessor engines to manage the cache contents independent from the directors. This provides increased parallelism by permitting concurrent channel or device operations to occur with cache operations. **(See Figure 6)**

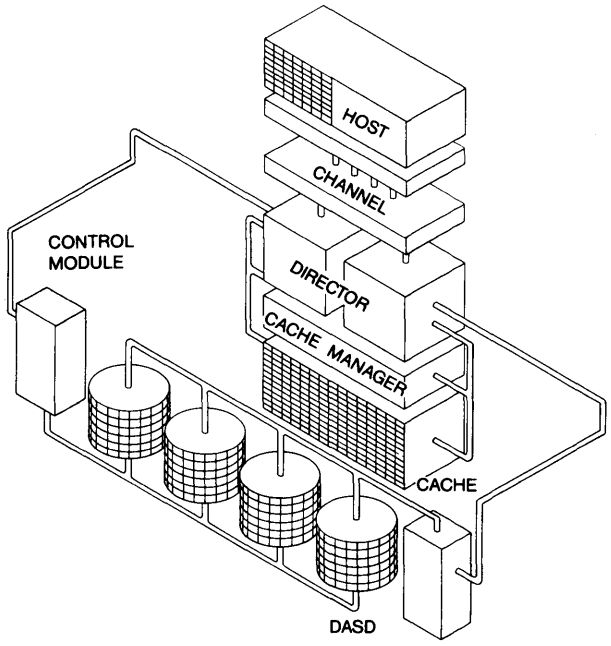

Figure 6.

PERFORMANCE

Cache provides the capability to anticipate host processor demand and manage the flow of data according to each program by directing operations to or from disk and cache. The higher the percentage of requests satisfied from the cache, the greater the performance improvement. Today's cache control units only benefit from high READ hit ratios as WRITES must always be directed to the DASD volume for data integrity purposes. Thus, for WRITES, a Device End interrupt is not posted until the data is written successfully on rotating DASD elongating I/O response times for the WRITE. A high percentage of READS compared to WRITES is most important for today's cache implementation. Most DASD volumes today demonstrate good caching characteristics. They include:

- Relatively high I/O rates
- High READ/WRITE ratios (at least 2:1)
- High data re-use (subsequent cache hits)
- A locality of reference (random or sequential access within)

The higher the percentage of I/O requests satisfied by the cache (hit ratio) the better or more consistent the performance. Devices that don't meet these characteristics actually can degrade performance. Figure 7 shows a DASD subsystem model using generalized trace facility (GTF) channel command word (CCW) trace. Note that volumes 302 and 307 actually degrade performance when placed behind the cache due to a high percentage of WRITES. Cache is therefore subject to misconfiguration and analysis of DASD volumes to be cached or not cached must occur normally. When properly configured, a cache subsystem will provide more consistent response for the attached DASD subsystem (six - 10 ms service time) and can improve channel utilization above the typical 35 percent busy threshold for non-cache DASD. Depending on the READ hit ratio, which eliminates RPS for the READS, channel utilizations can reach 60 percent or more.

Figure 7. Summary of Model Predictions of Performance

APPLICATIONS

The popularity of cache has grown steadily in the 1980's in conjunction with the growth in online and response critical applications. It is important to understand the characterization of DASD volumes to attain maximum cache benefit. DASD volumes with a high percentage of WRITES compared to READS would be bypassed from caching in today's cached architectures. Studies show that several applications benefit from cache and most often represent the good cache characteristics mentioned in the section on performance. These include:

Cache DASD Applications

- *Partitioned data sets (libraries)*
- *Data base indices*
- *Certain data bases*
- *Sequential data sets*
- *TSO user data sets*
- *Pageable Link Pack Area (PLPA)*
- *Catalogs with high read percent*

FUTURES

Today's cache architectures are somewhat dependent on the user's ability to configure a cache subsystem carefully. Misconfiguration can actually lead to reduced performance. Future cache controllers will begin to remove this responsibility from the user by placing more intelligence into the cache management function via software and microcode. The near-term enhancement is one that permits the cache to monitor good or poor performance and change cache algorithms accordingly. Without user intervention, therefore, the cache becomes more self tuning. The use of DEFINE EXTENT and LOCATE channel command words is the first step in this direction. These channel command words are used throughout many MVS/XA access methods, program products and utilities providing the intent of the channel program: i.e., READ or WRITE, and LOCATION information in advance of the actual I/O operations. Knowledge of this information in advance can provide valuable 'clues' to the cache control unit enabling functions such as anticipatory staging/de-staging and advanced purge of un-needed tracks or blocks. Exploitation of these commands through host software will enable more data to become a candidate for cache. Another future function for cache controllers is non-retentive WRITE. Non-retentive WRITE causes the WRITE I/O operation to post a device-end interrupt when the data is written into the cache.

Today, cache DASD subsystems don't post device end until the data has been successfully written on the back-end DASD. This results in a significant performance penalty for WRITES. The ability to cache WRITES without a performance penalty permits more data to become cacheable and can provide performance improvement for certain high READ- and high WRITE- intensive data. Some cache control units permit the user to use a software command called BIND to retain highly active data elements in cache at all times and permit the cache to approach the performance of high-performance DASD for this data. Further use of BIND and the implementation of non-retentive WRITES will require cache sizes to increase beyond the 64 to 72 megabyte cache sizes available today. Future directions for cache control units include:

Cache Futures

- *More intelligent cache management in control unit*
- *Further use of host software — less user envolvement*
- *Non-retentive writes (cache WRITES without penalty)*
- *Microprocessors providing parallelism for front-end and back-end separation*
- *Larger cache sizes*
- *Increased connectivity*
- *Faster I/O channel transfer rates*

DASD

ARCHITECTURE

The use of DASD as the primary online storage device continues to grow at over 35 percent annually. Coupling adequate performance with high capacity and non-volatile storage, DASD satisfies both online and batch requirements for information storage and retrieval. DASD also has the ability to overwrite old data with new data without any need for a separate erase pass. Today's DASD most often uses thin-film heads and magnetic oxide coated aluminum substrate media. The devices use a flying head non-contact recording method to avoid head media wear at the high rpm (typically 3,600 rpm) speeds. Present DASD drives fly the head at about 10 microinches above the disk surface. Ultra-smooth sputtered thin-film media has demonstrated glide testing capabilities at four to five microinches though this capability remains in the laboratory. Further lowering of the flying height is improbable as the rules of aerodynamics begin to fail as the flying height approaches the dimensions of the air molecules themselves. The thickness of the magnetic layer on media also has been reduced over time as flying heights are lowered and areal density increases. **(See Figures 8 and 9)**

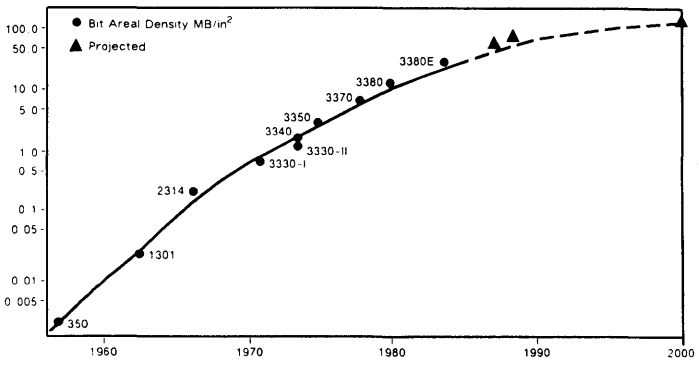

Figure 8. Rigid Disk Areal Density Trends

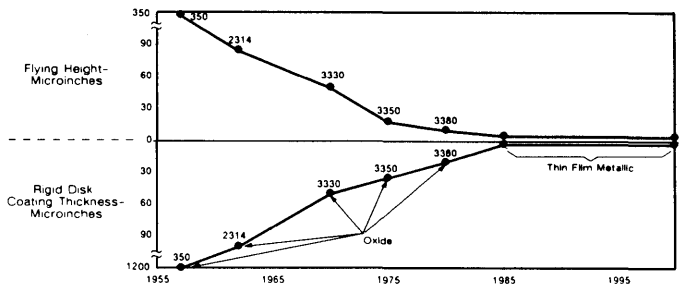

Figure 9. Flying Height Magnetic Media Coating Thickness

Ultra-low flying heights require a sealed and ultra-clean atmosphere as the slightest bit of microscopic debris will cause a head crash. The media used for DASD in the IBM large computer market has a diameter ranging from 10.5 to 14 inches with capacities per actuator (access mechanism) at 1.26 gigabytes.

PERFORMANCE

DASD represents the storage architecture of maximum surprise when it comes to I/O response time. SEEK, latency, data transfer and RPS miss are the major response components of a DASD I/O and all can vary as the device and I/O paths get busier. Unlike high-performance DASD where the RPS factor is zero, every RPS miss adds another 16.7 ms to DASD I/O response time. As path busy approaches 35 percent, queuing theory indicates that one full DASD revolution of 16.7 ms (at 3,600 rpm) will occur for every successful I/O. Dual ported I/O was introduced in the 1970s and significantly helps the RPS miss issue. In addition to dual port, dynamic path reconnect also helps reduce RPS miss by allowing the I/O operations from the device to reconnect to the host via a path other than the one on which it was initiated. This major I/O architectural change is available through the MVS/XA operating system and was the major I/O change from MVS/370. The following figure illustrates performance comparisons between high-performance DASD, cache DASD and non-cache DASD subsystems.

Performance Comparison

	Chan Busy Max Percent	I/O Rate (4K)/Sec	Initial Service Time
High Performance DASD			
	70 - 75	*700 - 800*	*1 - 3 ms*
Cache DASD			
	50 - 60	*200 - 300*	*5 - 20 ms*
DASD			
	35 - 45	*90 - 100*	*20 - 50 ms*

Another revealing measurement of DASD performance is access density or the I/O rate/second/gigabyte of storage. This index has declined steadily since 1970. On a per unit of storage basis, the unit of storage has less performance capability with each new device introduction. Performance per DASD actuator has not kept up with the increased capacity per actuator, in effect 'weakening' the I/O capabilities of the device per unit of storage. A strong case can be made that the practical limits of capacity per actuator are being reached calling for more actuators per unit of storage in future DASD.

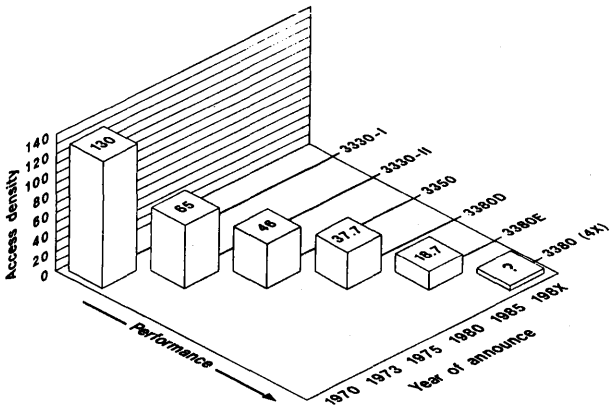

Figure 10.

Access Density

Year	Device	Subsystem Capacity	I/O Sec	Access Density
1970	*3330-1*	*400 MB*	*52*	*130*
1973	*3330-11*	*800 MB*	*52*	*65*
1975	*3350*	*1,270 MB*	*58.4*	*46*
1980	*3380(1X)*	*2,570 MB*	*95*	*37.7*
1985	*3380(2X)*	*5,040 MB*	*94*	*18.7*

Note: Subsystem includes two channel paths, two control units and four actuators.

APPLICATIONS

DASD is the most versatile of all storage devices permitting a non-volatile, relatively good performance for random, sequential, READ, WRITE and UPDATE uses. A GUIDE survey published in late 1984 indicated that the amount of allocated space per actuator was declining steadily. The access density decline of subsequent technologies has driven users to allocate less space on the DASD to reduce contention and maintain acceptable performance levels. (See Figure 11)

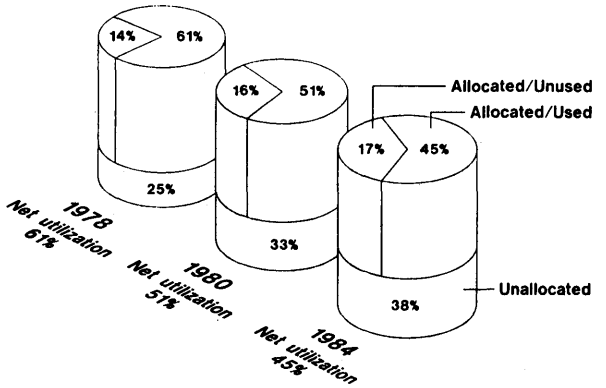

Figure 11. GUIDE DASD Usage Survey

Of the space allocated to DASD, not all is used. Over-allocation occurs if the data set is expected to expand requiring more space.and because of less than full-track blocking causing additional wasted space in count, key, data (CKD) format devices.

FUTURES

Future DASD directions include the implementation of smaller-diameter disks to reduce mass and provide a smaller form factor for making more effective use of valuable computer room space. The new, smaller form factors are likely to appear as a rack mounted device in the 1990 time frame. Smaller diameter disks also permit faster rotational speeds and therefore improved data transfer rates. Thin-film heads can be used to write narrower tracks and by using thin film or sputtered media, much higher aerial densities (megabits per square inch) are likely.
It is unlikely that the MVS operating system will support Fixed Block Architecture (FBA) in the near future. Other than VSAM, which comprises about 25 percent of the allocated DASD space (see Figure 12), there is little data that directly fits the FBA scheme. A feature of much promise is the actuator level buffer (ALB) which extends the concept of caching a step further to the actuator itself. The ALB virtually eliminates the latency issue by placing the data to be transferred in a high-speed RAM buffer. If the I/O path is busy at DASD reconnect time, the data is transferred to the ALB. As soon as the path is free, data transfer can begin without DASD latency occurring. Along with faster transfer rate capabilities comes the requirement for more concurrent I/O and increased availability. MVS/XA today supports up to eight paths to a device but no DASD subsystem yet exploits over two concurrent I/O operations. Future DASD will provide quad and possibly octal path connection capabilities.

Future DASD Directions

- *Smaller form factor*
- *Rack mountable*
- *Increased connectivity*
- *Higher availability*
- *Possible use of actuator level buffering*
- *Higher data porting capability*
- *Use thin film media*

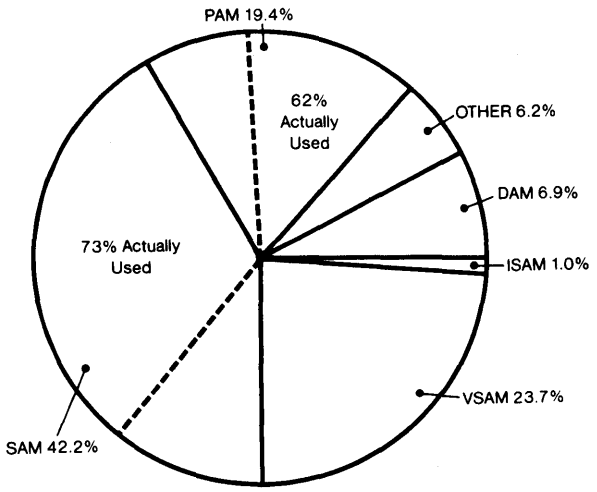

Figure 12.

MASS STORAGE

ARCHITECTURE (OVERVIEW)

Mass storage devices have existed for large computer users since the late 1960s with the IBM 2321 Data Cell. Since that initial offering, several mass storage products have been introduced though *none* have yet become a de facto standard for mass storage. Whereas high-performance DASD, cache DASD, and non-cache DASD all have access times measured in milliseconds, mass storage devices have access times measured in several seconds. Reliability and availability problems have surrounded mass storage products limiting their success. Suppliers of mass storage systems usually have chosen to discontinue such systems for a variety of marketing and technical reasons. Some mass storage systems have used a combination of accessors (picker arms) and data recording devices to transfer data from unique data storage cartridges or high-density video tape stored in a library. Others have chosen to use industry-standard media such as nine-track tape reels or, most recently, the 18-track cartridge. From an architectural point of view, using an industry standard media such as nine or 18-track tape has the advantage: If the mass storage system breaks down, the tapes can be read or written on any compatible nine- or 18-track drive. Today, the presence of robotics using software program control provides significantly higher reliability potential than some of the previous offerings. Improvements in recording density and packaging now provide the capability to connect several like mass storage systems together providing a nearly limitless storage capacity.

Mass Storage Systems should provide:

- *Relatively quick access*
- *Data access compatible with systems software and access methods*
- *Technologies which can be enhanced to provide long-term storage solutions*
- *System accessible storage media*
- *Cost effectiveness not only in price but operational and environmental measures*

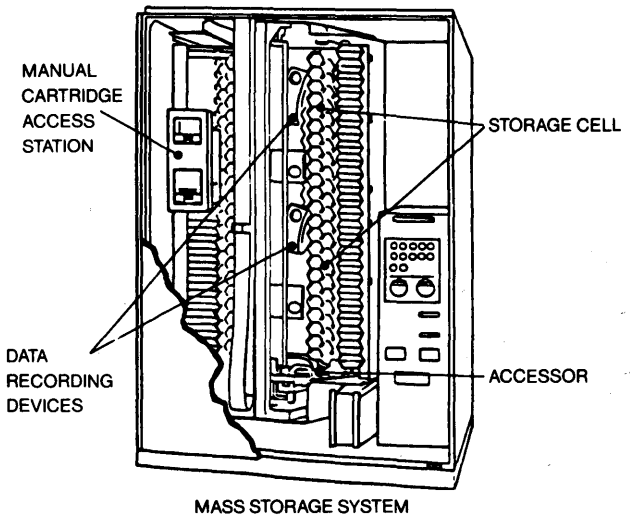

Figure 13. Mass Storage System

PERFORMANCE

The use of a mechanical accessor or robotic arm to access data provides performance improvements over manual mounting of media but cannot provide the sub-second access times of rotating DASD. Mass storage systems provide initial access times in the range of 10 to 25 seconds. The first question to consider regarding mass storage performance concerns the initial service time requirement. What is the time span between when the request for data is issued and the time the first byte of data arrives? If the answer is immediately, the data must reside on high-performance DASD (solid state) or DASD. If the answer is not immediately, the data can be stored offline. Although instant or online would be ideal, the decision-making process is influenced by the cost of online information and exacts a high price for a high level of initial service. The second question is what is the cost of storing the information? Data processing installations are faced with choosing online devices with a higher unit cost of storage, or offline devices with a much lower unit cost but a slow (sometimes several minutes) and inconsistent initial service time. Mass storage systems provide an excellent

solution for this requirement by combining the large capacity and low cost characteristics of offline storage with the quick initial access characteristics of online storage. The description of the performance requirements for the mass storage level are generally well understood. What remains to be seen is a truly successful implementation.

Mass Storage Performance Characteristics

- *Initial service 10-25 seconds*
- *Online or Nearline™*
- *Capable of bulk data transfer at current channel speeds*
- *Access by multiple requestors simultaneously*

Nearline™ is a trademark of Storage Technology Corporation

APPLICATIONS

The explosive growth of machine-readable information in the 1980s is likely to continue indefinitely. The advances in technology are opening new avenues for the use of information storage and retrieval throughout the business enterprise. The accumulation of historical information requiring long-term retention for legal and analytical purposes represents terabyte (trillion byte) storage requirements and is an area yet to be addressed effectively. Many organizations such as insurance companies must have access to all prior claims 10 years past or more. This amount of data cannot be stored effectively on microfilm or in file cabinets any more, due to its raw volume and labor-intensive management requirements. Technology has permitted the generation of information to grow. Today, point-of-sale terminals, automatic teller machines and electronic funds transfer provide for continuous information generation. A few of the more common applications ideally suited for mass storage systems include:

Generic Mass Storage Applications

- *Archive low-activity DASD files*
- *Scientific information*
- *Information required for long-term retention*
- *Record keeping*
- *Backup of select DASD files*
- *Numerous others . . . . . .*

FUTURES

Since a truly successful mass storage system does not yet exist, and the requirements for such a solution continue to mount, the future for such a system (if successful) is very promising. Technology improvements with program-controlled robotics, proven media, and microprocessors hint that a successful solution may be on the horizon. The most immediate solution would appear to be one employing proven storage media such as 18-track tape cartridges. This solution addresses the requirement for a storage media that can still be accessed should the mass storage system fail and removes human operators from the process of placing data on a channel. An automated cartridge system provides an ideal archive for low-activity DASD files, a major performance improvement over manual tape handling, and a cost-effective solution for new applications.

Another mass storage candidate is optical storage. A few false alarms and concern over the repeatability of re-reading optical media has caused concerns. Optical storage has the characteristic that it can be written only once and read many times in random or sequential mode. Re-writing data is not yet possible for optical, although this barrier for the large computer market should be passed successfully by 1990. Once optical possesses re-write capabilities, software applications will be able to access optical like rotating DASD with READ, WRITE and UPDATE functions at a lower cost per megabyte. However, due to positioning of the laser diode, the access times of optical drives can be five to 10 times greater than DASD. There are no flying height or head crash problems with optical and no contamination problems except contamination accidentally molded into the media itself during manufacturing. Should a reliable media be developed but not followed by the erasability, the future for optical storage is in application-specific markets and *not* for general-purpose use. Other storage media such as video tape exists though acceptance of such implementation has been slow.

The potential for mass storage systems is enormous. As the industry waits for a successful solution, the real success of a mass storage solution may very well rest in storage management software. The concern of how to place the right data on the right device remains unaddressed and requires a great deal of human involvement. The problems of today and tomorrow are identical to those of the past, but the sheer magnitude has increased by epic proportions. A storage management subsystem will be of utmost importance to the success of mass storage systems and to the management of the entire storage hierarchy.

Future Mass Storage Directions

- ► *Possess READ, WRITE and UPDATE capabilities*
- ► *Possess the ability to be connected for expanded capacity*
- ► *Low cost, automated access*
- ► *Access from multiple requestors*
- ► *No host operating system modifications*
- ► *Ease of data protection and recovery*
- ► *Provide a cost-effective storage management solution*
- ► *Use of fiber optic channel extenders for offsite archive*

MAGNETIC TAPE

ARCHITECTURE

Removable magnetic tape has been the media of choice for interchange backup and archive requirements for over 20 years. Magnetic tape storage offers high and continually improving storage capacity at ultra-low cost. Tape needs today consist of the traditional nine-track reel-to-reel tape and the newer 18-track cartridge tape subsystem. The 18-track cartridge system has a capacity of 200 megabytes and a nine-track reel consisting of 2,400 feet of tape can hold approximately 160 megabytes of data. The flux density has changed from 9,300 flux change per inch (fci) in nine-track to over 38,000 with the 18-track cartridge. It appears entirely feasible that track density could be doubled to 36 tracks per inch and both tape length and flux density increased to yield approximately a 1.0 gigabyte capacity for cartridge tape. The capacity of a nine-track reel is unlikely to change from the 160 megabyte level. Tape subsystems typically consist of two tape control units interfacing with four or eight host I/O channels and up to 16 tape transports or drives. Magnetic tape is erasable and overwriteable enhancing its usefulness and is a well proven and understood technology.

(See Figure 14)

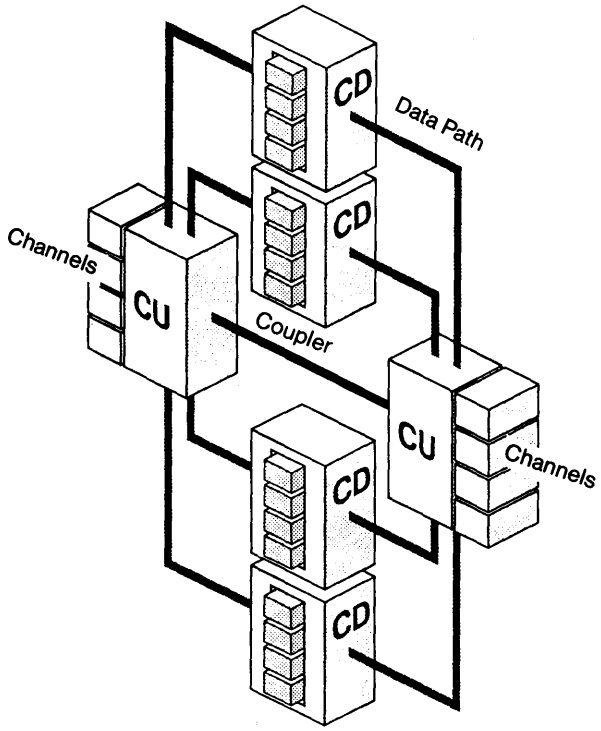

Figure 14.

PERFORMANCE

Access to manual tape is very slow compared to all other levels of the storage hierarchy resulting in initial access times ranging from one to three minutes. This is the mount time — the time it takes for a human to locate the reel or cartridge and mount it on an available tape transport. Eighteen-track systems can transfer data at today's channel speed limitation of three megabytes per second. These systems have the ability to transfer at higher channel speeds by using the tape cache to provide upward speed-match capabilities. Channel utilization for both 18- and nine-track tape subsystems can exceed 80 percent since tape does *not* suffer from the DASD RPS phenomenon of disconnect and reconnect. Though nine-track tape can only READ or WRITE data at a maximum of 1.25 megabytes per second, buffered tape control units allow transfer to occur between the buffer and I/O channels at three megabytes per second. The capability to buffer may have been the last major breakthrough for nine-track though the capability to buffer at faster channel speeds exists.

Tape Performance Summary

18-Track	9-Track
► *3 MB/sec data recording*	► *1.25 MB/sec data recording*
► *3 MB/sec channel transfer*	► *3 MB/sec channel transfer*
► *90 percent channel utilization*	► *80 percent + channel utilization*
► *20 ms start/stop time*	► *1.5 ms start/stop time*
► *Good with larger blocksizes*	► *Good with small and large blocksizes*
► *Caching at record level*	► *Buffering at record level*

APPLICATIONS

Tape is the primary data interchange media in use today. Ease of portability makes tape ideal for offsite storage and disaster recovery backup. The most popular use of tape today is for DASD backup. As information becomes more critical to the business, loss of information can be catastrophic; therefore, more backup occurs more often. Unlike DASD, tape has virtually no capacity limit and multi-volume tape data sets commonly exist. A survey of 20 large users conducted by Storage Technology Corporation in 1985 revealed the following distribution of tape data set sizes and uses. (See Figure 15)

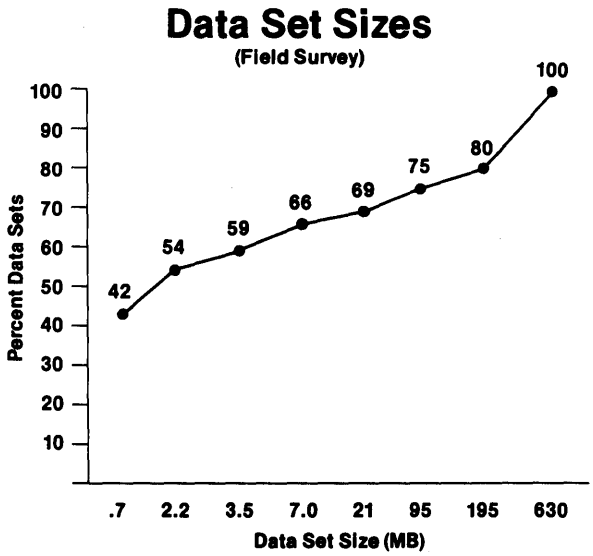

Figure 15. Data Set Sizes

Tape has also become the primary target for archiving low usage DASD files. In the absence of a successful mass storage solution, tape has had to assume the role of a partial alternative to mass storage. Few new applications are being developed for tape though the role of tape as *the* interchange and archive media is firmly established. (See Table 1)

Table 1. Tape Demand Profile Estimates (Field Survey)

Data Interchange	15%
Backup	25%
Archive	10%
Production	50%

— Few new applications written for tape

— More data is being backed up much more often

— Batch window down to a few hours for many users

FUTURES

It is likely that any future enhancements to nine-track tape will come primarily through supporting higher channel transfer rates using the buffer. Further advances in capacity for nine-track tape are much less likely to occur. By comparison, the future for 18-track includes a likely increase in track density to 36 tracks and further improvements in both tape length and flux changes per inch (linear density) resulting in higher capacities and transfer rates Continued advances in drive packaging are likely to improve the use of computer room floor space. Advances with fiber optic channel extenders will soon make it possible to extend tape connectivity to several kilometers away from the host computer. Coupled with automation, 18-track cartridge subsystems growth may prove to be a significant opportunity for cartridge tape.

CONCLUSION

The 1980 decade has brought a number of significant improvements to the storage hierarchy. From a user's perspective, these changes have brought improvements in price, performance and capacity while creating many new storage problems due to the vast amount of data to be managed. Clearly, technology permits this growth but does not drive it. The pressing issues for the remainder of the 1980s will become storage management. At present compounded annual growth rates, the magnitude of this problem — managing storage — may actually become a barrier to growth in the not too distant future. (See Table 2)

Table 2.

Growth Rate Projections				
	1984	1988	1992	CGR
MIPS	*28*	*112*	*448*	*35%*
GB (DASD)	*92*	*353*	*1279*	*40%*
Batch	*24*	*15*	*6*	*Percent*
Online	*55*	*62*	*69*	*workload*
Systems	*21*	*23*	*25*	*composition*

The challenge of managing over 1,000 gigabytes of online data will be aided to some degree by technology advances but the major responsibility will fall heavily into the area of software. A number of storage management software products exist that provide solutions to some of the problems but none offers a complete solution. In some user environments, several storage management products co-exist in attempts to balance weaknesses in one package with the strengths of another. For years the storage hierarchy has suggested hardware only. The storage hierarchy of tomorrow must include hardware and software to be ultimately successful. (See Figure 16)

Bull Moose Does TA:
A Manager's Guide to Transactional Analysis

Jim Stanton
Vice President
Morino Associates

ABSTRACT

Bull Moose is a highly successful technician recently promoted to the ranks of management. He has received no management training and has been learning the supervisory ropes by trial and sometimes humorous error. He has been the subject of a series of articles in the Morino Software News over the last few years and has fallen into most all of the managerial traps. Last year at CMG, the presentation on Bull Moose's transition into management received the award for best management tutorial. This year's presentation follows Bull Moose as he learns of a pragmatic technique for observing and dealing with both the natural and the unnatural behavior of others. He learns how to recognize dangerous political situations, identify and deal with "games" played by his staff and others, and learns how to deal more effectively with his peers and his boss. There is some of Bull Moose in us all, as you will see in this tutorial on using Transactional Analysis in the DP environment.

Introduction

First, we must introduce you to a character that all Information Systems (I/S) organizations can readily recognize -- Bull Moose. This is the technically brilliant, but temperamentally difficult individual who has saved the bacon for his superiors on countless occasions during their struggles to provide information technology to the enterprise.

The proud recipient of an enviable series of laurels for technical bravado, Bull wears the "MVS Availability During Prime Time" medallion with the triple oak leaf cluster. His left lapel sports the "TSO Response Time" badge with its twin silver stars.

His peers have unanimously named him to the "Putting Up With Management Honor Squad." And -- to the envy of systems programmers everywhere -- he is a recent inductee into the prestigious "Service Level Agreement Legion of Merit." It is widely rumored that Bull Moose knows more MVS record types than any technician anywhere -- from the highest mountaintop to the dankest basement -- wherever companies are held hostage by the computer industry.

In fact, the ability of our hero to single-handedly secure technical objectives while maintaining total disdain for management is the stuff of fairy tales. Bull Moose is, quite simply, a legend in his own time. That is, he was, right up until his recent promotion to Technical Services Manager.

A Deflating Promotion

In stark contrast to his former technical prowess, Bull has lately been spotted wandering all over the management battlefield, uncovering land mines that have blown his former self-confidence into oblivion. His medals have tarnished, the oak leaf clusters have wilted and drooped, and his silver stars have become millstones around his neck as he struggles to gain a foothold on the management ladder.

One by one, Bull's bold forays into the many delicate areas of technical management have ended with a sadder but wiser Bull. Thus far, we have seen Bull fumble his way through the snarly issues of corporate culture, department leadership, employee counseling, and most recently, staff recruiting. Like all intelligent managers, Bull is learning from his mistakes, but is coming to face the reality that as a manager, he will often have to deal with yet another brush fire before the previous one is completely out.

Bull Moose needs even more help, and fortunately this time some is on the way. As we catch up with Bull, he is about to reach a watershed in his "trial and error" approach to management. He is about to enter a new realm of enlightenment -- one in which he will discover one of the most useful tools ever developed for understanding and dealing with human behavior. Yet, every good lesson comes with some pain; thus, we are about to see Bull plop his right front hoof onto one of the biggest land mines in corporate America.

The Story

The atmosphere was calm in Bob's office as Bull arrived early for the usual Monday morning managers' meeting. Bob, Bull's boss, seemed cordial enough, but Bull felt uneasy. Several support problems had cropped up over the last few days and Bull was in a state of continual apprehension. He hadn't heard any encouraging words in weeks.

In fact, he had heard nothing but complaints as he and his group struggled diligently to support the Applications group in their attempts to implement a new corporate financial management system. The Applications group was in overdrive, running jobs around the clock, and generally driving Bull crazy.

Curt Camel, Manager of Applications Development, came in and took his usual seat. Bull thought Curt Camel was stupid. You could look him straight in the face and see that he was stupid. He seemed to be able to go on forever without a drink of knowledge; it was hard for Bull to contain his disdain for Curt and his plodding ways.

Sitting at the table, Bull could feel his antagonism rise as he watched Curt slowly

shuffle his papers, preparing for the meeting. He moved so slowly, so deliberately, as though he were in charge. Bull was getting angrier and angrier as he watched Curt.

Abruptly, Curt looked up, smiled, and said "How are you this morning, Bull?" Bull's anger peaked. Here was this Camel, who for the lack of ability to manage his stupid programmers, was causing Bull's group all kinds of grief over machine availability. And now, he was acting like he had Bull by the horns, smirking at him in front of the boss.

Bull rose to the occasion. "I'd be a lot better this morning, Mr. Camel, if someone were controlling the application development fanatics in their use of TSO. If they would spend more time checking their code instead of letting the computer stumble over their errors, we'd have more availability time for productive use." The smile slid from Curt's face to Bull's.

Curt responded: "Well Mr. Moose, I find it a shame that our company doesn't have the expertise to keep the gas tank full and the oil checked on our computer center. If it weren't faltering all the time, we wouldn't have nearly so many reruns." The sardonic smile crept back to Curt.

"We've got the best computer up-time in the industry," responded Bull as the smile, now waning, moved moved to Bull. "What industry?" countered Curt. "The funeral industry?" The smile had disappeared. So had Bob's patience.

Reading the Riot Act

"What's the matter with you two?" snapped Bob. "It seems to me that neither of you are meeting your schedules lately. If you'd spend less time bickering and more time solving problems, we'd all be better off!" The smile had moved to some other building. It would not surface again in this meeting.

Bob's diatribe gathered speed. Bull was devastated. Bob attacked him on several issues Bull didn't consider problems -- and surely not of a magnitude that concerned Bob.

One by one, others arrived for the staff meeting and found themselves submerged in the foul mood of the original three. No one was spared by Bob. Schedules were questioned, priorities challenged, the handling of issues Bull didn't consider problems -- and surely not of a magnitude that concerned Bob.

One by one, others arrived for the staff meeting and found themselves submerged in the foul mood of the original three. No one was spared by Bob. Schedules were questioned, priorities challenged, the handling of projects criticized. When anyone would try to raise a defense, Bob would swing deftly from his horse, lopping off heads with his sharpened saber.

After what seemed an eternity, the meeting ended, and Bull trudged back to his office, miserable. He couldn't believe some of the things Bob had said. And that stupid Curt Camel -- he had started it all. Bull was getting mad again. Then, Tom, the data center manager, came into Bull's office and closed the door behind him.

Misery Loves Company

"Man," he said, "what in the world got into Bob ? I saw him earlier this morning, and it seemed like he was in a good mood. We had a long discussion on the new procedures I want to implement for the remote sites. Then, in the meeting, he went after me on the same things we had just agreed on! What's wrong with that guy? His management style stinks. How does he expect me to do my job with a million changes in direction every nanosecond?"

"I know what you mean," Bull chimed. "Stupid Curt is his favorite manager, and now I think I know why. They're both stupid, and...."

This litany went on for some time. Soon, both Bull and Tom were starting to feel better. By the time Tom left, Bull was ruminating about certain of his staff members who were behind in their work.

Bull tramped over to Gail's cubicle and peeked over the top. "How are things going?" he asked. As Gail looked up, she thought: "Why doesn't he leave me alone? I already told him this morning before the meeting how things were going." She responded aloud to Bull: "Oh, about the same as I told you this morning. No changes in the last 10 minutes worth having a summit meeting about." The sarcasm in her voice was certainly not lost on the astute Bull Moose.

Nostrils flaring, Bull lowered his antlers and charged full speed into Gail. When he left, she was so angry and so fed up with Bull Moose and his constant heckling, his second-guessing, his directives to do it his way, his badgering style, that she couldn't see straight -- much less remember where she had left off on the intricate program problem she had been attempting to solve. She got up from her desk and made for John's cubicle, where she launched a quiet but stinging oratory on the probable nature of Bull's parents.

John looked up, surprised, then quickly entered into a supportive role with Gail. After all, this was a lot more interesting than the prolonged headache he was experiencing over his impossible-to-solve program problem. Besides, Bull hadn't done him any favors lately.

Just Another Day?

As we can see, a normal, potentially productive day has been disrupted to the point of no return -- and it's not even noon yet. What's happened to all our heroes? Has the world gone mad? Is this just another day in corporate America? Does this kind of nonsense really go on? You bet! Can any of this be prevented? You bet!

How? you ask. Well, several weeks ago, as

Bull was researching interviewing techniques at his local library, he stumbled across an introductory text on Transactional Analysis (TA). Intrigued, he took the book home, in hopes of gleaning some advice on how to work with the motley bunch of programmers in his group. As we witnessed in this morning's meeting, however, the principles and dynamics of TA have not begun to sink in on Mr. Moose. Let's see what would happen if Bull gained a working knowledge of TA through his readings, then began to apply it to the work environment.

What is TA?

TA is a tool for observing, understanding, and responding to human behavior. It provides a means for observing and analyzing verbal exchanges (transactions) between people. It is a positive communications tool that is practical and almost immediately useful. It can dramatically improve a person's on-the-job effectiveness by lending better self-understanding, greater insight into what makes other people tick, and a clear perception of what goes on when people try to communicate.

The beauty of TA is that it is not only easy to learn, but can also be applied successfully in personal and family situations. It can serve as a common language for people working together towards clearer understanding. It is a nonthreatening approach to self-evaluation that offers a method for analyzing not only people, but also organizational scripts.

The Ego States

TA is founded on the premise that everyone has three basic ego states: Parent, Child, and Adult. At any given moment (during waking hours), we are all in one of these states, dramatically coloring our interactions with others. How we communicate with others, how we receive their remarks, how we think, and how we react to the situations around us are all heavily dependent on our predominant ego state.

An easy way to understand ego states is by imagining three separate tape recorders in our heads. Each is continuously and simultaneously recording our feelings and the information presented to us by others -- called "stimuli" in TA terms.

"The Parent"

The first tape recorder represents the Parent ego state in all of us. The Parent provides us with our "taught" concepts of life. It contains recordings of imposed, unquestioned, external events we perceive from our birth up to age five. This data -- recorded straight and unedited -- is what gives us our "can-do" attitude. The Parent ego state, however, is fortified with feelings such as "never" and "always" -- typical words parents use with children.

The Parent provides us with some simple rules of living, and enables us to respond to certain situations without recalculating every time. For instance, our reactions to such dangers as a sharp knife or a loaded gun are part of our Parent ego. Also included are those parts of our personality that deal with values and opinions.

Within this ego state, we can easily identify two separate forms. The first is the Nurturing Parent. Here lie our yearnings to care for and protect, along with the unconditional acceptance of another's traits.

The second form is the Critical Parent -- that person who only accepts someone if he or she follows instructions closely. Certain verbal clues tell us when we are in the Critical Parent ego state. They include: "should, ought to, do, don't, and follow my example."

"The Child"

The Child ego state represents our "felt" concept of life. The Child consists of recordings of internal events, or feelings, that are a response to external events such as interactions with our parents. The Child contains our feelings of frustration, rejection, and abandonment. It also contains a vast storage of positive data. Certain verbal clues that tip us off when we are in the Child ego state include "I need, I feel, wow, gee, and I want it my way."

As with the Parent, there are two forms of the Child ego state. The first is the Natural Child -- that part of our personality that feels alternately crushed by disappointments and overjoyed by success. The Natural Child is the source of our feelings of self-doubt or inadequacy -- as well as pure emotions, creativity, and spontaneity. It provides the "want to" drive in all of us.

The second form of the Child ego state is the Adaptive Child, also known as the Compliant Child. Here is where we find thought patterns that can vent themselves as either rebellious or submissive behavior.

"The Adult"

The Adult ego state contains our "thought" concept of life. It's based on the gathering and processing of data acquired and computed through exploration and testing -- in, short, our life experiences so far. The Adult is a slow and continually developing state, and begins when we first begin to "think" about situations -- at about 10 months of age, rather than at birth.

The Adult comprises the rational part of our nature. Rather than relying on outdated parental dictums, the Adult in us acts as a computer, digesting current factual data for problem-solving purposes. The Adult often plays the role of executive, utilizing both Parent and Child data for decision-making and authorizing the other ego states to become dominant when appropriate.

The Adult knows no right or wrong; rather, it deals strictly in fact. It evaluates situations by looking at how decisions are derived -- not at the decisions themselves.

It examines the Parent and Child data and performs probability estimating in an attempt to maintain consistency in words and actions. It updates and validates the Parent, Adult, and Child data bases.

Conflict, when it occurs, causes a great deal of "data processing" in the Adult; unpleasant alternatives, in particular, cause considerable computer lag. Verbal clues to being in the Adult ego state include: "who, what, how, why, and let's consider this."

Thus, the three ego states give us our perceptions of the world. The Parent provides the rules for behavior from both the Critical and Nurturing frames of reference. The Child provides intuition, creativity, spontaneity, and enjoyment. And finally, the Adult provides the "data processing" and evaluation of options, in addition to regulating and coordinating the Parent and Child in us.

Here's the catch. We are constantly moving from one state to another, sometimes in response to what others say to us, or by how they say it; other times the shift is a result of our own perception of what is going on. When we change from one ego state to another, we say we have been "hooked," into the new predominant state. It is the dynamics of "hooking" and "being hooked" that make transactions so interesting.

Transactions

Whenever we speak to someone -- whether verbally or with gestures -- we provide a stimulus. This, in turn, engenders a reaction, or response. These activities -- stimulus and response -- are referred to as "transactions." Of these, there are two basic types: complementary and crossed, as illustrated in the accompanying diagram.

In Figure 1, you can see that complementary transactions result when the stimulus and response are parallel. In Figure 2, crossed transactions are occurring -- the result of a stimulus and response that are not parallel.

When we objectively consider Curt's question, "How are you this morning?," we can see that it was an Adult-originated transaction, targeted for Bull's Adult ego state. Curt was simply being polite. Had Bull responded with "I'm fine, Carl," we would have had complementary transactions between two Adult ego states. This exchange could be diagramed as in Figure 1.

Instead, Bull's response to Curt came from his Natural Child ego state and was aimed at Curt's Nurturing Parent ego state -- counter to the initial transaction. When such crossed transactions occur, real communication ceases. While the transactions themselves may not stop, the transfer of meaningful information has ground to a halt. So, while Bull and Carl pursued their verbal sparring, they had, in reality, ceased to communicate.

"Strokes"

Transactions -- parallel or crossed -- serve another purpose aside from the simple exchanging of information. They can also be used to convey "strokes." These are the feelings we transmit to others through our communications. Just as a cat purrs contentedly when stroked gently with the hand -- as opposed to aggressively with the vacuum cleaner -- people experience feelings of contentment when they receive positive communications about themselves. In the context of TA, however, strokes can also be negative and impart bad feelings to recipients of a message.

In fact, there are four basic kinds of strokes:

1) Positive - "You did a good job."

2) Negative - "You did a lousy job."

3) Plastic - "You did the best job I have ever seen in my entire life!"

4) Discounted - "You did a good job, for a change."

When we get strokes, we "file them away," in TA terms, for later reference. A good analogy is that of a stamp collector. For every genuine positive stroke we receive, we get a gold stamp for our book. If we are angered, we slap a red stamp into our book. Depression resulting from negative strokes leaves us with a gray stamp; while feelings of self-righteousness and indignation earn us white stamps.

Everybody needs strokes and everybody wants to collect gold stamps.. Those who don't get sufficient strokes from others are forced to take them by other means. One way they do this is by cashing in some stamps, that is, trading them with others for strokes. This is where it gets interesting.

Hooking Others' Ego States

In the case of severe "stroke deficiency," people will often enter different ego states in an attempt to "hook" or force others into whichever ego state will result in their collecting strokes. Let's see how this worked in Bull's infamous managers' meeting calamity.

Let's go back to the moment when Bull entered Bob's office. We recall he was feeling uneasy -- a lack of positive strokes. In fact, Bull was consumed by self-doubt and stress, stemming from his recent difficulties with the Applications group. Bull perceived -- correctly or not -- that the incidents reflected badly on his group and his leadership capabilities.

Without his knowing it, Bull's ego state had shifted from Adult into Natural Child, seeking comfort, approval, and unconditional acceptance. The Natural Child signals Bull put forth were intended to hook into someone's Nurturing Parent, where protectiveness and comforting strokes abound.

Instead, Bull's Child response to Curt's

attempted Adult transaction hooked straight into Curt's Critical Parent -- not at all what Bull had intended. The resulting admonition from Curt led straight into Bull's Rebellious Child outburst, and they were off to the races.

What Was Bob's Role in This Mess?

Bob had been doing just fine, rolling along in his Adult ego state until the skirmish between Bull and Carl broke out and hooked Bob's Critical Parent ego state. Bob's subsequent invective hooked the Child ego states of all those in the meeting. Each participant was put on the defensive, collecting not the positive strokes they had anticipated, but a barrage of stamps -- red, gray, and white -- which were stashed in their stampbooks for later use.

Now let's look at the stamp collecting score of the various participants. During his Parent-to-Child blitzkrieg, Bob collected several white stamps for his feelings of self-righteousness and a dozen or more red ones for his anger. The unfortunate subjects of Bob's wrath, caught in their Child egos, collected a fistful of red stamps for anger and an additional sprinkling of gray for their despair and anxiety.

The Stamp Collections Grow

When Bull and Tom collaborated in Bull's office after the meeting, they continued collecting stamps. At that point, they were moving from their Child into their Parent ego states and entered readily into a favorite TA game called "Ain't It Awful." After collecting many red stamps with Bob's name on them, they gradually moved on to garner a few white stamps of self-righteousness for the moral indignities suffered at Bob's hands. In the process, they exchanged positive strokes by agreeing that Bob was wrong, and they were right.

Bull, feeling considerably better after his session with Tom, then took his bulging stampbook into Gail's cubicle, where he cashed in several red and a few white stamps at her expense. In so doing, he hooked Gail out of her usual Adult state and into her Rebellious Child, where she took a licking and collected a hailstorm of red, white, and gray stamps.

When Bull finally left, her anger had reached such a level that she stormed from her office to John's, where she was quickly able to hook John out of his Adult and into his Nurturing Parent. There, she succeeded in trading several red stamps for a few gold stamps of agreement, which helped to smooth her ruffled feathers.

As we leave the scene, John is headed for the water cooler, where he will try to unload some of his red stamps on someone else for a few positive strokes....

An Ounce of Prevention?

The irony of this whole disquieting scenario is that it could have been prevented. Any one of the players in the game could have simply refused to leave his or her Adult ego state, and focused on getting everyone else back into theirs. Or, when appropriate, he or she could move intentionally into whichever ego state would best deal with a problem transaction until the other party was able to return to an Adult state. Since the Adult state is where most productive business transactions and professional communication should take place, a good management meeting could have been ensured.

Bull can see this now, as he finishes Chapter One of his TA manual and reflects back on the dynamics of the meeting. Unfortunately, Bull still lacks sufficient insight into TA to fully understand why he feels the way he does, when he does or how to change his ego states at will. He isn't equipped just yet to put the brakes on a fracas like the managers' meeting. But, he has a good start!

Vienna, Va.

Abstract

Historically, one of the most difficult problems encountered by the capacity planner has been the forecasting of the resource requirements of specific applications. A popular approach has been to use business element data (sometimes called natural forecast units or key volume indicators) to develop relationships between the volume of business activity in the sector which uses the application and the amount of resource consumption. This paper will explore the techniques which have evolved for developing a model to relate business activity to computer resource usage, and suggest how to initiate a business element forecasting plan in an organization.

Introduction

Capacity planning has been defined as the process of configuring a data processing system to meet the organization's business requirements. This is a very broad definition which has been interpreted to mean a great many different things by practitioners and theorists over the lifetime of the discipline. Generally the process of capacity planning is subdivided into four basic areas, understanding the current usage of the system, understanding the future requirements for the system, determining the ability of various configurations to support specified levels of usage, and relating the cost of these configurations to the value of the services provided.

Over the past few years a number of capacity planning methodologies have been developed. The literature abounds with articles promoting the use of various techniques, and studies which analyze the success and failure of these techniques in various environments. To date, a single comprehensive methodology has not emerged which can be used to implement a capacity planning program which is widely accepted by all practitioners.

It is the author's opinion that the lack of a comprehensive methodology is due to the very broad nature of the problems addressed by the capacity planner. The capacity planner must deal with technical issues such as relative CPU power, memory sizes, and I/O configuration. In addition she or he must understand the business requirements which drive the demand for the hardware and software resources. The planner needs a background in financial concepts so that cost comparisons may be made. Finally the planner must understand the structure of the applications which run on the system so that business requirements can be translated into hardware and software configurations.

Business element forecasting is one technique in the arsenal of tools which can be used to attack capacity planning problems in the I/S management organization. The purpose of business element forecasting is to relate business requirements to the demand for resources of specific applications.

The term "Business Element" refers to a data element which measures the amount of activity in a business division which uses I/S resources. Some authors use the term "Key Volume Indicator" or KVI to refer to this measurement. Other authors use the term "Natural Forecast Unit" or NFU. The differences in terminology can be confusing, but the underlying concepts are the same in most published approaches.

Business element forecasting is implemented by building statistical models which relate the amount of activity in a business division with the computer resources required to support the activity. Once the model is built, the capacity planner can forecast future values of the business elements, and employ the model to determine the level of capacity needed to satisfy these requirements.

The motivation behind this technique is the need for the capacity planner to look outside the I/S organization for estimates of future capacity requirements, and to quantitatively tie future I/S expenditures to the business plans of the divisions which I/S serves. If this process can be successfully implemented it provides the quantitative information needed to make management decisions about future I/S expenditures, since the cost of I/S resources can be directly related to the value of the business plans in the user divisions.

A business element forecasting approach is not the only method which can be used to plan for capacity requirements, nor is it an appropriate method for use in all situations. This method can be used in cases where an organization in the corporation uses a substantial amount of computer resources in the course of their production operations, and where the volume of activity in that organization is related to the use of these resources.

For example, an automated order entry system, where the sales force enters customer orders directly into a data base system which is then used to feed the manufacturing, warehousing, shipping, and billing processes, is a good candidate for business element forecasting. A system which is used by wide variety of corporate divisions, for a number of purposes, such as general purpose TSO system, may not be driven by business requirements in other areas. This type of system may be better forecasted by studying historical usage trends.

Requirements for the Methodology

The successful implementation of a business element based forecasting program will require the I/S organization to have already established some basic parts of a capacity planning program. The information which is needed is a definition and characterization of the workloads on the system, and an understanding of the divisions within the corporate organization which are served by these workloads.

The development of this characterization of the workloads is part of the natural evolution of a capacity planning program. Howe (HOWE85) gives a more detailed discussion of many of these issues and outlines how to approach the initial development of a capacity planning program. To better understand the base upon which a business element forecasting program is built, consider the following evolution of a capacity planning program.

Analysis of Global Utilization

The key ingredients to any capacity planning program are a basic understanding of what levels of resource usage are being attained, who is using the resources, and what future growth is expected in the usage of these resources. This understanding forms the basis for the capacity plan which addresses the relationship of business requirements to a final data processing configuration.

When an I/S organization initially implements a capacity planning function the first objective is to start collecting data on usage of the computer system so that this information can be tracked over time, and trend analysis may be performed. Tools currently exist for organizing data from system logs and monitors, such as SMF and RMF, so that this data may be extracted and analyzed.

In the early stages of a capacity planning program the I/S organization may only collect statistics on the global usage of system resources. Trends will be made on total CPU utilization, aggregate volume of online DASD storage, number of logged on TSO users, total volume of batch jobs, or total volume of online DB/DC transactions. These statistics show the aggregate usage of all I/S resources, and hence are related to the total costs of the installed hardware and software.

The best use of aggregate statistics is to analyze the profile of system usage so that peak periods may be identified. In today's online and competitive business environment, there is need to plan the maximum capacity of the system around the demand for resources in peak usage windows. While aggregate statistics are useful for identifying peak usage periods they are notoriously weak for trend analysis. Trends based on aggregate usage can show a need to increase capacity, but they cannot relate the need for additional capacity to specific business requirements. This means that aggregate statistics do not carry sufficient information upon which to base management decisions on upgrade expenditures.

Understanding Technical Subsystems

The next phase of a capacity planning program is to break down the aggregate statistics into their component parts. The first cut at this effort is often based on technical, rather than business, concerns. The data sources used for this analysis are specific to the technical implementation of the applications. For example a CICS online application is tracked by CMF, a batch application is tracked by SMF, a program development effort by RMF or TSO/MON, and the like. This activity allows the planner to understand the different data sources, and to learn what quantities are measurable within the applications.

Trends based on a technical breakdown of the resource usage add more illumination to the capacity planning process. These highlight growth by technical subcomponent, and may suggest alternate methods for providing new capacity. For example, if program development is showing significant growth, one may choose to migrate developers from TSO to VM/CMS, since CMS capacity can be acquired in smaller increments than additional TSO capacity (using 93xx or 43xx scale processors).

This analysis provides more technical detail and begins to suggest how solutions to capacity requirements may be engineered. Analysis at this level may sometimes address a business requirement, if the business requirement is the driving force behind a particular technical subcomponent of the resource usage. For many applications a more specific relationship to the business plan is still required.

Add Usage by Business Segment

Once the technical subsystems are understood the capacity planner can move into a planning environment which relates resource usage to specific business divisions. This involves breaking down the resource usage of the technical subsystems into components which are used by the various corporate divisions which use the I/S services. The goal of this analysis is to determine who is using the resources, and to quantify their level of consumption.

At this level of granularity the planner begins to have the information needed to present the business case for a capacity upgrade. A specific capacity requirement can be stated in both business and technical terms. The business usage is stated by major application, or by division within the organization. The technical usage is stated in terms of major subsystem usage, with individual statistics on TSO, batch, DB/DC, etc. The information can be visualized as filling in the cells of the following resource usage or demand matrix:

Columns: Technical Subcomponent
Rows: Business Division consuming the resource
Cells: Resources consumed (CPU seconds, EXCPS, transactions, etc.)

	TSO	Batch	CICS	IMS	.....
Finance	x	x			
Engineering	x	x	x		
Manufacturing		x		x	
Sales	x	x	x		
Marketing	x				
Etc.

Obviously, the corporate divisions, and the technical subsystems will be chosen according to the structure of the corporation, and the technical requirements for computer resources. Usually more than one matrix of this type will be required. Each matrix will contain data for a specific time period, or time zone, upon which the capacity plan is based. These matrices will be used in various parts of the capacity plan, and provide input to

guide the business element forecasting process. The primary matrices which are needed are:

1. Load during peak periods
2. Load during prime shift
3. Total load for all shifts

In an online environment the total capacity of the system must be configured to support the peak demand periods, which typically occur in the mid-morning and mid-afternoon. This means that the costs born by the I/S organization are determined by the demand for resources during peak periods. The second two matrices are needed for correlating the business element data and for supplimentary management reporting.

Targeting the Business Element Forecasting Effort

The analysis of global system utilization leads to identification of the peak periods. Further analysis of the load by technical subsystem or application adds insight into the specific subsystems, usually the online systems, which provide the demand during these peaks. When the demand matrix is completed the planner knows which divisions of the corporation are responsible for this demand.

The business divisions which use significant portions of available resources during the peak periods are the ones which are targeted for further investigation. These business divisions are the ones which drive the requirements for additional capacity. As such, quantification of the benefit derived from this usage is the key to providing the justification for capacity upgrades.

A demand matrix for the prime shift is needed for correlation with business elements which are obtained outside the I/S organization. This is because the capacity planner must obtain historical data on values of the business elements from the business divisions which use the resources.

Unless business divisions outside of I/S maintain very detailed statistics on their volume of activity by hour of the day, or by week of the month, it will not be possible to obtain business elements which correspond exactly to the peak periods of resource demand. Since most activity occurs during standard business hours it is much easier to correlate business elements with prime shift loads.

In some environments, especially manufacturing, where production occurs around the clock, it may be necessary to correlate business activity with total I/S resource usage without regard to time. These environments need to construct a demand matrix for total load over all shifts.

Business Element Methodology

The basic hypothesis which underlies the business element forecasting methodology is that the volume of business activity in the corporate divisions which are served by the I/S organization may be related to the demand for computer resources. Furthermore, the methodology assumes not only that this relationship exists, but also that it may be quantified using a statistical model so that estimates of the volume of future business activity may be directly translated into specific quantities of computer resources.

The methodology can be subdivided into three parts. The first part identifies the business elements which can be obtained from the users of the I/S resources. The second part uses statistical procedures to relate, or correlate, historical observations on business data with computer resource usage. This analysis leads to the development of a model in which computer resources are represented as a function of the values of the business elements. The last part of the methodology involves forecasting future values for the business elements. These forecasts can used as input to the model developed in the second part to predict computer usage.

Identifying Business Elements

Successful identification of the business elements is, perhaps, the most difficult part of the methodology. This is because the capacity planner must work with the users of the system to determine the elements which the users feel best characterize their levels of activity. The capacity planner must shed her or his perceptions of the computer system and learn to see the application from the user's perspective.

This is where the peak period demand matrix is used. The capacity planner cannot hope to interact with every business division which uses I/S resources. By studying the peak period demand matrix the business divisions which drive the capacity requirements can be quickly identified and the process of identifying business elements can be focused on these divisions.

The next step is for the capacity planner to interview the developers of the application to determine the characteristics which they believe have the most significant influence on the resource requirements of the system. This type of information will include the number and type of transactions which are executed to perform a particular business function. The capacity planner is interested in developing a conceptual overview of the logic of the system which relates end user function to measurable resource quantities.

Understanding the logic of the application will not yield the business elements, but rather give the capacity planner the perspective to discuss use of the system in the terms most familiar to the end user.

Once the system is understood, the users of the system should be interviewed to determine how they measure their volume of usage of the system. This interview should be viewed as an iterative process. This interview is intended to lead to identification of the business elements themselves. To successfully implement this methodology the capacity planner needs not only to identify possible business elements but to obtain historical observations on these elements for correlation to the historical patterns of resource usage.

The capacity planner should recognize that planning resources to meet business requirements is an activity which is practiced in all parts of the corporation. In the I/S arena, we plan hardware upgrades, raised floor space, power and cooling capacity, staff levels for system programmers, and similar things. The business divisions which use the I/S services also plan to meet their production targets in units such as office space, staff levels, number of machines, capacity of production lines, and the like.

As a starting point, ask the users what statistics they report to their management to quantify the level of work processed by their department. When the business division is requesting additional staffing, or capital investment, what units do they use to justify these needs? What statistics are used to regularly track their progress against targets established in their business plans?

In some industries, most notably the insurance industry, the volume of future business activity can be very accurately determined. The financial management of an insurance company is absolutely dependent on the ability to forecast future claim activity. As a result, insurance companies have actuarial departments devoted to this activity. The capacity planner should seek this type of information whenever possible.

The advantage to using statistics which business divisions use for tracking and reporting on their own level of activity is that historical observations on these statistics are readily available in the user's management reporting. This provides the data needed to build the business element model. In addition, these statistics are the same measures, in the same units, that are used to formulate the business plans of the business division under study. A model based on these statistics ties the user's business plan to the capacity plan for the I/S organization in a very natural manner.

Preparing to Build the Business Element Model

The process of building a model to relate the business elements to the demand for computer resources has two sources of input. The first source are the historical observations of the business elements which were obtained in the previous step of the methodology. The second source are historical observations of computer resource usage.

The data needed is the same data used to build the demand matrices which break down resource consumption by business division and technical subsystem. This data is available from system logs and monitors such as SMF and RMF for MVS systems, CMF for CICS, the IMS log tape, and other similar measurement products.

Historical resource statistics should be extracted over the same time period from which historical business element data was collected. These statistics should be summarized to the same level of granularity as the business element data. If the business element data shows monthly aggregate activity volume, then the resource data should be summarized to monthly level. This process creates a common time scale which is critical to the use of the statistical correlation process.

Formulation of a Business Element Model

A business element forecasting model is a linear equation of the form:

$$Y = A0 + A1*X1 + A2*X2 + A3*X3 + A4*X4 +...+ An*Xn$$

In this equation the variable Y represents the observed value of a resource data element, such as CPU time or total EXCP's. This is called the dependent variable. The variables X1, X2, through Xn represent the observed values of the business elements. These are known as the independent variables. The A0, A1, through An are coefficients which relate the business elements to the resource element.

This model can be interpreted to mean that resource consumption, Y, can be expressed as some underlying constant, A0, plus a factor, A1, times the value of the first business element, X1, a second factor, A2, time the value of the second business element, X2, and so on. This model is expressed in a form which can be solved using multiple linear regression, a common statistical technique which is implemented in most statistical packages. The goal of the multiple regression analysis is to estimate the values of the coefficients, A0, A1, through An, to completely specify the model.

The choice of a multiple regression model is motivated by several factors. Foremost is the simplicity of the model and its intuitive appeal. In addition, multiple regression models are widely used in various disciplines to model this relationships of this type. The form of the model is similar to models used in medical research to relate risk factors to incidence of disease. Regression models are also widely used in economic analysis and in psychological research.

The form of the model shown above assumes a purely theoretical relationship, where the resource consumption is exactly related to the values of the business elements. Since our data is collected from a real world environment we cannot hope to obtain an exact relationship. The model which we will attempt to estimate can be written in the following form:

$$y = a0 + a1 * x1 + a2 * x2 + ... an * xn + u$$

This is the same form above as above, with the dependent variable Y, replaced by the observed values of historical resource consumption elements denoted by lower case y. In a similar manner the theoretical values, X, of the business elements are replaced by the sample of data gathered from the users, which are denoted by a lower case x1, x2, through xn. The estimated values of the coefficients are denoted by lower case a1, a2, through an. Finally we add an error term, denoted by u, which contains the residual difference between the linear combination of the coefficients times the observed values of the business elements.

Basic Assumptions

Several basic assumptions are needed for the statistical formulation of this model. These are:

1. the x1, x2, through xn, are statistically independent
2. the theoretical mean value of the error term is zero
3. the error term has a constant variance
4. the error terms are statistically independent
5. the error term is independent of the x1 through xn

These assumptions introduce some statistical terminology which requires definition. A complete definition of these terms is beyond the scope of this paper, but can be found in most texts on linear regression (KEL74). To develop a business element model a full theoretical understanding of these terms is not required. To judge the validity of the model the capacity planner does need to understand the importance of these assumptions.

Assumption 1 requires that the business elements be statistically independent. This implies that each business element represents a unique data point which cannot be expressed as a function of one or more of the other business elements. The statistical term for a model which fails to meet this assumption is multicollinearity.

Failure to satisfy this assumption implies that you have not found a complete set of business elements upon which the model may be estimated. When the business elements are related to each other the model will not be able to determine which of several related business elements have predictive power on the dependent resource element.

Independence of the business elements is a major problem in formulating a business element model. You should intuitively expect a high degree of relationship between the business elements. For example suppose you have collected business element data on sales contact activity, number of orders entered, number of units manufactured, and the number of customer shipments.

These are all very naturally related to each other. The independence of these elements is highly suspect, and will depend on the size of the inventory maintained by the corporation, and the length of the sales to shipment cycle. If the inventory is low and the sales cycle is short there may be a very strong correlation between all the elements. When inventory is high, or if the cycle is long, then the correlation will be weaker, in that order entry is correlated to sales activity in an earlier month, manufacturing appears to be more driven by the need to maintain inventory, and the like.

Assumption 2 requires that the error term have a theoretical mean of zero. Failure to meet this assumption implies that there are other factors, aside from sampling and data error, which influence resource consumption. This means that the group of business elements which have been identified are incomplete. The full predictive power of the model cannot be realized until the unknown factors are identified.

Assumptions 3 through 5 all concern the statistical properties of the error term. Taken together they require that the error term be a well behaved random variable which can be quantified using statistical techniques.

A variance is a statistical parameter which controls the amount of dispersion of a variable about its mean value. To say that the error term has a constant variance is to say that the size of the error term is bounded in probability. This does not imply that there is a maximum value to the potential error, but rather than the probability of seeing an error greater than a specified value is small. In statistical terms, the model is said to be homoscedastic if this assumption is met and heteroscedastic otherwise.

Like multicollinearity, heteroscedasticity is a common problem in relating business element data to resource usage. As an example consider the problem of tracking corporate divisions of different sizes. A very large division typically has a large budget, more discretionary capital, and a strong motivation to exploit economies of scale. These factors suggest high variability from mean computer resource usage. An extreme example is an automotive assembly line which runs at maximum capacity for the first half of the model year to build inventory, then shuts down entirely for retooling for the next model year. A smaller division does not have this flexibility, so you would expect lower variance in their resource usage.

The final assumptions concern the independence of the error terms from other error terms and from the values of the business elements. Like the other assumptions this assumption assures us that the model contains all the factors which influence on the dependent variable. This assumption is violated when there is a systematic pattern to the error terms in the model. This problem is known as autocorrelation.

Autocorrelation is not typically a major problem in business element models. Where autocorrelation does cause problems is in using regression models to track historical trends over time. To illustrate consider a tracking of a division which operates under very tight budget constraints. If the resources usage in any month exceeds their budget allocation they restrict usage in the following month to recover the costs. This may put them behind schedule, thus causing them to exceed the budget in the third month. The error term in this model will swing from positive to negative and back in each successive month.

Solution Techniques

With the form of the model specified there are two questions which need to be investigated by the statistical procedure:

1. Which business elements should be used in the model?
2. How can reliable coefficients be estimated?

The first question arises from the process used to collect the business element data. In interviewing the users the capacity planner has sought business element data which appears to be related to resource usage. The choice of elements relies heavily on the judgement of the user and ability of the capacity planner to understand what drives the resource usage of the application. The choice of business elements is also influenced by the need for historical data. In many cases the capacity planner will be using historical data based on its availability more than its intuitive appeal for forecasting.

The issue of which business elements to include in the model can be addressed through the use of stepwise regression techniques. A stepwise regression is used to survey a large number of possible choices for independent variables and select the subset which creates a model which best fits the historical trend of resource consumption.

There are a number of different stepwise techniques which can be used. All of these techniques select a subset of the independent variables, solve the model, and calculate a statistic which measures the strength of the model. The value of this statistic is then used to weigh this subset of independent variables against other subsets. If the current subset is the best possible subset the process stops.

The technique which is used in the SAS system (SASS85) is known as the MAXR approach. This approach starts with a pool of business elements and evaluates every business element individually to determine which yields the strongest model. The selection is based on the value of r-square, with the highest r-square being chosen as the best model.

The r-square is formed by calculating two measures of variability. The first is the sum of the squared differences between the predicted values of the dependent variable from the mean value. The second is the sum of the squared differences between the observed values of the dependent variable from the mean. The ratio of these values may be interpreted as the proportion of the variability of the dependent variable which is explained by the model.

The technique proceeds to evaluate all two element models, all three element models, all four element models, and so on, until it determines that the value of r-square cannot be increased by adding more business elements to the model.

The result of this procedure is a model based only on the business elements which have the strongest predictive power. The procedure also estimates the coefficients which are applied to business elements, and generates a number of statistical tests of the strength of the model.

Validating the Model

The strength of the business element model may be determined in several ways. For a business element model to be useful it must have good predictive power on the dependent variable. This means that the model must explain a large percentage of the variation in the dependent variable.

Beyond predictive power in general, the business element model must be capable of predicting changes in the dependent variable as each business element variable changes. This means that the models needs to be tested in each of its multiple dimensions to determine the validity of each coefficient on each business element.

Lastly, the model should provide good estimates of future values of the dependent variable. This is related to the overall strength of the model in which we stated that the model should explain a large percentage of the variation. This variation effects the level of confidence which the capacity planner can have in the predicted values. Intuitively, being able to predict a future value within 20% is useful, while predicting within 400% is totally worthless.

Overall Strength of the Model

The strength of the model as a whole is judged on the basis of the level of the r-square which is attained, evaluation of the F-statistic generated by the statistical package, and the judgement of the capacity planner.

As discussed earlier the r-square measures the amount of variability in the dependent element which is explained by the model. If all the variability is explained, then the model is perfect, in that there is no error in prediction. The r-square test is not, however, an absolute test. A model can have poor predictive power but still generate a high value of r-square.

The F-statistic is a random variable which measures the probability that the model would have arisen due only to chance. To phrase this another way, make the basic assumption that there is no underlying relationship between the business elements and calculate the probability of seeing the results which have been produced. If the probability of seeing this F-statistic under this assumption is very small, usually less than 0.05, then you can safely conclude that there is a valid relationship expressed by the model.

The final, and often the most important, test of a model is the judgement of the capacity planner. The planner must ask herself or himself if the results of the model make sense. When your intuition and experience are in line with the model you are on the right track. If this is not the case, then either the model is wrong, or your intuition is lacking. The situation requires further investigation.

Testing Individual Business Elements

When the overall model has been validated, the capacity planner should turn her or his attention to the coefficient estimates for the individual business elements. Ask yourself whether there is sufficient justification for each business element to be included in the model.

The t-statistic from the statistical package is used to perform this test. This is another random variable which measures the strength of each coefficient estimate, in the same way that the F-statistic measures the power of the entire model. To apply the test, make the assumption that the coefficient for a particular business element is zero. This is to say that business element should really not be used in the model. If the probability of seeing generated value of the t-statistic is small, or less than 0.05, you can reasonably conclude that this business element has predictive power.

One of the most common problems in business element forecasting is a high level of correlation between the supposedly independent business elements. This violates the first of the basic assumptions of the model, and leads to a situation known as multicollinearity.

The classical tracks of a multicollinearity problem are very good statistics on the overall model, combined with low t-statistics on all or most of the business elements. In this type model the r-square and F-statistics are almost always highly significant, so the problem is not detected until you attempt to validate the coefficients on the individual business elements.

In a multicollinear model the statistics are trying to tell you that when you consider all of the business elements together, as a group, that they have a great deal of predictive power. However, this predictive power is so confounded by relationships between the business elements that the solution techniques cannot determine the predictive power of any single business element. This makes the model useless for forecasting, since you cannot expect to add future estimates of the business elements and get reliable results.

Testing the Predictive Power of the Model

The final test of the validity of a business element model is in its ability to predict future levels of resource consumption within a reasonable tolerance. This involves calculation of what are known as confidence limits for the predicted values.

A statistical model cannot actually predict the future, it can only estimate the most likely, or expected value for a forecast. This is a probabilistic estimate of the average, or mean, value of a random variable. Confidence limits are a boundary which is put around this predicted value to establish the probability that the observed value in a future time will fall within a certain range.

The important criteria for a confidence limit is the width of the limit around the predicted value. Generally confidence limits are drawn with either a 90% or a 95% probability.

To illustrate the use of a confidence limit assume that a model has been built to predict the CPU time required by an application, and that the statistical package has generated an estimate of 12.5 hours/month, with a 90% confidence limit of plus or minus 2.3 hours. On the basis of this model, the capacity planner can make the statement that there is a 90% probability that the future value of the CPU time is between 10.2 and 14.8 hours/month.

This model is clearly more useful than it would have been if the confidence limit was 10.8 hours. Had the confidence limit been 10.8 hours, the capacity planner would have only been able to say that the future value of CPU time would fall between 1.7 and 23.3 hours. This interval is so wide that the estimate is of little value.

Generating Predictions

The final phase of a business element forecasting study is the use of the model to predict future resource requirements. The model takes as input the predicted values for future levels of business elements. It then produces estimates, and confidence limits, for the level or resource consumption which is to be expected. Therefore the input needed for the forecasting study is predicted values of the business elements.

There are two ways to obtain estimates for future values of the business elements. One approach is to go back to the business divisions who provided the initial historical data upon which the business element model was based. These divisions should be forecasting their own requirements as part of their normal planning progress. If you are using the same statistics that the business divisions use for tracking their activity the forecasts will already be available.

This approach will provide the strongest business case for your capacity plan. If the plans which the business division have already been approved by corporate management, your capacity plans have all the justification they need, as they are additional requirements which are directly in support of a committed business plan. If the plans for the business division have not been approved by corporate management, your capacity plans should be presented in conjunction with the plans for the business division. This gives management the information that they need to make a quantitative decision.

The second approach to forecasting business elements is to apply any available forecasting technique directly to the historical values of the business elements. A large number of possible techniques are available in commercial software packages (SASE82, MAKR83). Several published papers have explored this technique. Hoffman (HOF82) showed an application of a three component model which measured trend, season, and cycle to the message rates of an airline reservation system. This technique showed that a simple model could be used to predict future volumes upon which a business element model could be based. Lo (LO86) explored the use of different types of forecasting algorithms which use data smoothing on historical series of business elements.

In either case, be aware that the accuracy of a business element forecasting study depends on both the characteristics of the statistical model proposed, and on the accuracy of the forecasts provided by the business divisions which measure the business units. Each of these items of must be periodically reviewed.

The process of obtaining estimates of future business elements can be proceduralized as part of the regular corporate planning cycle. This will help ensure that the activity receives the attention that it requires in the user's business division. Salesmanship is important in obtaining cooperation from the user. The goal of a successful business element forecasting study is the accurate planning of computer resources which is highly beneficial to the user.

The statistical model can be rederived periodically from updated observations on the business elements. Since it is a statistical model, the exact values of the coefficient estimates will change slightly each time the model is run. This should not be a concern if the amount of change is small. Should the coefficients change greatly the basic model should be redeveloped using the same procedures used to develop the original model.

Conclusions

This paper has been a introduction to a business element based capacity planning methodology. This methodology requires the I/S organization to have a capacity planning project in place, which has identified peaks load periods, understands the technical subsystems, and can separate measurement data from various business divisions which use the I/S resource. The evolution of a capacity planning project up to the required point has been traced briefly.

The basic assumptions of a business element forecasting methodology have been stated, and a procedure by which the methodology may be implemented have been described. This procedure is composed of three major parts, identification of business elements, development of a model, and generating predictions. Suggestions have been given for identifying and collecting business element data, for using statistical tools, and for how the model can be used to generate forecasts.

THE USE OF NATURAL FORECASTING UNITS

John M. Reyland
Community Mutual Blue Cross & Blue Shield
Cincinnati, Ohio

ABSTRACT

The use of Natural Forecasting Units (NFU's) within capacity planning programs has proven to be an effective procedure. This tutorial considers the identification and measurements of NFU's and their use to project future computer system requirements based on planned or statistically projected NFU changes. It continues with a general report of a real experience utilizing NFU's, how their use not only projected future computer system resources, but also reported unexpected capacity and performance problems for a converting IMS system. The tutorial is structured around two different approaches in the use of NFU's and the capacity planning program.

INTRODUCTION

The NFU is a business element measurement from the business side of an organization which can be related to the use of computer systems resources by workloads. Examples of potential NFU's are purchase orders, production output counts, insurance contracts, accounting data, etc.. The purpose of NFU's can be twofold. The first deals with measuring and evaluating current system workloads as to their capacities and performance relative to selected business elements. The second deals with the impact of planned NFU changes as to their future impact on system configurations, workload capacities and performance, capital investments and budgets.

T. L. Lo [1] succinctly defines the NFU concept as attempts to link business activities/plans to DP activities/plans. Such linkage enables the data processing function to develop DP plans based on corporate plans, which is very important because of large capital investments needed to maintain adequate computer support.

The number of manufactured widgets might be directly related to a particular system workload and its CPU time. This would be expressed as a CPU time unit per manufactured widget. If this is a valid functional relationship between these two measurements, then one would observe during a given time period that a change in the number of manufactured widgets would cause a corresponding change in the total CPU time for the particular workload. Such a coorelation makes it possible to predict future system resources by workloads.

It is essential that one understands the functional relationship between NFU's and computer system resources by workloads. This is the basis of the NFU concept and its use to predict future computer system requirements. The above example of the academic widgets is simplistic, but it illustrates this functional relationship. The system resource side of this relationship is sometimes referred to as Data Processing Units (DPU's). Thus the relationship is between NFU's and DPU's.

THE NFU COMPONENT

Depending upon the business environment, there are many possible approaches to measuring and evaluating NFU's, which will functionally relate to computer system resources by workloads. There are some general considerations when selecting potential NFU's.

The first consideration is measurability, which is the ability to identify and count the occurrences of NFU's. This must be done with ease of identification and with consistency from reliable sources.

For purposes of this tutorial, NFU's can be categorized as contractual services or product lines. An example of a business industry that provides contractual services would be the insurance industry. Product line business would be the manufacturing of cars or television sets.

Identification deals with the terminology about contractual services and/or product lines. This can prove to be difficult, especially in the areas of contractual services. Services like medical insurance plans, which have evolved over time, have an ever changing realm of terminology. Terminology difficulties can also be found in product line businesses. The history of product diversification, model numbers, product specifications can all contribute to the problem of identification. Such instability makes it difficult to identify and track NFU's over long periods of time.

Consistency deals with the measurability of NFU's across business segments of the same organization. This is especially true within organizations that provide essentially the same service by its business segments, but the service has been tailored for particular client groups. This is probably a lesser problem in product line businesses.

The second consideration deals with the quality of the functional relationship between a potential NFU and its DPU. This quality is statistically referred to as correlation. Examples of the quality of correlation are illustrated by the following environments:

* The best measure of correlation can be found in a dedicated online system, which has individually identified transaction codes that support specific services.
* Correlation would diminish if the above services were supported by an online system that simultaneously processed multiple functions with a limited number of transaction codes.
* Batch processing would probably provide the least amount of correlation. To identify and count types of input records by type process is a less dependable procedure.
* If contractual services and/or product lines do not have direct data processing support, then correlation must be determined by some indirect means. This might involve sales records, accounting data or the use of manufacturing resources.

The ability to identify and use NFU's from the business side of an organization is greatly dependent upon one's understanding of the business organization. One should study the formal, and if possible, the informal structure of the business organization. Within this study, one must be careful to identify line and staff functions. It is within the line function that most NFU's will be identified, even if measured by a staff function such as accounting. The ability to identify and measure NFU's will also depend to great extent on the dynamics of an organization. Business and non-business organizations must continuously change to be competitive.

It is risky to select NFU's by a trial-and-error approach. The risk involves the reliability of selected NFU's, and the credibility of the capacity program. NFU's only become reliable when they have a history of being useful and dependent upon to make valid projections of required computer system resources.

COMPUTER SYSTEM RESOURCE COMPONENT (DPU)

The identification of a computer system resources unit (DPU) is found by examining workloads that directly support an NFU. This identification can become difficult because workloads may contain composites of work. A batch workload may contain both test and production work. An IMS system may have multiple IMS systems, or a transaction may perform multiple functions and call other transactions. To avoid this kind of problem, it is essential to identify specific workloads by assigning them to unique performance groups within the IPS of the System Resource Manager, a component of the IBM's MVS operating system. Non-IBM computer systems need to have similar features to isolate workloads.

Performance groups can be used to isolate types of workloads, which also isolates system resource utilization by such workloads. Depending upon the type of workload, not all system resources are reported by SMF/RMF at a great enough detail to be useful.

SMF/RMF will report by performance groups system resources utilization for batch workloads. Typically this includes CPU times, execution times, elapsed times, allocation times and for devices their I/O counts and service times, etc.. There still remains hundreds of other batch workload measurements.

TSO workloads are very much like batch. In addition to typical system resources being reported, TSO also reports Puts and Gets as terminal activity, and in some environments, TSO commands.

Beyond batch and TSO, data about the utilization of system resources must come from other dedicated sources. IMS and CICS have their own programs to reduce log data to meaningful reports. IMS PARS provides extensive data about individual transaction codes, elapsed times, processor times, data base calls, etc.. IMS also has DB/DC real time monitors that provide even greater detail than data reduction programs for log files. CICS systems have similar capabilities to obtain detail data about transactions and system resources.

There are communications packages that sample, and in some cases, report actual system resource utilization which can be used for communication workloads.

Most IBM compatible software vendors do provide some SMF recording about system resource utilization and transaction counts. This data, along with standard SMF and RMF data, can provide enough data to include such workloads within a capacity program.

NFU PROJECTIONS

There are several approaches in the use of NFU's to project the need for future system resources.

The first approach is to relate NFU's to input counts such as IMS or CICS transactions. These counts are used to drive a queueing or simulation model to change workload demands within a model. Projected IMS or CICS transaction counts are determined by an NFU conversion factor, which is calculated by relating NFU's and actual transaction counts. Future system resource requirements are determined from the changes within the model.

Such models usually require a preprocessor program to reduce SMF, RMF or other system data to workload characteristics. These programs will also generate input files for models, which contain required system resource measurements by workload. Morino's model generator and BGS's Capture program are examples of such software.

The second approach is to statistically project NFU's for purposes of determining changes in DPU's. Such changes are then translated into new hardware and software requirements.

NFU CONVERSION FOR MODELING

The needed functional relationship for the NFU is between the NFU counts and the model's input transactions. Such a relationship could be between policy holders and actual IMS transactions. There is also a need to mark this relationship at a point in time, possibly month end. All counts must also be scaled down as required by modeling software, which usually operate at hourly intervals. The selected hourly interval can represent a peak processing period or can average value.

More importantly the relationship must be functional. If there is an increase in policy holders and such policies are supported by a dedicated IMS system, then an increase in policy holders will cause a corresponding change in the number of IMS transactions. Such IMS transactions can be categorized as those that update policy information, inquire against the policy holder's databases and process policy holder's claims. The opposite is true, a decrease in the number of policy holders would result in a decrease in the number of supporting IMS transactions by transaction category.

These relationships must correlate either directly or indirectly. They may be simple, involving one NFU component or a string of individually weighted components. The more complicated a function becomes, the more difficult it is to measure and validate the relationship. The complexity of such relationships would be determined by the business environment. The mathematics usually involves the division of the transaction counts by the NFU component. This produces a conversion factor of IMS transactions per policy holder during the same time interval. This relationship can be expressed by categories of supporting IMS transactions. Conversion factors could be developed for IMS transactions per inquiry, IMS transactions per claim and IMS transactions per miscellaneous task. For each conversion factor there must have been an identifiable system workload with dedicated performance groups and IMS transaction codes.

Conversion factors from one time period to another should have approximate values. Historically they should have statistical distributions, which can be evaluated by standard statistical methods.

An example of a conversion process will serve to bring together the concepts about NFU's and their use for modeling. The example relates policy holders to IMS transactions. The process counts the NFU's, policy holders at month end and then scales selected IMS transactions to hourly averages. The NFU's are categorized as claims processing and non-claims processing. Dividing the hourly IMS transactions by the respective NFU will result in two conversion factors. The first would be average hourly IMS transaction for claims. The second would be the average hourly IMS transactions for non-claims processing. This assumes that the IMS system has been set up so that IMS transactions used to process claims have been uniquely defined and assigned to message processing regions (MPR's) and performance groups. The same would be true for the non-claims processing.

Sequence of steps to complete the conversions and utilize the NFU for projections:

* Assign IMS transaction codes to MPR's as claims and non-claims processing. Assign MPR's to dedicated performance groups.
* Count IMS transactions by selected IMS transaction codes needed for claims and non-claims processing.
* Scale IMS transactions to hourly rates. This can be done by having available hourly counts that correspond to the desired hour selected to be used by the model. If hourly IMS transaction counts are unavailable, then daily IMS transaction counts can be scaled by use of measured factors. Experience in our environment indicates that 12.78% of the daily IMS transactions will provide a peak hourly rate of IMS transactions.
* Perform the respective divisions to obtain the conversion factors for the hourly number of IMS transactions per claim and non-claim processing.
* Define the performance groups to the enqueueing or simulation model and execute the data reduction programs needed to process SMF and RMF data for the model.
* Distribute IMS system resources to IMS workloads within the model. This is necessary because SMF and RMF recording of IMS I/O's and CPU times are aggregate values for a processing period. By means of the DC monitor, the percentage distribution of these system resources can be determined. Such IMS resources usually involve the CPU times of the control region to MPR's and the distribution of I/O's by DDNAME to storage devices.
* Validate the model from actual system performance values and system measurements.
* Project the IMS workloads by using the conversion factors with planned changes of NFU's. This involves the multiplication of the monthly conversion factor by the planned monthly changes in NFU's. This is done on a monthly increment, since NFU's and IMS transactions are counted at month end.
* It is assumed that the model is being executed with all its other workloads, and that they are changing or remaining the same during the projections. It is also assumed that with the current workloads, the system is operating at over 85% CPU utilization and that there is a shortage of DASD storage.
* As the NFU's are converted to greater number of IMS transactions, the system would saturate with infinite response times because of the lack of system resources. It would be necessary to add system resources and to reconfigure the total system to process the increasing number of IMS transactions, while maintaining desired performance levels.
* The model's report of changed system resources are the future system requirements to process the planned NFU changes.

A REAL EXPERIENCE WITH NFU's AND MODELING

The above example is representative of our NFU program during the past 18 months. The purpose of our NFU program is to track, analyze and make recommendations for future system requirements, as part of a multi-year conversion effort. The conversion involved the replacement of an older IMS health insurance system, which does not have online claims processing, to a newer system with online claims processing and other desirable features.

There have been three stages which can be reported on in general terms, as means to present some realism of an on-going NFU program.

The first stage was early in the conversion schedule. Actual sample sizes of converted contracts were nonexistent. In place of these samples, there was another health insurance system, similar to the new system, which was used to obtain system utilization and IMS data. There was not an official consolidated schedule for the conversion of contracts by the five business segments of the organization. By means of a telephone we were able to consolidate the individual conversion schedules.

The contract counts functionally related to IMS data. The conversion factors were stable and useful to compute IMS transaction levels as input to the model. The results of the model indicated an inordinate amount of system resources needed to process online claims in the outer time periods. This was disconcerning, but our measurements lack sufficient sample sizes and we used a mirror image of the new system for system utilization and IMS data.

The second stage proved to be very much like the first, because very little of the scheduled conversion had occurred.

The third stage was the start of a new game. A group was established to officially set a conversion schedule and track its progress. In doing so, a new term appeared that was different than ours. The term contract was replaced with the term policy holder. Technically they are different, which changed our initial NFU measurements. At this point we had to align our NFU measurements with the new terminology, and recalculate conversion factors.

With better sample sizes, an official schedule of NFU's, good functional relationships and conversion factors, we were able to do more reliable modeling. The output of the model still indicated an inordinate amount of system resources needed to process online claims.

This became the center of concern for the business segments, data operations and systems and programming. Capacity planning and performance management suggested a limited amount of online claims processing with the remainder in batch. This was unacceptable to the business segments because they had been promised full online claims processing.

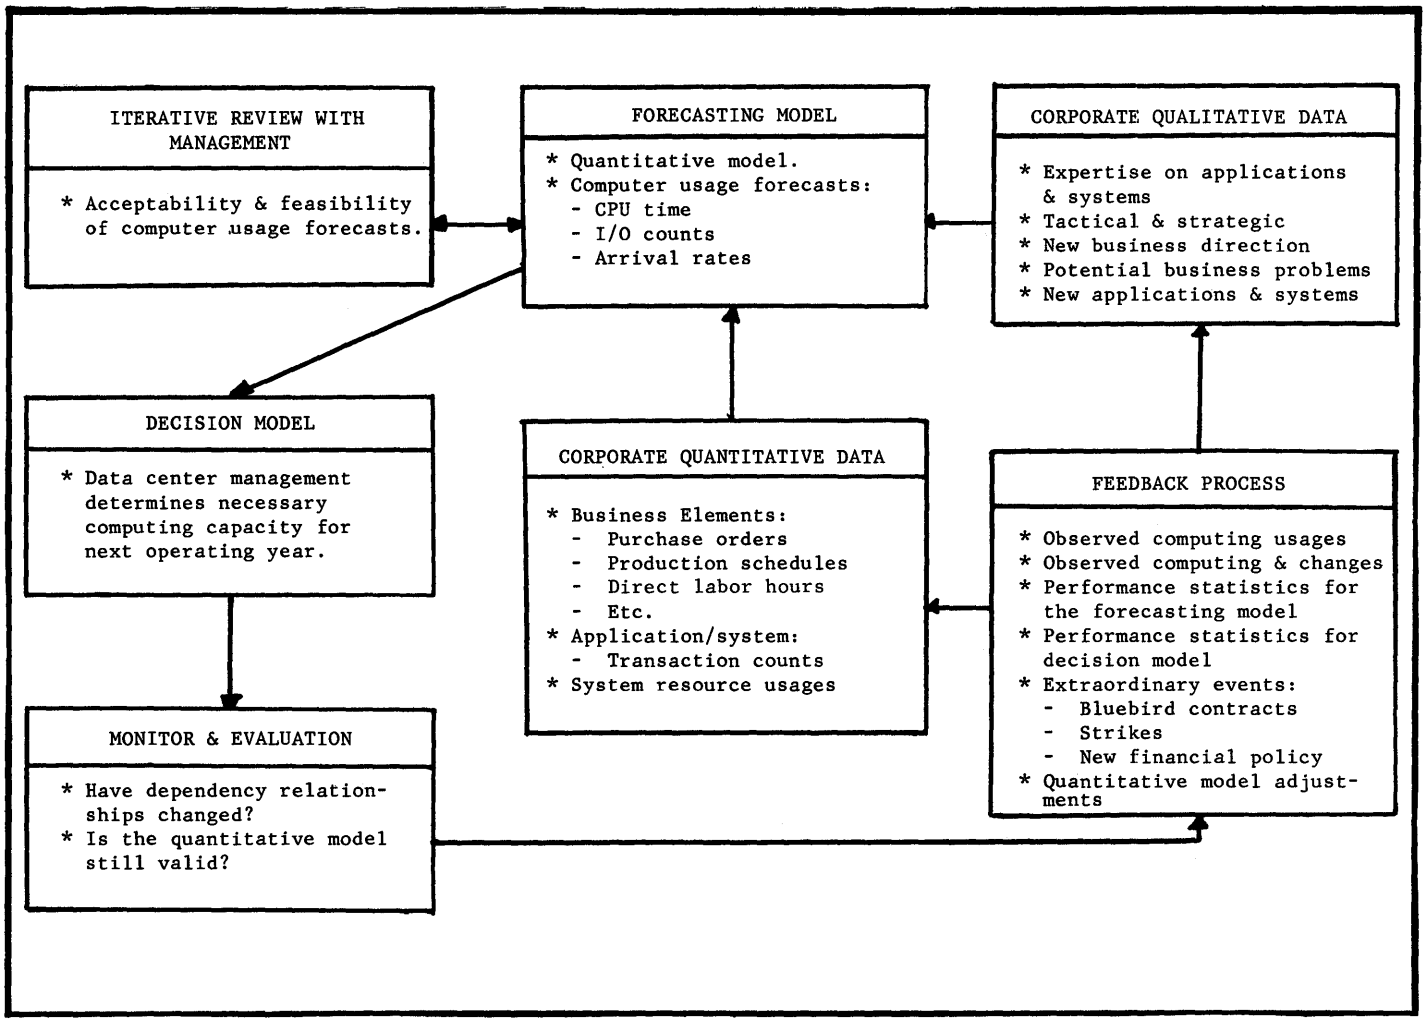
The system designers, data base people and programmers have studied and corrected this performance by a code change for claims processing. Today our projection models are reporting a totally convert system on one side of a 3090/400E with good response times.

NFU FOR DPU STATISTICAL PROJECTIONS

T. L. Lo [1] made a presentation at the CMG86 conference which gave details about their capacity program and how they statistically projected NFU's to determine DPU's. In summary, their capacity program has the following steps:

* Identify business elements at NFU's and data collection.
* Determine DPU's and their data collection.
* NFU/DPU dependency analysis.
* Forecasting process.
* Determine capacity requirements.
* Iterative review and revision.

The following chart, Lo [1] is a high level flow of their capacity program.



ITERATIVE REVIEW WITH MANAGEMENT
* Acceptability & feasibility of computer usage forecasts.
FORECASTING MODEL
* Quantitative model.
* Computer usage forecasts:
- CPU time
- I/O counts
- Arrival rates
CORPORATE QUALITATIVE DATA
* Expertise on applications & systems
* Tactical & strategic
* New business direction
* Potential business problems
* New applications & systems
DECISION MODEL
* Data center management determines necessary computing capacity for next operating year.
CORPORATE QUANTITATIVE DATA
* Business Elements:
- Purchase orders
- Production schedules
- Direct labor hours
- Etc.
* Application/system:
- Transaction counts
* System resource usages
FEEDBACK PROCESS
* Observed computing usages
* Observed computing & changes
* Performance statistics for the forecasting model
* Performance statistics for decision model
* Extraordinary events:
- Bluebird contracts
- Strikes
- New financial policy
* Quantitative model adjustments
MONITOR & EVALUATION
* Have dependency relationships changed?
* Is the quantitative model still valid?

The center piece of their program is the forecasting model and how it interfaces with other managerial functions of the flow. The forecasting model is designed around the dependency of the NFU and DPU, which is usually a linear relationship. In general, the forecasting process involves the following steps:

* Collect the NFU data from a historical source and use smoothing techniques to reduce randomness of the input data while determining projected values.
* Pass the smoothed NFU projected values to a Boole & Babbage program, the Workload Planner. This program produces projected DPU values (CPU times and I/O counts) from a historical source of system data. Such values are generated by a stepwise regression that uses the most affecting NFU's.
* Projected DPU values are used to determine future hardware and software system requirements.
* This process is iterated through the management flow for monitoring and evaluation, and for feedback.

CONTRASTING THE NFU APPROACHES

The first approach, preparing NFU's for modeling, is practical in smaller business organizations, which are stable and have a limited number of potential NFU's. This approach is particularly good in those system environments where the performance and capacity planners have control over the SRM parameters.

The second approach, projecting NFU's with statistical processes, is used within large business organizations having many segments that dynamically change their organizational structures and strategies. Such organizations potentially have a large number of NFU's that probably do not directly relate to unique workloads.

AFTER THE STUDY IS OVER

Craig A. Cooley
National Advanced Systems

ABSTRACT

Today's complex data processing environments have driven most companies to implement capacity planning functions. However, only the largest corporations can afford to have a full-time staff dedicated exclusively to performance reviews and workload capacity projections. As a result of this corporate posture, the systems programmer dons the hats of the capacity planner and the performance analyst. Frequently, the systems programmer will provide overly detailed technically oriented reports that are meaningless to the upper level decision-making management within a corporation.

This paper will provide some examples of reporting techniques that will prove effective for the technician who has to make recommendations to non-technical decision makers.

1.0 INTRODUCTION

Mark Twain said "Get your facts first, then distort 'em as you please."[1] The preceding quotation is a summary of what can happen in the computer capacity planning environment when technicians are attempting to communicate with non-technical managerial decision makers. The technician becomes extremely frustrated and begins to tell the non-technical person what he thinks that manager wants to hear rather than what is needed to make effective corporate decisions.

When data is presented to non-technical management in simple to understand formats the non-technical person will feel as though he has a full understanding of the material. This will also make the non-technical manager feel that he is making the decision to purchase new equipment. When the non-technical management feels that this decision is theirs, the performance analyst and capacity planner have done their job effectively.

The intent of the remainder of this paper is to provide the technician with some simple techniques that will bring about the required configuration changes through mutually agreed upon understandings of simply prepared data.

2.0 FUNCTION

The organization diagram in FIGURE-I depicts a typical MIS reporting structure employed by many companies. Generally anyone from the MIS director up in this type of organization has been recruited from non-technical ranks and may have only a cursory knowledge of computing systems.

MIS ORGANIZATION

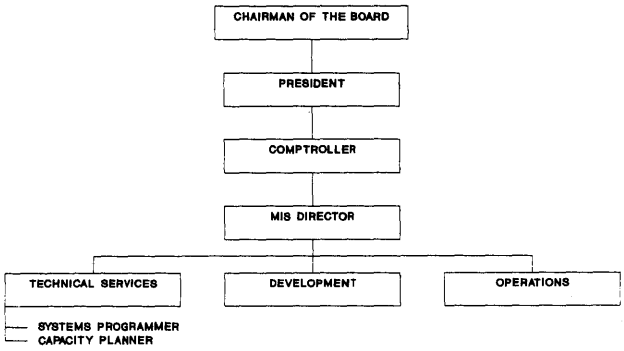

FIGURE-1

The capacity planner and performance analyst's functions found in the lower levels of the organization chart require them to review detailed data that is reported in some of the following technical terms:

- **SERVICE UNITS**
- **SIO'S**
- **MAIN STORAGE OCCUPANCY**
- **PAGING RATES**
- **PAGE MIGRATION RATES**
- **MEGABYTES**
- **GIGABYTES**
- **BYTES OF DATA TRANSFERRED**
- **BYTES OF MAIN MEMORY CONSUMED**
- **% DEVICE BUSY**
- **QUEUE's**

These terms are significant when talking to one's peers; however, when discussing these items with non-technical management, the performance analyst or capacity planner must show these items in units that non-technicians understand. Some of these units are as follows:

- **DOLLARS**
- **HOURS**
- **CHARACTERS**
- **GROWTH POTENTIAL**
- **TRANSACTIONS**
- **LETTERS**
- **INSURANCE POLICIES**
- **INQUIRIES**
- **ELEPHANTS**
- **ITEMS SOLD**
- **PATIENTS SERVICED**

As a result of these differences in terms, the general capacity and performance reporting procedure in these organizations becomes an interactive process as outlined in FIGURE-1A. This interactive process requires additional time from all parties involved in the reporting process. When the time spent passing through this process can be minimized, the corporation can gain significant hardware and "peopleware" productivity. These savings range from not having to hire an additional intermediate level manager as an interpreter, to obtaining six months, or better, of corporate cash flow through the timely acquisition of computing center resources. The following case studies introduced in this paper are the author's attempt at showing ways the technician can reduce the reporting cycle.

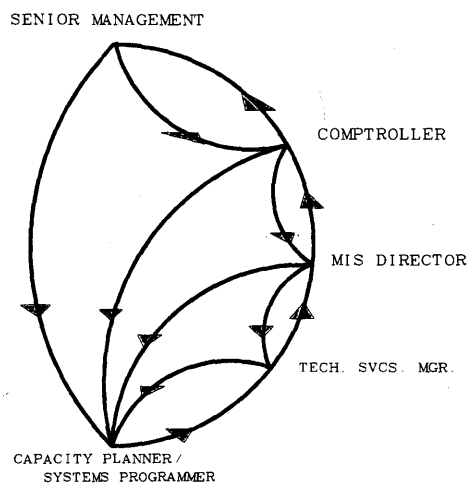

FIGURE-1A

3.0 REPORTING PROCEDURE

3.1 CASE STUDY 1

FIGURE-2 is an excerpt from a management report prepared by a competent MVS systems programmer. The intent of this report was to provide MIS management with processing figures that could be used as CPU capacity planning input during the annual budget process. Please note the similarity of the data presentation to the RMF monitor reporting format.

FIGURE-2

The MIS management team who received this report was completely bewildered by what the technician was trying to tell them and was reluctant to introduce any system changes, such as a verbally recommended CPU upgrade, until they understood the data.

The systems programmer's report contained less than one year's worth of actual data. These figures, plus some additional sketchy historical statistics, were then entered into a spread sheet program and reduced to the visual report shown in FIGURE-3. This visual report was then submitted to the same management team.

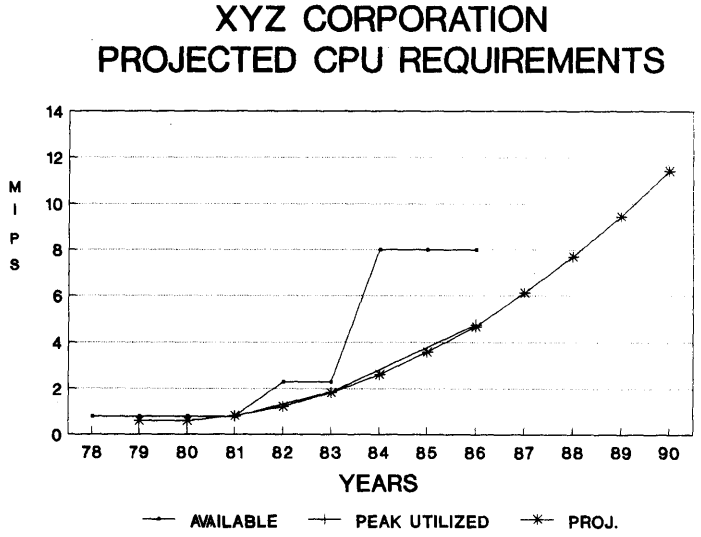

FIGURE-3

The graph presented in FIGURE-3 prompted the management team to reveal some new projects under consideration. These projects created CPU resource requirements in excess of the normal growth. The charts were then updated to reflect the additional growth items and the graph in FIGURE-4 was produced. Note the identification of a growth range in this report.

With FIGURE-4 available, the management team was able to start budgeting for CPU upgrades. This final capacity projection visual was included in the document that was submitted to the budget committee for approval.

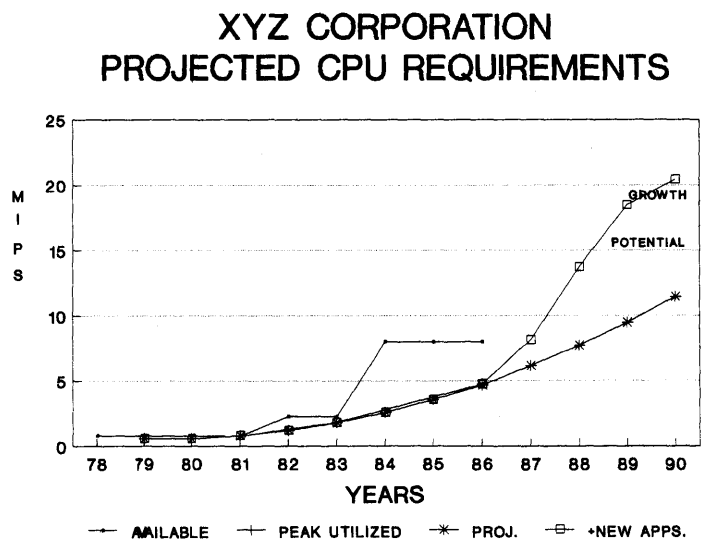

FIGURE-4

3.2 CASE STUDY 2

This corporation has utilized capacity planning techniques for many years; however, no one person was dedicated to the planning and reporting process.

The corporation employs a short-term upgrade policy. This policy was adopted as a method of controlling data processing growth through controlled resource availability.

The technical personnel have been providing management with the monthly CPU utilization report shown in FIGURE-5. Notice that the chart only depicts the CPU growth requirements in terms of the currently installed processor. The

chart does not provide an easily identifiable managerial method of predicting upgrade paths. This deficiency often forced management to pick upgrade paths that have led to less than one-year solutions, thus invalidating their fiscal data processing budget on several occasions.

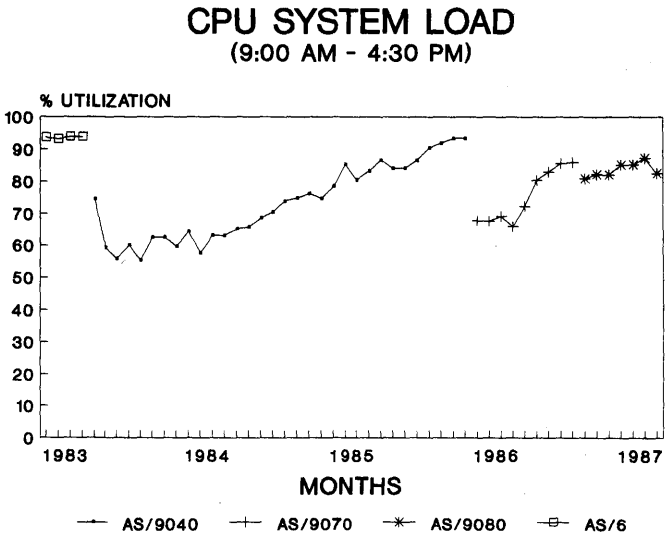

FIGURE-5

After recommendations from the computer vendor and an outside data processing consulting firm, the technical personnel are now producing the monthly CPU utilization report shown in FIGURE-6. Notice how the current chart attempts to normalize the data processing CPU utilization units in a manner that provides the administrative staff with predicted growth information.

By using the chart in FIGURE-6 and a minimal amount of information about the selected computer vendor's hardware, the management team is now better positioned to determine annual CPU growth requirements and processor upgrade paths. This prediction ability gives the management team better control over their CPU budgeting process, thus controlling the requirement of having to "go to the well" multiple times in a fiscal year.

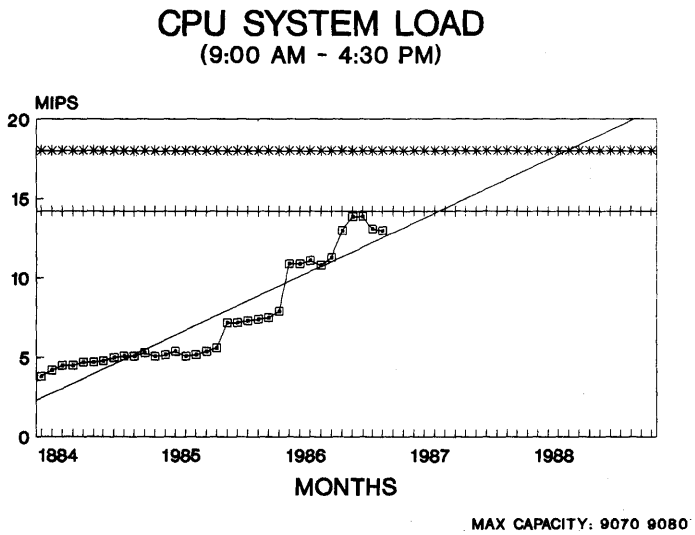

FIGURE-6

3.3 CASE STUDY 3

This corporation had never attempted capacity planning. The philosophy of this corporation was to saturate their processing environment and then purchase a new CPU when the users began to complain loudly. This philosophy was predicated by consistently tight budgets enforced through multiple external managing organizations.

In an attempt to force the managing bodies to realize the true processing needs of this organization, the capacity requirements chart in FIGURE-7 was produced. The basis of this chart was some very sketchy historical data and a series of verbal inputs from the systems users as to their future system requirements and projected CPU resource requirements.

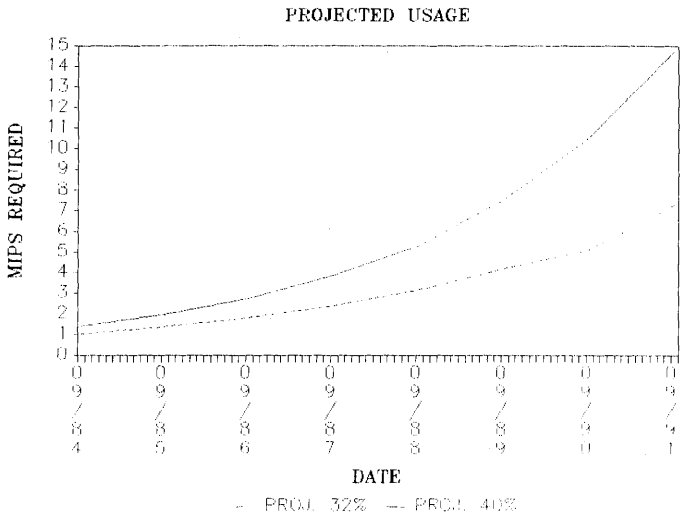

FIGURE-7

The inputs led to two growth scenario patterns that were plotted in FIGURE-7. The data center manager then went to his managing body with this chart and explained the growth requirements. As a result of this action, the data center was given money to proceed with a CPU upgrade, built on the conservative normal growth curve.

The managing body then asked the data center manager to track the current CPU utilization and report back on a regular basis. As a result of this management request, the report in FIGURE-8 was designed. Notice how FIGURE-7 is utilized as a

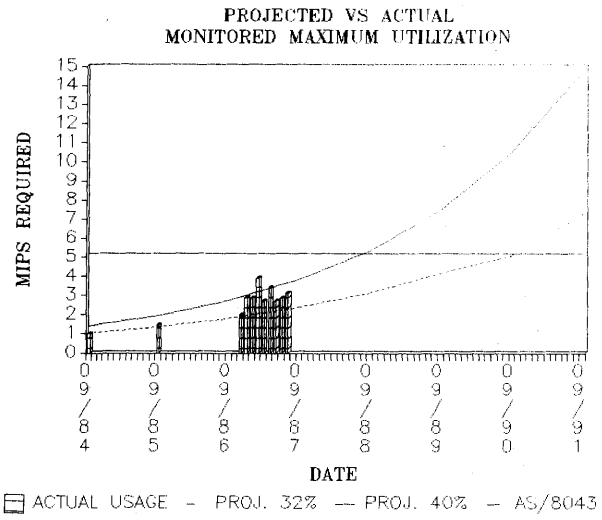

FIGURE-8

base mutually agreed upon capacity projection chart, augmented by an easily identifiable actual peak utilization function.

This tracking process has already assisted the managing body of this data center to understand the peak load CPU processing requirements. In addition to this understanding of processing requirements, the report has instilled a high level of confidence in recommendations made by the Operations Manager.

The ability of FIGURE-8 to track growth will assist the data center management in justifying future CPU acquisitions, thus providing a highly effective, ongoing capacity planning tool.

3.4 CASE STUDY 4

This company was in the process of evaluating upgrades to a two-processor environment, one of which was running a VM and DOS/VSE environment, and the other processor a native DOS/VSE environment. The response time on the VM and DOS/VSE machine had reached extremely poor levels.

A study of this environment was done using the KREUTER technique.[2] Kreuter reports are easily read by both technical and non-technical management after a brief set of ground rules are established.

Some of the ground rules for this study were as follows:

1. All decisions are made on observations rather than theory. The observations were made through a combination of VMAP and DOS/PT data.

2. The following rules of "thumb" were employed for each of the devices measured.

a. CPU capacity limit uniprocessor-90%
b. Channel capacity limit-25% each
c. Control unit DASD capacity limit-25% each
d. Device capacity limit-15% each.

3. All observations were made during peak periods of utilization.

4. All capacity projections were built around the concept of an average peak period derived from at least ten (10) normal processing days of data.

5. Annual growth rate was a number determined by the installation's management.

6. The technique is independent of any operating system environment.

7. The analysis of data looked for items that approached or exceeded the agreed upon rule of thumb numbers printed above. A review of that resource was then made in more detail to determine if there was a bottleneck to the system caused by this resource.

8. The analysis of data was done around an average peak period developed from 10 days of observations.

9. The matrix derived for analysis was cleaned of any anomalies and the results of these ignored in the averaging process.

10. MO used = (growth potential/annual growth) * 12. This figure does not account for compounded annual growth rates and is fairly accurate for the short-term predictions; however, it is the opinion of the author that long-term projections may be suspect.

The CPU and DASD management report for this installation is shown in FIGURE-9.

ON-LINE PEAK PERIOD CAPACITY SUMMARY

RESOURCE	BASE USE	CAPACITY LIMIT	GROWTH POTENTIAL	ANNUAL GROWTH	MONTHS LEFT
CPU					
AS/6620	20%	90%	350%	27%	155 MO
IBM 4341	72%	90%	25%	27%	11 MO
DASD					
CHN AS/6620	22%	100%	355%	26%	163 MO
CHN 1	1%	25%	2400%	26%	1107 MO
CHN 3	2%	25%	1150%	26%	530 MO
CHN 4	8%	25%	213%	26%	98 MO
CHN 5	11%	25%	127%	26%	58 MO
DASD					
CHN IBM 4341	53%	100%	89%	26%	41 MO
CHN 1	13%	25%	92%	26%	42 MO
CHN 3	14%	25%	78%	26%	36 MO
CHN 4	14%	25%	78%	26%	36 MO
CHN 5	12%	25%	108%	26%	49 MO
DASD CTL	75%	100%	33%	36%	15 MO
AS/7350(32)	259%	420%	62%	26%	28 MO

FIGURE-9

The above report led management to conclude that there were enough sources available to run their data center for at least another year. The technical support group was charged with the task of evaluating and tuning the DASD subsystems.

This management directive led the technical personnel to produce the report in Figure 10 showing the activity experienced against the heaviest utilized DASD subsystem.

The report in FIGURE-10 showed extremely high utilization by one control unit and specifically against the VM page and spool volume associated with that control unit.

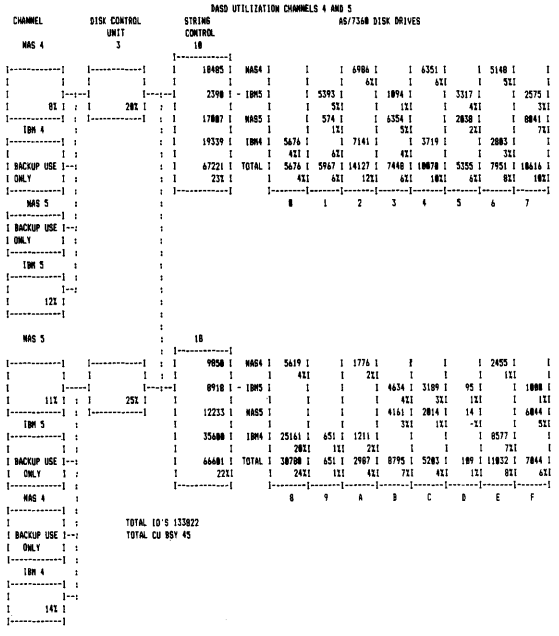

FIGURE-10

The technical personnel then began to look at the VM system's paging functions and determined that a 4-megabyte machine was insufficient for their workload and recommended to management that an additional 4 megabytes of memory were required for the 4341 processor.

The memory was purchased and the system response time improved dramatically. Additionally, the DASD activity against the most active control unit was reduced significantly through the elimination of paging I/O. The account also gained back between 10 and 15% of his 4341 processor cycles. These efforts have allowed the account to postpone a major CPU upgrade for approximately 18 months.

4.0 SUMMARY

Today's performance analysts and capacity planners have an abundance of technical measurement data available. This data is provided by both vendor supplied operating systems and second party monitoring products. The major challenge to the performance analyst or capacity planner is the reduction of this mountain of technically oriented data into simple, clear, management oriented, decision-making documents.

The techniques presented in the preceding case studies are intended to be starting points for the experienced and "green" capacity planner. These starting points are intended to reduce the often long and frustrating reporting cycles experienced when making management recommendations. The key to all of the examples is simplicity. A document that is self-explanatory will direct non-technical management to sound, effective data processing decisions. When this happens, the performance analysts and capacity planners have done their job effectively.

COMPUTER ACQUISITION AFTER THE TAX REFORM ACT OF 1986: EXPLORING THE POSSIBILITIES

Sudhir P. Amembal
Shawn D. Halladay
Amembal & Isom, Lease Education & Consulting

Everyone by now is, to some degree, familiar with the major provisions of the Tax Reform Act of 1986. Yet, even as we enter the second year of this legislation, there is still confusion regarding both the application and consequences of certain aspects of the law. Because of this confusion the full impact of the Act is yet to be seen. The leasing of computers, however, will continue in popularity as portions of the new law such as alternative minimum tax and the mid-quarter convention are added to the many other nontax reasons to lease.

The changes in the law, as they relate to computer leasing, can be broken down into four basic areas. The first is the change in tax rates from 46 to 34 percent, effective July 1, 1987. This change alters the aftertax cost of debt for lessees, as well as affecting lease rates. As a result, costs of acquiring computers have gone up. To the extent a lessor's borrowing costs are different from the lessee who is acquiring the computer the lease versus buy decision will be impacted.

The second, and most obvious in its impact, is the repeal of the investment tax credit, effective December 31, 1985. There is no longer that major government incentive to purchase and own new computer equipment. Potential acquirers of computer equipment will look at leasing more closely, now that the major impetus for buying the equipment has disappeared. From a quantitative perspective the cost of buying in lease buy decisions will have gone up substantially, buy leasing costs will also increase. Another result of the repeal of ITC will be a surge in the used equipment market. Without the government subsidizing purchases of new equipment used computer leasing becomes a more viable alternative.

The Alternative Cost Recovery System for tax depreciation has been modified, effective December 31, 1986. The modifications include changes in class lives, rates and methods of calculating the deduction. There have been shifts in depreciation lives for certain types of equipment, but none which affect computer leasing. This is not to say that there are not any depreciation issues affecting the acquisition of computer equipment. The depreciable life of a computer is still classified as five years but, due to a change in computing the yearly depreciation to 200% declining balance, it must now be depreciated over six years instead of five. Interestingly enough, although the period was lengthened, the actual depreciation was accelerated somewhat. Under the old law, 37% of the computer equipment could be written off during the first two years but, under new law, 52% can be written off. Again this type of change affects the buy side of lease versus buy, and also the lease side as lessors adjust their rates downward to reflect these changes.

A new twist in the law called the mid-quarter convention certainly has an impact on computer acquisition. Under this convention, if a computer user acquires more than 40% of its equipment (this includes equipment of any type acquired by the corporation) in the last quarter it will have to use a different depreciation method. This method, not only becomes a bookkeeping nightmare, but also lowers the value of depreciation in that year, is a definite tax disincentive.

This mid-quarter convention, however, only applies to equipment which is purchased, not leased. It is plain to see, then, that leasing provides a mechanism through which the lowering of depreciation value can be avoided. By properly matching their own and lessor year ends so as to avoid those lessors who themselves are in the mid-quarter penalty, a lessee can obtain the most favorable rates. This is another factor to be considered in the lease versus buy decision and while, perhaps, not causing everyone to lease, it will certainly cause acquirers of equipment to again consider leasing more favorably.

All aspects of the new tax law impact the lease versus buy decision, but none is as difficult to comprehend and apply as the alternative minimum tax ("AMT"). The concept of the AMT is that all corporations will pay at least some minimum level of tax. While simple in theory, this provision represents one of the most complex and pervasive changes in the law. The tax itself is based upon regular taxable income plus certain preference items. This total is multiplied by the AMT rate of 20% to derive the tax (preference items are certain items used to reduce taxes, the nature of which are often times thought of as "tax sheltering" devices). Many corporations may not owe regular taxes because of their deductions but, after adding back their preference items to regular taxable income, they most likely will owe an alternative minimum tax. Because the greater of the AMT or the regular tax must be paid it is plain to see that a corporation would want to avoid being an AMT taxpayer.

The two preferences of major concern to acquirers of computer equipment are the preference on accelerated depreciation and the pretax book income preference. These preferences may be explained as follows:

1. Depreciation Preference. Any excess of the regular accelerated depreciation (200% declining balance) over 150% declining balance must be added back to regular taxable income as a preference. This reduces the benefits of depreciation to those users who purchase computer equipment.

2. Pretax Book Preference. One half of the excess of a corporations's pretax book income over its AMT income must also be added back to regular taxable income as a preference. This preference affects both purchasers and lessees albeit differently for both.

Lease versus buy under AMT becomes incredibly complex as now the potential lessee must know exactly what its AMT position is, and then integrate it into the analysis. Many acquirers, however, will find it advantageous to lease because the leasing of equipment does not create the depreciation preference. Leasing, in effect, become a means to avoid AMT or to bring a lessee out of an AMT position more quickly. In this respect leasing can be expected to grow as lessees take advantage of this tax planning alternative.

Corollary to the aforementioned advantage, lessees will also be able to shop around for better rates because of the effect of AMT on lessor pricing. Since AMT lessors pay more taxes, their rates should theoretically be higher. It would behoove lessees to seek out non-AMT lessors through appropriate rate comparisions.

All things considered, the Tax Reform Act of 1986 has created opportunities for computer equipment acquisition through leasing. The opportunities take the form of direct lessee advantages, such as avoiding the AMT through leasing, and indirect advantages, such as the impact of the AMT on lessor pricing. Those acquiring computer equipment should carefully study the ramifications of the new tax act and then take advantage of the opportunities which it offers.

INCORPORATING EXPERT SYSTEMS TECHNOLOGY INTO SOFTWARE PERFORMANCE ENGINEERING

Major Doyle J. Weishar
U.S. Army Information Systems Engineering Command

ABSTRACT

Software performance engineering is the process of considering performance goals when software is initially designed in order to achieve maximum effectiveness at minimum cost. Software performance engineering is traditionally conducted by assigning a performance analyst to conduct a study of a designated system under development. In the United States Army Information Systems Engineering Command (USAISEC), we are embarking upon a new approach: we are striving to place the tools and techniques into the hands of the applications software developers. In this paper we describe our efforts to develop the intelligent tools needed to transfer the domain expertise of a performance analyst to a non-performance oriented person.

1. INTRODUCTION

In the late 1970s researchers in the area of artificial intelligence began to realize that the problem solving power of a program comes from the knowledge it possesses, not just from the formalisms and inference schemes it employs. This realization led to development of special-purpose computer programs that came to be called expert systems [1]. Since that time expert systems research has received much notoriety. Expert systems technology has been used to solve problems in many disciplines. The most notable expert systems applications have been in the fields of chemistry, geology, medicine, and computer systems. This paper describes the entrance of expert systems technology into yet another field: software performance engineering. We first offer the reader a short description of software performance engineering. From there we describe how software performance engineering is conducted within the United States Army Information Systems Engineering Command (USAISEC) and then what motivated us to venture into the expert systems area. Finally, we describe the new tools that we are developing in order to foster software performance engineering within USAISEC.

2. SOFTWARE PERFORMANCE ENGINEERING

Software performance engineering is the process of considering performance goals when software is initially designed in order to achieve maximum effectiveness at minimum cost. Implementation of software performance engineering begins early in the development of a system and continues throughout the system life cycle. During the requirements definition and preliminary design stages, the performance analyst checks the feasibility and desirability of the functional architecture. In the later stages of the software life cycle, software performance engineering concepts are used to study algorithms, monitor progress toward meeting performance goals, and assess the impact of design changes [2].

Software performance engineering offers many benefits for system development. Among the most notable benefits include: the capability for early evaluation of design alternatives; the ability to isolate potential system bottlenecks and assess system performance; it results in increased productivity by making better use of the resources that would have been required to fix problems later; and finally, software performance engineering improves software quality since performance is an important aspect of software quality that is often overlooked [2]. An in depth discussion of software performance engineering is beyond the scope of this paper. Significant references in this field are [2], [3], and [4].

3. SOFTWARE PERFORMANCE ENGINEERING IN USAISEC

The charter for the software performance engineering program lies within USAISEC in the Systems Performance Division of its Quality Assurance Directorate (QAD). QAD has traditionally conducted software performance engineering by assigning a performance analyst to conduct a study of a designated system under development. In the conduct of his (her) study, the QAD analyst will collect pertinent data, build a model using those data, and apply the principles of software performance engineering in the analysis of the modeled system. To date, QAD has analyzed a number of systems. These include financial, logistical and personnel systems. In USAISEC there are a great many systems in development -- many more than the three to four performance analysts assigned to the Command can effectively analyze. When we in QAD began looking at this problem, the obvious solution was to hire more analysts. However, this was not an option. Therefore, we were required to look for new ways in order to foster an active software performance engineering program. One of the actions that we took was to publish the Command's Software Performance Engineering Handbook [5]. The handbook identifies tools and techniques for implementing software performance engineering. It is oriented towards systems developers (rather than performance analysts). Despite this, our feedback has been that the developers tend to believe that these concepts and methodologies are difficult to learn, are of questionable value, and take them away from their primary function which is to develop systems. To overcome this recalcitrance, we are incorporating expert systems technology into our program. Our intent is to offer software developers easy to use tools that will ingest the performance analyst's domain expertise into the development process in a painless manner. In the remainder of this paper we describe our efforts to develop these tools.

4. BLDR: AN AUTOMATED CRYSTAL MODEL GENERATOR

Modeling is the cornerstone of a software performance engineering analysis. Modeling ranges from pen and pencil exercises to very sophisticated simulations. With the possible exception of the pen and pencil exercises, modeling of a computer system is a very complicated task. Our performance analysts are capable of constructing the entire range of models, but most often construct analytic models. While analytic models are not as precise as simulations, they have been shown to be quite effective for modeling most computer system applications [6]. We use a tool developed by BGS Systems to construct our analytical models. This tool is called CRYSTAL. CRYSTAL has been developed specifically for modeling new software applications. This tool eliminates much of the tedium involved with analytic model construction by eliminating the need to code the underlying mathematical equations necessary to solve the queueing model. Despite this, there is a

reasonable amount of performance analyst knowledge required to use the tool effectively. As stated earlier, we did not want to require systems analysts to spend a lot of time learning the performance trade. But since modeling is so important, we had to think of a way to easily place the powerful modeling tool in their hands. We will do this with a tool called BLDR.

BLDR is essentially a preprocessor to the actual CRYSTAL analytical modeling routines. BLDR takes screen input from a user and constructs a model that can be read into CRYSTAL. The user is not required to have any performance background, only an idea of the hardware and software environment in which the application is to be run, and an idea of how the proposed application works. The following is a subset of a typical BLDR/user dialogue:

How many disk drives will you be using? 8
What type? STC 8380
List the names of the logical files and the logical record lengths you will be using? Finance_Master_File, 80, SSN_File,128

Once the user has completed his (her) description of the new application and its environment, BLDR automatically constructs the CRYSTAL model. We have tailored BLDR to suit our particular environment. Therefore, many system parameters do not need to be input by the user. We are trying not to make this a cumbersome tool to use. We are implementing BLDR in PASCAL/VS. It is approximately 50% complete. In its current version it will construct models of simple applications. We hope to have it building detailed models soon.

5. EXPERT SOFTWARE PERFORMANCE ENGINEERING

When BLDR is complete it will be an effective and easy to use tool. However, BLDR alone does not satisfy our goal -- a user still has to know performance to use the CRYSTAL tool. Therefore, we are building two tools that are designed to place software performance engineering expertise into the hands of our software developers. Our tools are called QAXPRT and DBXPRT. QAXPRT is a mainframe tool used in consonance with BLDR to assess overall system performance. DBXPRT is a personal computer based tool that is used to assist in database design. The next two sections describe these tools and highlight our progress in their development.

6. QAXPRT

QAXPRT is a rule-based expert system being implemented in PASCAL/VS. It consists of a collection of domain knowledge, called the knowledge base, and general problem-solving knowledge, called the inference engine. The knowledge base contains facts (data) and rules [1]. The rules express a conditional, with an antecedent and a consequent component. The facts express assertions about properties, relations, and propositions [7]. The rules and facts in our knowledge base have been formed using our collective expertise and guidelines in the performance literature. The rules use those facts as the basis for decision making. We use IF THEN constructs to represent our rules. An example of typical facts and rules in QAXPRT is as follows:

FACTS: User requires response time <= 3 secs.
Workload X is in application of user.

RULES: IF workload X response time > 3 secs
and > user_defined_limit
THEN warn user and look for cause

When the current problem situation satisfies or matches the IF part of a rule, the action by the THEN part of the rule is performed. In our example, if workload X's response time is greater than the user's acceptable limitation, then the system will notify the user and try to find a cause.

The second component of our expert system is the inference engine. The inference engine works by the matching of rule IF portions to the facts. We use a method of backward chaining by which inferences are formed from successive execution of rules.

QAXPRT assesses the overall performance of the application modeled by BLDR. After the BLDR model is evaluated by CRYSTAL, QAXPRT scans the user.CRYSTAL.LOG file and highlights possible performance problems. Recalling our earlier example will illustrate how QAXPRT works. In that example, QAXPRT notices that response times are above the user defined acceptable level. After notifying the user, QAXPRT begins looking for a cause. It is likely that QAXPRT may discover that certain disk devices are overly utilized. QAXPRT would infer this by matching the following fact and rule.

FACT: A disk is overly utilized if its utilization > 40%

RULE: IF disk X U > 40%
THEN redistribute files

Knowing that a disk is overly utilized, QAXPRT would begin to search for underutilized disks. Upon finding a candidate (disk Y), it will recommend to the user that one or more files residing on disk X be shifted to disk Y. The user then takes this recommendation and inputs the change through BLDR to CRYSTAL for reevaluation of the model.

As mentioned earlier, QAXPRT is being implemented in PASCAL/VS. Our knowledge base is over 50% complete, but our inference engine is still in the design phase.

7. DBXPRT

DBXPRT is a rule-based assistant for database design. It is being implemented in PROLOG on a personal computer. The conceptual framework of DBXPRT is the same as QAXPRT (i.e., it consists of a knowledge base and an inference engine). DBXPRT differs, however, in its intended use. Instead of assessing performance for an entirely new application, DBXPRT is being developed to be able to predict the change in loading that would result from adding a proposed transaction to an existing application. Specifically, DBXPRT concentrates on diagnosing potential performance problems associated with queries to large databases.

We have developed a prototype system that is able to predict response times associated with various types of queries (keyed, non-keyed, sorted, etc.) to different types of databases (VSAM, ISAM, sequential, DBMS, etc.). While there is much to be completed, we can see the light at the end of the tunnel with DBXPRT. Despite being only a simple prototype system, it has already demonstrated the ability to win arguments with "experts" by correctly predicting results that at first sight appeared to be counterintuitive.

8. CONCLUSIONS

In this paper we have shown how expert systems technology can be incorporated into the field of software performance engineering. We have shown that an automated model builder can be used in conjunction with a commercial modeling package and an expert analyzer to analyze the design of software, and assess the performance of that software. While there is much work to be completed, we feel that definite progress is being made. Ultimately, we will achieve our goal of providing easy to use intelligent performance engineering tools to our software developers.

THE GOLDILOCKS SYNDROME

Mike Berry
Amdahl Corporation

ABSTRACT

For some time now I have admired the medical profession's use of the word syndrome. Once they have attached some named syndrome to a set of symptoms and manifestations, they create an incredible shorthand way of communicating a related set of issues and problems, and where one exists, identify a solution. Now, the simplest of phrases, e.g., Downs Syndrome, Tourette Syndrome, conveys a book's worth of knowledge to the listener, and assuming the listener is a similar professional, the partnership can expend all their energies on the solution. What, I wondered, could we do in Data Processing (DP), a scenario that abounds in issues and problems, and always a plethora of solutions.

Another "coding" scheme that has long since caught my attention is Richard Nolan's Stages of Growth theory. As well as being convinced by the content of Nolan's theory, I am very impressed with the "lifetime" nature of this theory, i.e. Nolan started with Stages I to IV, then told us about Stages V to VIII, and then comes IX to XII, and so on.

So, I thought, if I could invent DP "syndromes", a) I can bring the power of the "shorthand" system to our dialogues, b) I can start a series that will see me through to retirement, and c) while I cannot put "Berry" to all my syndromes (as the medical profession does), I can become famous just like Nolan. The fact that I am here today tells you all you need to know about how famous I am--most of you never heard of me. However, the syndrome thing is working--elsewhere I have described the following syndromes.

- the Shredded Wheat Box syndrome
- the Condensed Milk syndrome
- the Infinite Capacity syndrome
- the Four-Eyes syndrome

AND NOW -- THE GOLDILOCKS SYNDROME

This is a lighthearted, but deadly serious examination of how Data Processing (DP) can change the way technology is promoted, quantified and valued. I want to focus particularity on the way capacity is determined, dispensed and valued. In doing that I seem to cast some doubt on practices sometimes seen. The extremes to which I point are deliberately overstated. I want you to leave here today with the syndrome firmly fixed, then from hereon we can use the power of that "shorthand" to quickly identify the problem and get to the solution. So, if you are in capacity planning and capacity management, go with the extremes. I've been in capacity management too, and I am here as a friend, and here to help!.

The core of this presentation is to do with how we have traditionally brought technology (i.e. capacity) to the client, why we now need to change the way we do that and how to change it. BUT FIRST.....

WHAT DOES THAT HAVE TO DO WITH GOLDILOCKS???

I am going to develop an analogy between the way capacity planning is sometimes done (NOT OF COURSE, BY ANY OF THE ORGANIZATIONS REPRESENTED IN THIS ROOM), and the "Goldilocks and the Three Bears" story. There are no prizes for guessing that Goldilocks is the client, the Bears are the Capacity Planners and the Bear's house is the Data Center. Incidentally note if you would, that I use the word "client", not "user". As far as I know, DP and the drug-pushing business are the only ones that call their customers "Users." DP stands for "drug pushing"??? Let's start calling them "Clients".

My first question is "Were the Bears too possessive?" Why go out for a walk leaving the house open if you don't want anyone to wander in perhaps to use the facilities. By the way, from now on, since I gave you the capacity planners, data centers, clients analogy, any pictures that appear in your head are yours, not mine!

Do we get too possessive about the capacity we plan? Do we almost become irritated when someone uses it? Even if we do not become irritated, do we watch them as they use it? Do we have some notion that there are "good" ways to use capacity and that clients do not know how: Do we WATCH them.

My next question is, "What example were the managers (Mama and Papa Bear) setting for Baby Bear? Did he/she behave that way from their example? Could the Bears have achieved much more out of the situation? Any lessons for DP here? Remember, any pictures running through your heads, any "Bears" and "Goldilocks" you are identifying are your responsibility.

ARE WE TOO POSSESSIVE IN DP?

DO WE PUSH TECHNOLOGY FOR TECHNOLOGY'S SAKE?

DO WE SEE CAPACITY AS OUR SANDBOX?

IS THE CAPACITY "OURS" OR "THEIRS"?

HOW DID ALL THIS COME ABOUT?

What has been our traditional approach to what technology (capacity) we do need, who can best select it, who needs to watch how it is used? Traditionally we have assumed that only we in DP can select technology (capacity). Only we know how to use it well. We need to watch the client's use of it. Clients do not know enough to be "accountable".

THE RESULT OF THIS STRATEGY?

TO OUR CLIENTS--WE LOOK LIKE POLICEMEN!!

Most people would see being a policemen as "not a nice job". The capacity planners in the audience--did you know that was what you were signing up for? The capacity managers in the audience--did you tell the new recruits what the job was really about?

DO YOUR CLIENTS SEE YOU AS "GUARDING" THAT CAPACITY, DISPENSING "APPROVED USAGE", "ALL VIOLATORS WILL BE PROSECUTED?"

Let's spend a few minutes looking at the kind of words we use when we set annual objectives for our capacity planners and resource managers. (You do set objectives, don't you?) "CONTROL-CONSTRAIN-RECLAIM-MONITOR-IDENTIFY HOGS, etc." i.e. "POLICEMEN" like words.

If you do nothing else when you get back to the workplace--look at the words that are used in the annual objectives of people in Revenue Center or Profit Center occupations. I guarantee you will see words like "PROMISE-GROW-INCREASE-SERVICE" -- all proactive "do-more-of-it" words.

IN OTHER WORDS -- SELL!

Let me come back to the concept of selling. First let's look at another traditional approach we take in DP when delivering (explaining) technology (capacity). Don't we all too often, buzzword/acronym our client to death? Don't you sometimes get the feeling (like a young bride might get on her honeymoon) -- "never mind the technicalities, just let me enjoy it"?

Let's return to this notion that we can "sell" our capacity rather than "police" it. The selling process implies "seller", "buyer", "price" and "value". How can we best put a value on capacity?

Let's ask a few questions.

- "Who knows most about,
  - Technology
  - The Business
  - Organizational Values
  - Corporate Budget
  - LRP?

THE CLIENT EVERY TIME -- Except technology. (We hope we know technology or we are in trouble.) But the client certainly knows the rest. Does this give us a lead to how we might manage this "supplier/customer" relationship? Isn't what we are looking at the classical supply/demand situation?

Simple supply and demand makes sure that the price fits the demand, the price stays right, whatever right means, and also has a fundamental concept. And, that is--that while we might start off thinking price equates to cost, it does not have to.

YES FOLKS, WE ARE TALKING ABOUT BILLING FOR SERVICES!!!

WHY? o being a policeman means being a worrier.

- Now what's going on?
- Where shall I look for rogues and vagabonds next?
- What on earth are they up to now? Etc.
- Guess What! We in DP do not know all we need to know to worry at our best.
- But, we insist on doing it. We insist on being the organization's "conscience".
  - Are we/they doing it right?

THE CLIENT DOES!

PLACE THE ACCOUNTABILITY WHERE THE VALUE CAN BEST BE DETERMINED. NOW DP IS SEEN AS A SUPPLIER OF VALUED SERVICES -- NOT AS A NECESSARY EVIL.

NOW, BACK TO THOSE BEARS.....

HOW COULD WE HAVE HELPED THEM?

IT'S CLEAR, ISN'T IT--THEY SHOULD HAVE OPENED A HOTEL!!!

So, DP isn't that simple, but we can start encouraging our capacity planners/resource managers to look outwards/not inwards. Worry less about what's going on in the system, more about what's going on in the business. Provide a mechanism for valuing the services. BILLING.

We can bill for services, but:

- Keep It Simple
- Keep It Consistent
- Encourage "Good"
- Discourage "Bad"
- Probably Just CPU/Storage/Printing/ Terminals

Encourage Capacity Planners/Resource Managers to get out into the business community--NOT JUST AT BUDGET TIME.

Change the tone of Objectives/Measurements.

Make VALUE the watchword. And, above all.....

SELL - SELL - SELL !

System Performance Management and Capacity Planning

Abstract

This tutorial is designed to introduce the manager/analyst to a variety of techniques and methodologies for capacity planning and performance evaluation. In particular, the system life cycle model, benchmarking, modeling techniques, workload characterization, and performance management will be discussed. While no new results are presented here, this tutorial will provide an introduction for the novice and an overview for the manager.

The presentation will be divided into three sections. They are:

1. A General Systems approach to Performance Management and Capacity Planning.
2. Workload Characterization and Prediction Techniques.
3. Simple Performance Calculation.

This paper is intended to expose some of the many facets of Computer Performance Evaluation (CPE), and augments the technical content of the presented sessions.

1. Introduction

Large computer systems incorporate many features such as multiprogramming, database management, virtual memory and complex operating systems. These features make performance management and capacity planning of these systems particularly difficult. The purpose of this paper is to outline those aspects of capacity planning and performance management that are the most critical in viewing a complex computer system. Topics to be covered include the system life cycle model, benchmarking, modeling techniques such as operational analysis and queuing theory, simulation, workload characterization and performance management. While none of the topics will be covered in great detail, enough information and references will be provided so that the reader may peruse topics of interest on his/her own.

2. The System Life Cycle Model

A systems' life cycle can be represented in many ways. Figure 2.1 is one model of the systems life cycle.

THE SYSTEM LIFE CYCLE MODEL

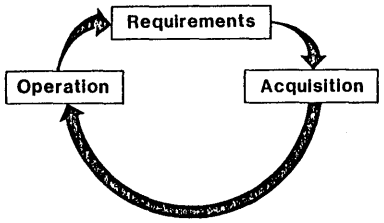

Figure 2.1

Expanding on this model, we note that during the requirements phase we need to understand the role (objectives) of the system, the load the system must support and the service the system is required to provide. During this phase, one must define more clearly the functionality of the desired system.

Once the requirements are identified, we begin to enter a phase of acquiring the needed resources to support the system requirements. Here we usually must compare among a set of alternatives over the entire expected life of the

*** This author is currently on sabbatical leave from the Computer Science department of the City University of New York at the College of Staten Island. Portions of this work were conceived and performed at Bell Communications Research, Inc., Piscataway, New Jersey 08854.

system. That is, as the system matures, the load that it supports will normally increase and the resources required to support this increased load should be identified during the acquisition phase. Thus, a plan should exist to support the system requirements over its expected life cycle. In essence there are two "types" of comparisons going on here:

- For each alternative "vendor" or set of resources, one must compare alternative changes in the set of resources (more memory, disks, etc.) over the life of the required system, thus producing a plan.
- One must also compare alternative "vendor" plans.

After we have compared and selected (obtained) the needed resources, we must operate the system including all the resources acquired to support the system. In essence, we must manage the system so that it meets its required goals in a timely fashion given the load. We, therefore, must manage the set of resources to ensure that the resources provide the required service given the load. This is sometimes referred to as Performance Management.

Figure 2.2 is an expanded view of the System Life Cycle.

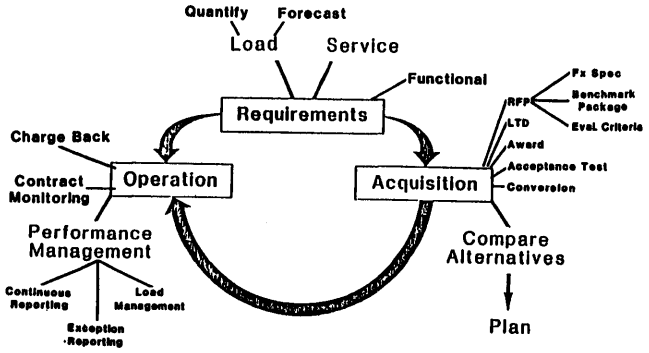

Figure 2.2

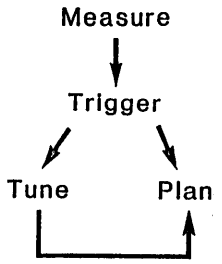
Performance Management then consists of measuring the system's service during its operating phase and comparing the observed service measurements against the planned or required service. When the observed differs enough from the planned, some action is triggered. Normally one tends to tune the set of resources in some way first to improve the overall system service. If tuning was successful, one tends to update the initial plan and continue. If tuning was not successful or possible, one tends to enter into a major planning activity usually to acquire additional resources to support the system.

Figure 2.3 represents the Performance Management process.



Performance Management

Figure 2.3

Now during the tuning process one tends to have several alternative optimization approaches suggested by the measurement data. At least conceptually one must compare these choices and select an alternative to implement. Also, during the triggered plan or re-plan process, one tends to have several alternative implementation plans from which to choose. Again, one must compare from among a set of alternatives. To get a larger perspective on the system life cycle, figure 2.4 pulls the major components together. Appendix A contains several diagrams that are referred to in the presentation.

THE SYSTEM LIFE CYCLE MODEL

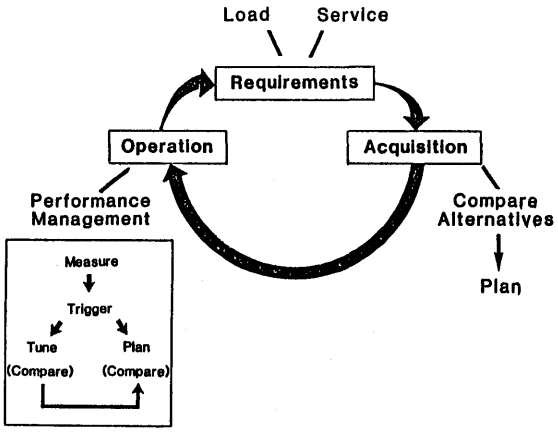


Figure 2.4

3. Benchmarking

A Benchmark is defined by Webster as a point of reference for measurement. The act of obtaining the point or point(s) of reference is defined as benchmarking.

An important aspect of benchmarking is a clear experimental design. One needs to have identified the questions being addressed, the definition of the system boundaries of interest, a representation of the load for which the system is to respond, and a means by which the load can be presented to the system under test and service data collected.

If, for example, we were comparing two processors to answer the question "which processor does the floating point operations more effectively?", then the system boundaries could be just the processor (possibly processor and memory) and the load needed to represent the floating point operations. Let us assume the load consisted of a set of floating point operations, then this set of operations would be presented to each of the processors and one would measure how long it took the set to complete. (See figure 3.1.) The operations might be presented to the system as machine instructions.

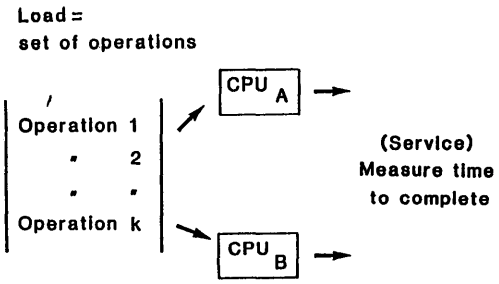

Figure 3.1

If the questions were: which system does the matrix inversion the best? Then the system boundaries change and the representation of the load changes. For example, if the matrix inversion involves using a FORTRAN program to do the matrix inversion, then, we are interested in how efficient the FORTRAN compilers are on the alternative system(s). One would tend to take the original FORTRAN program and have each system generate the compiled object code. Then one would simulate each system to measure the service by timing how long it took for each system's object code to run. The differences in the observed measured data (across system) might be because the hardware or the efficiency of the FORTRAN compiler(s) to generate good object code. As long as the original question was to determine which system did the best FORTRAN-based matrix inversion, the measured data would present a reasonable estimate.

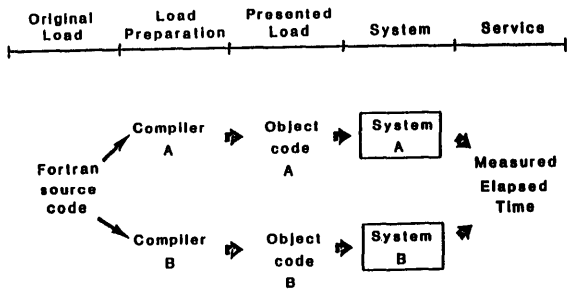

Figure 3.2

As we better understand the work that the final system is to do, we will be more able to represent the load and the means of loading and measuring the system(s). Let us assume that we have the representative workload and we are interested in determining the configuration(s) for a timesharing system. The question becomes: What system configuration will support the load (provide acceptable service) over the system's life?

This leads us to generate a set of subquestions that come from hypotheses about the system being considered. That is, knowledge about the computer system allows us to think of alternative configurations.

Question: What initial system configuration will support the load?

Subquestions:

Initial configuration

- memory needs?
- processing needs?
- storage needs?
- communication needs?
- software needs?

From these subquestions, a set of alternative initial configurations tend to be generated. It is these alternative configurations that we must obtain load-service relationships to compare these alternatives. It is a result of comparing these alternatives that we really develop the computer capacity plan.

Let us assume that several alternative configurations are proposed for evaluation. Figure 3.3 represents key alternatives that must be understood to select the initial configuration.

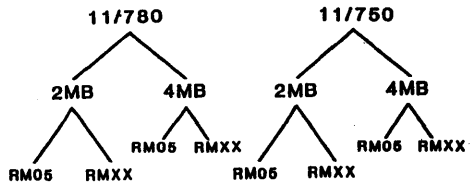

Figure 3.3

That is, to select the initial hardware configuration, we ideally need to compare eight load-service relationships (curves) as partially shown in Figure 3.4. To create the load-service relationships we must collect response time values for selected terminal levels and hardware configurations. From Figure 3.5 we see that for a single representative program that 32 "tests" might be performed to collect the desired data to make the comparison.

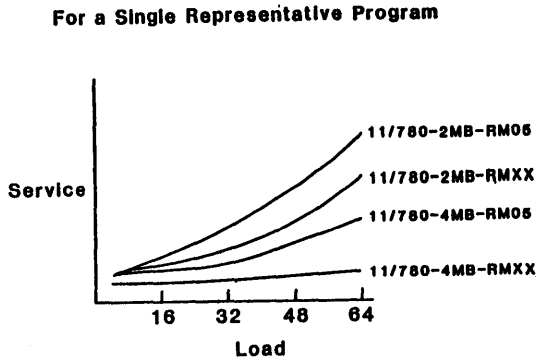

Figure 3.4

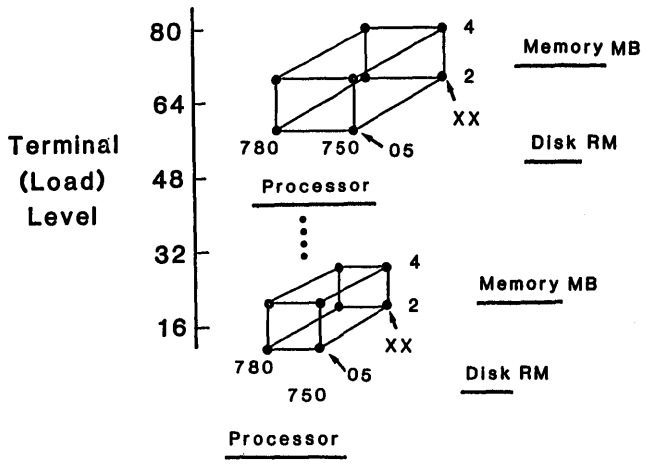

Figure 3.5

If we decide to collect this data from a live system, we might need about 32 hours of test time. We would also need a way to present the load to the system configurations under test and measure the time it took to process the load. This is usually done with an RTE (Remote Terminal Emulator).

Remote Terminal Emulation is an approach to the testing and evaluation of computer systems in which a driver is implemented external to and independent of the system being tested. The driver, called the Remote Terminal Emulator (RTE), applies a specified workload to the system such that it appears to the System Under Test (SUT) that it is connected to live terminals. The objective of remote terminal emulation is to drive a SUT in a way that is controllable, repeatable, economical and realistic. Figure 3.6 is a schematic of the flow of information in a remote terminal emulation experiment.

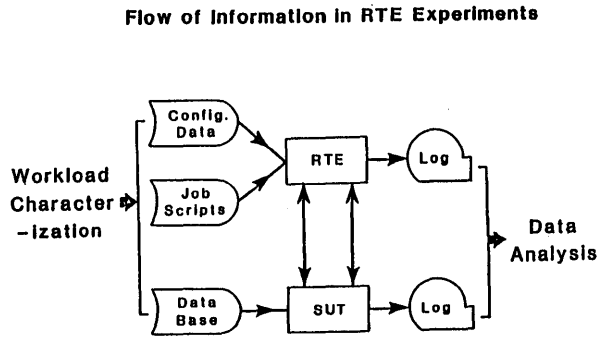

Figure 3.6

In general the workload or representative program(s), etc., must be represented in some way to the RTE so that the system under test (SUT) believes it is the real world presenting the load. This tends to be done by creating SCRIPTS that contain message text and control information. Figure 3.7 is one example of what would be included in a SCRIPT.

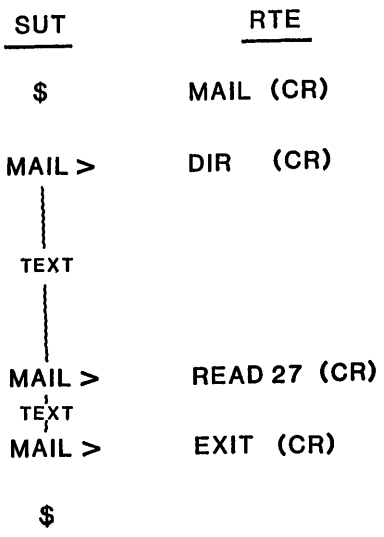

Figure 3.7

In general the SCRIPT has the information about what needs to be sent to the system under test and what it should expect. All the interactions with the SUT are time-stamped and put on a log file for later reduction and analyses. If Figure 3.7 represented a MAIL user and we ran an experiment where there were 16 such users, our RTE log file might look like Figure 3.8 if it were sorted by terminal number and time of day.

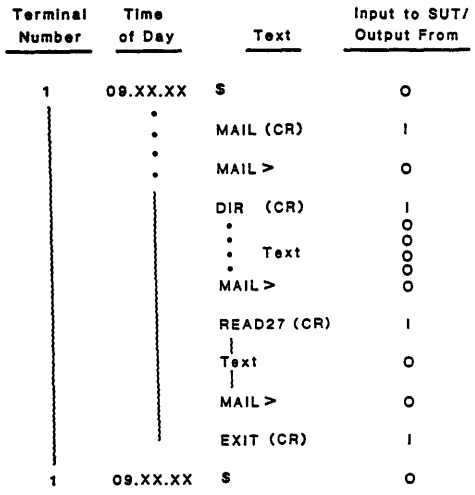

Figure 3.8

Much work has been done using RTE's and the reader is referred to [Domanski, B., "Load Driving A System," Computer Performance, Vol. 3, No. 4, Dec. 1982].

Another approach to obtaining the load service relationship is via modeling instead of benchmarking the actual system. The next section will present an overview of Modeling.

4. Modeling

A model of a system is a representation of the system that consists of a certain amount of information about the *organization* of the system, and is built to to study it. Since different kinds of questions can be asked about a system, several different types of models can be constructed. They all represent the same system, but look at the system for different purposes or they contain varying amounts of detail.

A model can be viewed as a system (here *system* is not an abbreviation of a computer system). Various models correspond to partitioning the system into different components, representing the interactions between components and its operating environment. These conceptual models play a fundamental role in evaluating computer system performance. They consist of all the information the evaluator has about the behavior and structure of the actual system. The deeper the knowledge of a system, the better the conceptual model and the easier and more successful the study is likely to be.

Characterizing the behavior of a system is often done using the concepts of state transitions.

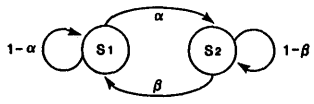

Figure 4.1

The state of the system at time *t* is defined as the values of the system parameters of interest at time t. Any variation in these values is viewed as a transition to another state, i.e., a *state transition.* A state transition model associates *probabilities* with each state transition.

A *simulation* model reproduces the behavior of the actual system over time. Its behavior in time, under stimuli that represents the actual systems environment, is observed, and performance data is collected. In this way, the simulation model is treated just like the actual system. Thus, designing experiments for simulation models is the same as designing experiments for the actual system.

An *analytic* model consists of a set of mathematical equations that are solved by following the evolution of their solutions over time. Computer systems are seen as discrete systems; that is, they evolve by discontinuous state transitions called *events.* These models include equations expressing the logical conditions under which these events occur.

Queuing Concepts and Operational Analysis

Queueing models are popular analytic models. As an example to illustrate the concepts underlying queuing models, consider a barber shop.

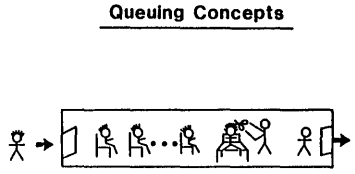

Figure 4.2

Here customers enter the barber shop, and wait until the barber is available to cut their hair. It takes some amount of time to cut their hair, after which they leave the barber shop. This is known as a single server queuing system, and is formally denoted by the following diagrams.

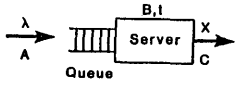

Figure 4.3

Problems analyzing these systems are all derived by making assumptions, which are testable, about the queuing model. This simple approach is called *operational analysis,* developed by Buzen & Denning (The Operational Analysis of Queuing Network Models, Computing surveys, Vol, 10, No. 3, September 1978). Appendix B contains definitions and basic formulas used in Operational Analysis.

In both the benchmarking and modeling approaches to obtaining load-service relationship there is a need to characterize and forecast the load. The next section presents an overview of load characterization and forecasting.

5. Load Characterization and Forecasting

The objective in load characterization is generally to represent in some way the load that is required to obtain a load-service relationship. That is, represent the load in enough detail to used in either a benchmarking or modeling approach to obtaining the load-service relationship.

The load on the system can be represented in some abstract way by collecting some resource or functional oriented data and reducing it to model the load. Here, resource oriented work units would be designed to consume system resources such as CPU, memory, I/O, etc. Functionally oriented work units are those that do some predefined function such as FORTRAN compile, text-edit, electronic mail, and even DB query or update. Representing the work units in this way is sometimes referred to as creating synthetic workloads. Of course, one could combine the functional and resource oriented approach in an attempt to create synthetic workloads for benchmarking.

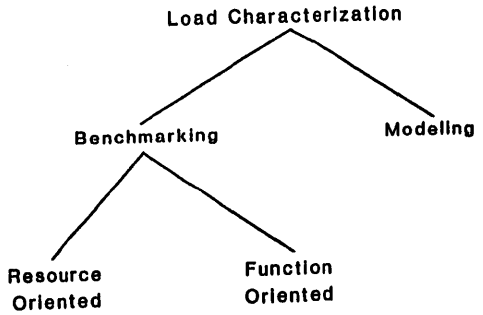

Figure 5.1

Several tools can be used to help create the synthetic workload(s) including hardware/software monitors, log files, survey data and even console logs. These tools might interrelate in the following way (see figure 5.2).

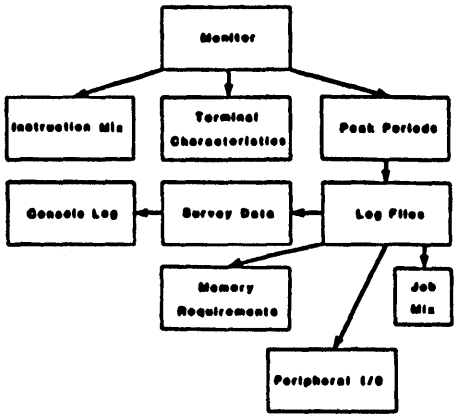

Figure 5.2

The statistical approach known as *clustering* has been used successfully to identify a small set of resources consuming work units. The reader is referred to work by Artis for more information [Artis, H. P., "Capacity Planning for MVS Computer Systems," D. Ferrari, ed., Performance of Computer Installations, North Holland Publishing, 1978]. Appendix C contains additional diagrams that will be used in the actual presentation.

6. Performance Management

Introduction

THE SYSTEM LIFE CYCLE MODEL

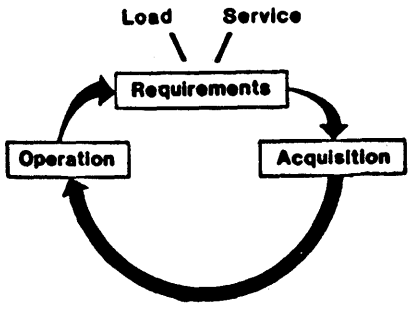

Figure 6.1

The System Life Cycle Model has previously been shown to accurately reflect the different phases of a computer system, from inception through actual modification and change. The requirements phase involves the specification of functions and perhaps even the behavior of a proposed computer system. For example, the requirements for a time sharing based application would specify the different types of work that are to be performed, e.g. inquiries about a customer, and they might also specify the expected response time for each different type of work. Let a work unit be defined as the accomplishment of some function(s) during some period of time, where a work unit is a task in a batch environment, and a work unit is a transaction in a timesharing environment. Given a list of required work units a system will do, an analyst moves onto the acquisition phase of the model.

Acquisition involves transferring the requirements into a set of hardware and software components to be obtained, which ultimately, will provide the functionality and behavior specified in the requirements.

Once the set of components are derived, an analyst goes thru a somewhat detailed phase of evaluating different alternatives (i.e. configurations) that are available, to derive that set of components that (1) is the most cost effective and (2) satisfies the initial requirements.

As a direct outgrowth of the acquisition phase, the analyst is, in essence, deriving a capacity management plan. This consists of three elements:

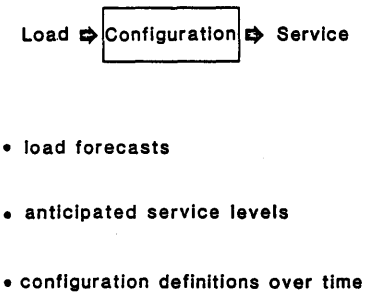

Figure 6.2

These elements address the primitive model of a computer system, namely the expected load on the system over time, the expected level of service the system provides over time, and the different configurations of both hardware and software over time that will handle the expected load.

Comparing alternatives in the acquisition phase of the system life cycle model will provide different load/service relationships for each unique configuration. Using these relationships, the analyst can define control limits for the load and service levels.

Thus, if load is increasing (or if service is degrading) at a rate faster than expected, changes to the capacity management plan should be reviewed. For example, a new cpu whose need is expected one year from the initial operation of the system, may be required after only six months, because of either a higher load than expected or because of a lower level of service than what is required.

By measuring the system regularly, the analyst can compare actual load/service levels with control limits established from the acquisition phase. Thus, a performance management plan is conceived, within the operations phase of the system life cycle model.

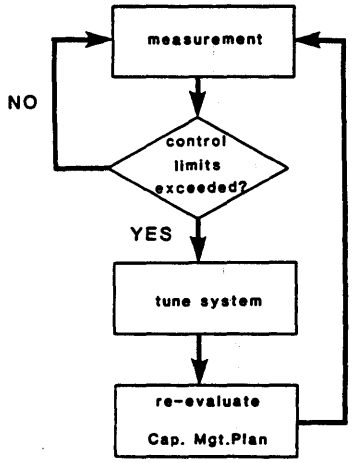

Figure 6.3

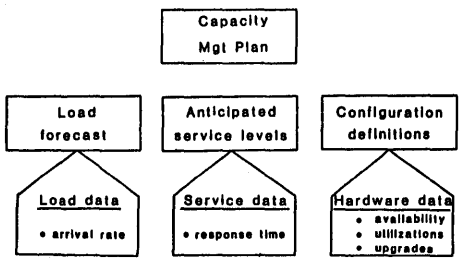
Elements of a Capacity Management Plan

Before measurement of the system, it is assumed that a capacity management plan has been defined. As stated before, it is composed of 3 elements: a load forecast, expected levels of service, and a configuration definition over time. "Levels" of load and service are defined as control limits. Here, the problem of identifying the data items that are used to compare against control limits is addressed.



Elements of a Capacity Management Plan
Figure 6.4

Load forecasts are composed of arrival rates for the different work units entering the system. For example, the number of FORTRAN compiles in a given hour, or the number of arrivals of a specific time-sharing transaction in a day. Arrival rates for each unique work unit entering the system could later be compared against control limit values for these work units.

Service levels are composed of processing or throughput rates for the different work units acted on by the system. For example, the number of FORTRAN compiles completed in a hour, or the number of completions of a specific transaction in a day. Service level data items may also address the response time of a work unit. For example, control limits for specific time-sharing transactions may have a maximum response time of ten seconds, and a minimum response time of three seconds. A natural question is posed here; namely, why worry about not achieving a minimum response time? If this is the case, one may want to delay any planned configuration changes e.g., hardware upgrades.

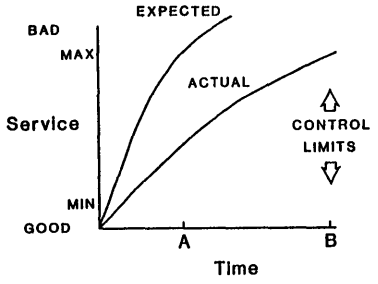


Figure 6.5

By observing that the minimal response time is being achieved later, this may imply that time A, the time at which a hardware upgrade is to be made, is too early. It may be possible to delay the upgrade until time B. All these questions are addressed in greater detail when discussing the re-evaluation of the capacity management plan.

Hardware data is composed of three components: availability information, resource utilizations, and component upgrades/replacements.

Availability information analyzes the time between component failures, and the time required to repair the failed components. Though intuitively obvious, it is worth stating that during a component repair period, little, if any, use of the system will be made. Thus, it is important in defining the times at which hardware upgrades will be made, that mean time to repair and mean time between failures be carefully considered. Vendors usually supply this information by component.

Resource utilizations are measures of how much (little) hardware components are being used. For instance, cpu 70% busy, disk drive 1 is 20% busy are examples of resource utilizations. The resources of a computer system fall into three classes: cpu, memory, and I/O. These utilizations are traditionally used to spot "bottlenecks" in system throughput, resulting in a degradation of service. Control limits for resource utilizations are usually established by "rules-of-thumbs"; that is, intelligent guesses are made based upon previous observations of similar systems using these components.

Data used in a capacity management plan can be partitioned into two classes: low versus high levels of resolution. Low resolution data items correspond to viewing load, configuration, and service with respect to the entire system. For example, low resolution load data would be number of tasks arriving to the configuration in a certain time, perhaps being further classified by type of work unit. Examples of low resolution data items are in Figure 6.6.

Low Resolution Data

Load	Configuration	Service
• # of FORTRAN compiles	• System mttr, mtbf	• 4000 transactions per day
• # of EDITs	• CPU 70% busy	• Average response time of 6 seconds

Figure 6.6

Given appropriate measurement tools and reports, the performance management process is summarized in Figure 6.7. Measurement tools like software monitors, hardware monitors, accounting files and system "snapshots" provide the necessary measurements. Graphic as well as tabular reports are necessary to analyze the status of a system. Boolean data analysis techniques have been successful in problem determination.

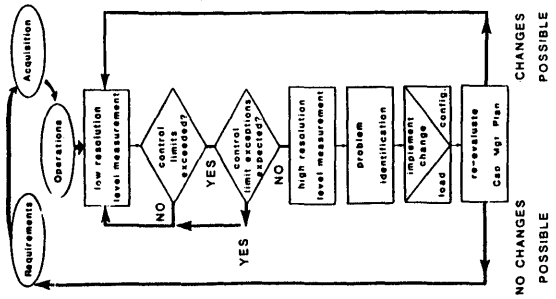

Figure 6.7

7. Summary

This tutorial introduced the reader to a variety of techniques used in the capacity planning/performance evaluation process. Where possible, references are given to direct the reader to more detailed sources of information.

8. Bibliography

It has been our experience that at the conclusion of the presentation, the audience requests additional information about many of the topics presented. Rather than providing a detailed bibliography, we have attached a list of papers by topic that we believe would be beneficial to the interested reader.

Four basic quantities typify this system

T = Length of observation period

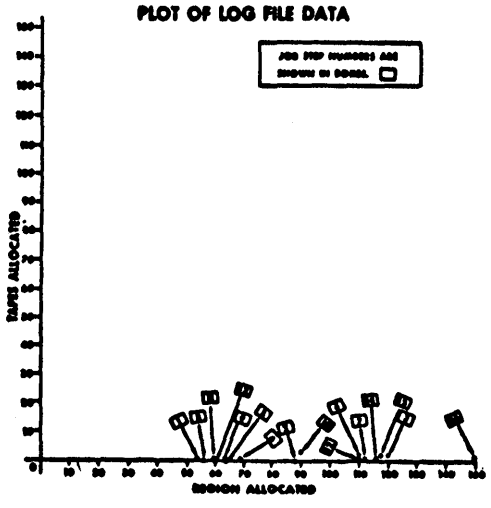
A = # of arrivals during period

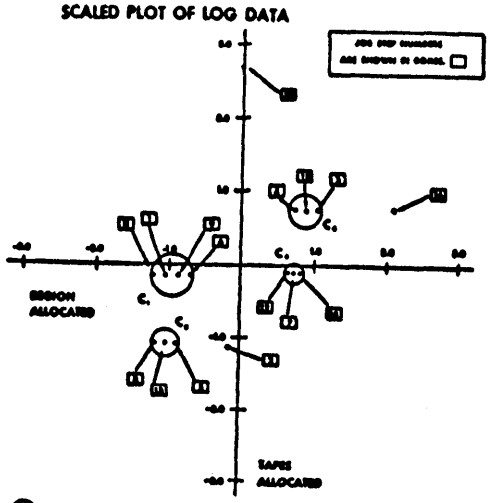
B = Total time system is busy

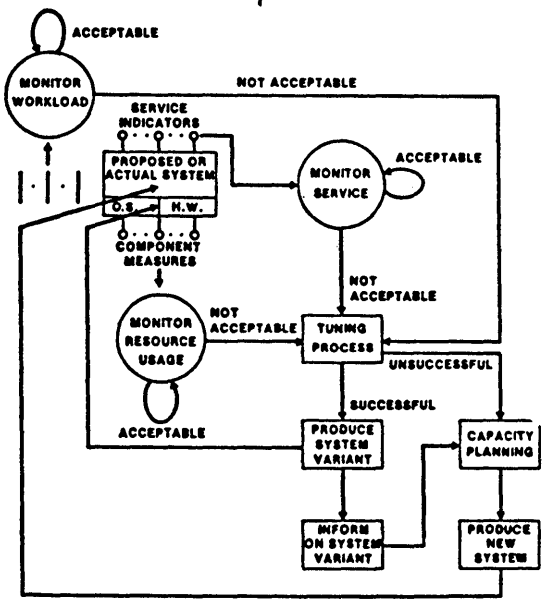
C = Number of completions occuring during period

Four important derived quantities also exist

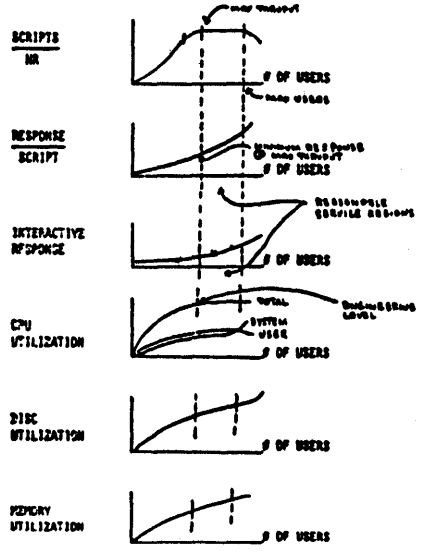
$\lambda = A/T$	Arrival rate
$X = C/T$	Output rate
$U = B/T$	Utilization
$S = B/C$	Mean service time







S = F(L,C)	PERFORMANCE PROBLEMS
C = G(L,S)	CONFIGURATION PLANNING
L = H(C,S)	CAPACITY EXHAUST



Fundamentals of Statistical Workload Forecasting

H. Pat Artis
Performance Associates
Vienna, VA 22180

Abstract: This tutorial will examine a variety of statistical methods that can be used to forecast computer workloads. The tutorial will discuss simple regression, multiple regression, and time series analysis techniques as well as statistical metrics for evaluating the goodness-of-fit of the proposed models.

1.0 Case 1: Time Based Regression

Perhaps the commonly used forecasting tool by performance analysts is linear regression. Linear regression develops a model based on the assumption that a dependent variable, *Y*, is related to an independent variable, *X*, as a linear function of a constant, *b*, and a slope variable, *m*. Time based linear regression is the most common application of this technique. To illustrate the strengths and pitfalls of the approach, a time based regression model of weekly average CPU utilization will be developed. This exercise will be used to introduce:

- residual values,
- R-squared, the coefficient of determination,
- F and t values,
- estimates of the standard error, *SE* and mean squared error, *MSE*,
- and confidence limits and prediction intervals.

One of the limitations of linear forecasting will be illustrated by introducing an example of a *step function decrease* that occurs when a processor is upgraded.

2.0 Case 2: Using Dummy Variables

The second case study will demonstrate how dummy variables can be used to address the problems of step function increases (decreases) in the dependent variable. Dummy variables, column vectors comprised of 0's and 1's, allow multiple regression models to treat one or more step functions in the historical data series as constants that are added or subtracted from the Y observations by the model prior to the development of the linear model.

While dummy variables allow multiple regression models to address step function changes in historical data series, they cannot address the problems introduced by apparently random or periodic variations in the historical data. Approaches to these problems will be discussed in the following sections.

3.0 Case 3: Multiple Regression Applications

When a single application dominates a system, or an interval during the day, the underlying business activities that drive the application often cause significant variations in the day-to-day utilizations recorded for the system. To address such environments, the analyst must work with the application's users to identify the business elements that drive the application's consumption of resources. **If the user can forecast these business elements,** then the analyst can employ stepwise multiple regression to develop models that forecast future resource requirements based on the user's estimate of the business elements. **It should be noted that the analyst can never assure that business element forecasting will work. Even if a historical relationship exists between the business elements and resource utilization, there is no guarantee that the users can accurately predict the business elements in the future.**

The case study will introduce an online order entry system with significant weekly and monthly variations in resource utilization. After the model has been developed, the use of **accounting rate table elements** to translate the predicted resource requirements into future budget dollars will be discussed.

4.0 Case 4: Time Series Applications

The final case study will introduce the use of time series analysis to address workloads that have repeating periodic variations in their resource demands. Simply described, time series analysis techniques repeatedly subtracts various periodic (i.e., *seasonal*) functions from the prior observations until the the remaining historical series of observations can be modeled by a linear regression model that represents the long term growth rate of the application. Forecasts are developed by first predicting the long term trend and then adding the periodic functions back into the predicted values.

5.0 Remarks

While statistical workload forecasting techniques provide the analyst with powerful tools for estimating future demands, they can never replace a detailed understanding by the analyst of the users' requirements and future business plans. Rather, these tools should viewed as a means of better understanding problems... not providing a panacea for their solution!

A CAPACITY PLANNING/QUEUEING THEORY PRIMER OR HOW FAR CAN YOU GO ON THE BACK/OF/AN/ENVELOPE?

Ethan D. Bolker
BGS Systems, Inc.

ABSTRACT

Most of the benefits of capacity planning for computer systems come from applying common sense principles to easily understood (if not easily measured) data. If you can estimate business growth you need only simple arithmetic to figure out how busy your computer will be. But sometimes the fact that the system is subtle does matter: it's hard to predict response times. Then you must use mathematics (instead of arithmetic) or software which knows some - typically, a package incorporating a queueing network model of your computer system. You can (and should) think of the package as a black box whose sophisticated mathematical contents need not concern you. In this top down view such products are worth what they cost because they're cost effective. But from time to time you may want to peek into the box - to satisfy a healthy curiosity, or to convince yourself that the mathematics there makes sense, so that you can use its output with confidence or explain its function to your manager. (But exercise care - you can sell your manager your services only by showing why s/he needs them, not by describing the mathematical magic which helps you do your job.)

This introductory tutorial moves from simple capacity planning arithmetic to a glimpse of queueing theory - how it solves relevant problems, and why it's for a less technical audience too - managers, secretaries, planners' husbands and wives - anyone who wants to know a little about how a queueing theory package earns its keep. It's essentially what I tell my friends (outside the industry) when they ask what I do.

1. THE NUMBERS GAME

Imagine that you are managing a bank's Cash Machines, and that you know something about how much business a particular machine will be called upon to do. To be specific, suppose you anticipate that

30 customers will visit the Machine in an hour.

Each will use it for a minute and a half.

You need answers to two questions

How busy is the Cash Machine?

How long do customers wait?

Before we answer them, we can note a pattern. We know about customer behavior: how often they arrive (30 customer/hour) and how much service each requires (1.5 minutes/customer). What we need to know depends on how the customers interact with the system: the percentage of time the Machine is busy and the average customer wait.

You can measure all of these numbers by hiring a High School student to watch the Machine, count customers and time their transactions. Or you can program the Cash Machine to keep track of the first three while it does the business it was bought to do, and program the door to the room in which the Machine lives to find the last one. That's "Computer Measurement". But CMG members don't just measure, they plan. In a planning scenario the first two numbers - the customer arrival rate and the service each customer requires - aren't measured, they're part of the business forecast. The planner needs to predict the second two: how busy the machine will be, and the waiting times. That's where mathematics come in.

Simple arithmetic tells us about the Machine:

$$30\ \frac{\text{customers}}{\text{hour}} * 1.5\ \frac{\text{minutes}}{\text{customer}} = 45\ \frac{\text{minutes}}{\text{hour}}$$

The Cash Machine is in use for 45 minutes each hour, so it is busy 75% of the time. The underlying algebra is quite straightforward, and not all mysterious. It even has a name - the Utilization Law:

arrival rate * service time = utilization

(when the named quantities are expressed in appropriate units).

2. THE WAITING GAME

The second question is harder. Let's reflect on it a bit. Suppose the 30 hourly customers came at scheduled times 2 minutes apart, and that each customer was an average customer and did just 1.5 minutes of banking. Then no one would have to wait, and the Cash Machine would rest for 30 seconds between jobs. But common sense and our own banking experience tell us these are unrealistic assumptions. Customers come one every two minutes on the average. But sometimes there will be long idle times; sometimes several customers will arrive nearly at the same time. And although on the average customers spend 1.5 minutes at the Cash Machine some are just getting FastCash while others do a week's worth of banking all at once. The more variability of this kind the more time customers will spend waiting while someone else is using the Cash Machine - even though the average arrival rate and average service time stay the same. Predicting the response time - the average time spent (waiting and working) is harder than calculating the utilization of 0.75. The formula which helps us out is

$$\text{response time} = \frac{\text{service time}}{1 - \text{utilization}}$$

In our example, since the Cash Machine is 75% busy, and the service time is 1.5 minutes,

response time = 1.5/(1-0.75) = 6 minutes

The formula we've just used is not nearly as straightforward as the Utilization Law. To discover it requires some mathematics at about the college (Calculus) level. Fortunately, we needn't discover it - we need only understand it. And to see why it's reasonable all that's required is some High School algebra, which we'll see in the tutorial, and Little's Law, which says that

$$\text{arrival rate} * \text{response time} = \text{Average number of customers at the Cash Machine}$$

Don't worry. This is not an infinite regress. In the tutorial we'll see where Little's Law comes from, and so assemble all the pieces.

To use Little's Law in our example we must make the units match. The service and response times are measured in minutes. The arrival rate, 30 customer/hour, is 0.5 customers/minute. Then the average number of customers at the Cash Machine is 0.5 * 6 = 3.

The response time calculation takes some getting used to. People often find its predictions counter intuitive. For example, even though our Cash Machine is idle 25% of the time, so that 1/4 of the arriving customers need not wait at all, on the average a new arrival will see 3 people already at the Machine (including the one currently using it), and will use 6 minutes of his time to do 1.5 minutes of banking business. He waits 4.5 minutes, for the 3 customers ahead of him in line.

The answers to our two questions sharply focus the capacity planning dilemma you face as the Cash Machine Manager: dissatisfaction both because

the 75% utilization is too low.

the 4.5 minute wait is too long.

3. WHAT IF?

The response time calculation vividly quantifies the compromise you must make. It shows you exactly how decreasing your unhappiness with one of the answers will increase it with the other.

For example, if you expect Cash Machine customers will soon be arriving at a rate of 36 rather than 30 per hour (a 20% increase) then Machine utilization will increase to 90% (which makes you happy) but the response time will increase to 15 minutes, of which 13.5 is spent waiting. This is three times the current 4.5 minute wait, which makes you - and the customer - unhappy.

So far all the arithmetic fits on the back of an envelope.

You know your customers will not tolerate those long waits (they can't appreciate the fact that you like to keep the machine busy) so you decide to install a second machine next to the first.

What are the answers now to the two central capacity planning questions? Will each machine be busy 45% of the time? Will the average wait be half of 13.5 minutes? Again, the first question is easy; the second is hard.

Each of the two Machines will indeed be in use just 45% of the time. That follows from the Utilization Law. But the average number of customers present at the pair of Machines turns out to be a mere 1.3, and, on the average, an arriving customer will wait less than two minutes before his turn comes. We will briefly discuss the mathematics which produces these numbers. The resulting formulas are still simple enough to evaluate with a calculator, but showing where the formulas come from is a little too complicated for an introductory tutorial.

4. PARALLEL PROCESSING

Moreover, if we install the second Cash Machine and measure waiting times we will discover that our predictions are too optimistic (and that's the wrong direction in which a planner should err.) To understand why we must think more carefully about what happens when both Cash Machines are in use.

Let us analyze the 1.5 minutes each customer spends standing at the lone Cash Machine before we install the second one. Some of that time, say, 1 minute, is time spent reading the instructions on the screen, deciding what to do, removing cash or filling out the envelope to hold the deposit. The remaining 0.5 minute is the time it takes the computer behind the Cash Machine to process the transactions.

To study that half minute, first imagine the bank in the days before computers, when the Cash Machines were tellers. The teller took the customer's request to the bookkeeper, (suppose there was just one bookkeeper) who asked a clerk to bring him the customer's account record from the appropriate filing cabinet. When the record arrived the bookkeeper did the necessary arithmetic, sent the teller back with an answer for the customer and sent the clerk back to file the updated account record. This sequence of jobs, which used to take, say, 3 minutes, accounts for the 30 seconds we measure now when computers do the bookkeeping and record management.

Look how wasteful it was (and is). The bookkeeper was (presumably) better paid than the clerk and the teller, but was idle most of the time, since she did her arithmetic in a small fraction of the 3 minutes of processing time. The retrieval and refiling of the record took up the rest. That's why it would be economical to hire several tellers and clerks to keep one bookkeeper busier.

But then each customer would spend more than 3 minutes at the teller's window. The time spent actually working on his business would be the same, but customers' jobs could get in each others' way. Even though several tellers could serve several customers simultaneously the bookkeeper worked on only one record at a time. And only one clerk could use a filing cabinet at a time. (Although two clerks could get accounts from separate filing cabinets while the bookkeeper worked on a third account.) Therefore, some of the time one customer's work would have to wait while the bookkeeper was busy with another's, or while the right filing cabinet was in use. These internal delays account for the time each customer waits in excess of the 3 minutes of real processing his job requires. Moreover, our analogy works even when the teller is a Cash Machine and the bookkeeper and file cabinets have been replaced by a computer. The computer can process only one job at a time at the CPU (the Central Processing Unit, which is the computer's bookkeeping hardware) and can look up only one account at a time on each disk (the computer equivalent of a file cabinet), although it can look up one account while it is processing work for another. Therefore, as before, some of the time one customer's work will have to wait while another's is being done. Similarly, when there are two Cash Machines active simultaneously the computer needs more than 1/2 minute to process each customer's work. Just how much more is the crucial question.

5. BLACK BOXES

We will conclude the tutorial by discussing how one might calculate how long each job will wait at the disks and at the CPU and thus predict how long the average customer will have to spend between the time he arrives to wait for the Cash Machine and the time his banking is complete. The calculations resemble the ones we have just looked at but they are so much more complicated that they can be done rapidly and economically only by a computer program - a software package which knows queueing theory. As a planner, you speak to the package in the language you use to describe your computer system - not the mathematical language it uses internally to predict how the system will behave. It answers you in your terms too, telling you about utilizations and response times. You use those numbers to plan computer capacity to cope with expected business needs. And now, when you do, you'll know a little more about where those numbers come from.

HIGH-PERFORMANCE PROCESSOR DESIGN

Bill McCormack, Jay Michlin, Larry Brisson, and Andy Martin
Amdahl Corporation

ABSTRACT

One purpose of large mainframe computers is to execute machine instructions in the shortest time possible. In this paper, we discuss some of the factors introduced into processors that help achieve this purpose. In particular, we explain how computer designers use parallelism, caches, and pipelines to make modern mainframe computers faster. We also discuss some of the factors that limit the effectiveness of these features.

INTRODUCTION

Processor design involves translating a high-level view of the design into a detailed description of the implementation. In this process, designers have some flexibility and must make many decisions that have reliability and performance implications. In this tutorial, we discuss some of the design decisions and the impact they have on processor performance.

In the next section, we describe the performance metrics we use in this paper. We also discuss some of the reasons for using these metrics. Following that, we discuss the effect that caches, parallelism within the execution of a single instruction, and processor pipelines have on performance. The use of these and other design features greatly improves the performance of a processor.

To show the performance effects, we break down the execution of a typical instruction into the steps that must be performed and the approximate number of processor cycles required for each step. We then show the reduction in processor cycles used as a result of introducing caches, parallelism, and a pipeline. Finally, we discuss some of the factors that limit the effectiveness of these features.

MEASURES OF PERFORMANCE

Many articles have been written debating the merits of various performance measures. Two measures frequently discussed are internal and external throughput rates [1]. Without getting into that discussion, we can say that both measures are valid when used in context, and both are affected by factors other than just the processor. For example, real storage, I/O bottlenecks, and the number of processors all affect these throughput rates.

When designing the processor itself, one must focus on a measure that reflects only the processor. Designers commonly use one of the following two measures: mean instruction execution rate (IER, usually stated in millions of instructions per second or MIPS) and average number of cycles per instruction. We discuss both of these and their relationship.

IER is widely used (and abused) as a measure of performance. As discussed by MacDougall [2], the execution rate of applications can vary greatly. In addition, changes to the architecture (e.g., using microcode to replace functions previously performed by the operating system) or changes to the code in the operating system can cause the mean instruction execution rate to decrease, but the system throughput to increase [1]. Thus, in most customer environments, instruction execution rate is an inappropriate performance measure. However, IER is a useful measure for comparing different processors or processor designs of the same architecture.

MIPS is the number of instructions executed per second; thus, if we take the reciprocal, we get the average time per machine instruction in microseconds or nanoseconds per instruction. (LaMaire and White [3] use nanoseconds per instruction in their study.)

Average time per instruction can be further broken down into its two components: the average number of machine cycles per instruction (I) and the cycle time of the machine (C) in microseconds. Thus, we can write

$$MIPS = 1 / (C * I).$$

Processor designers usually treat the two factors, C and I, separately. A cycle is the basic unit of time for the processor. The technology available largely determines the cycle time; current cycle times for large mainframes range from 10-20 nanoseconds. One reason for treating the two factors separately is that the cycle time of the processor may not be finalized until late in the design of the machine. Thus, the designers work with a cycle time goal.

Some instructions can be completed in one cycle, but many cannot. The number of cycles required for each instruction depends on the instruction, its operands, "nearby" instructions, and the design of the processor. Thus, the cleverness of designers is reflected in the number of cycles per instruction.

Just like IER, the average number of cycles per instruction can be abused. If only very simple instructions are executed, then it is possible to have a low number of cycles per instruction (and hence a high IER). The average number of cycles per instruction also varies from application to application and environment to environment. Thus, for the same machine, one often produces different estimates for the average number of cycles depending on the environment. These estimates are based on the types and frequencies of the instructions found in each environment. MacDougall [2] discusses a methodology for these estimates.

In the remainder of this paper, we concentrate on the number of cycles per instruction. However, for our examples we assume a cycle time of 15 nanoseconds (0.015 microseconds); this assumption allows us to translate the cycles per instruction into MIPS.

TYPICAL INSTRUCTION EXECUTION

In Figure 1, we show the steps required to execute a representative machine instruction. Beside each step, we list the approximate number of machine cycles needed for that step.

	Cycles
Fetch Instruction from Memory	20
Decode Instruction	1
Generate Address of Storage Operand	1
Translate Address	1
Fetch Operand from Memory	20
Read Register Operand	1
Perform Arithmetic/Logical Operation	1
Write Result (Usually to a Register)	1
Compute Next Instruction Address	1
Total:	47

Figure 1: Typical Instruction Execution

First, we must fetch the instruction from the physical memory of the processor. The memory cycle time (time to get something from memory) is typically much longer than the (processor) cycle time; here we assume it takes 20 cycles. Then, we must decode the instruction to determine what is to be done (e.g., an ADD, a BRANCH). The next three steps are used to fetch the operand from memory. First, we generate the virtual address of the operand. Then, we must translate the virtual address into a physical address (here, we assume a system with virtual addresses). Then, we can fetch the operand from memory.

We assume that the second operand is in a register; thus, no memory access is required for this operand. Finally, we are ready to perform the operation itself. In this case, we assume a simple operation that can take place in one processor cycle. Examples of such operations might be an integer add, a load, or a store. Many instructions take more than one cycle; examples include floating point arithmetic operations and moving many bytes of data.

After execution, we assume the result is stored into a register. Lastly, we determine the address of the next instruction to be executed so we can repeat these steps.

In total, it took 47 cycles to complete a simple instruction involving a one-cycle operation. To translate this into MIPS, we apply the formula stated earlier: MIPS = 1 / (C * I), where C = 0.015 microseconds and I = 47. Thus, this processor executes at about 1.4 MIPS! Current large mainframe processors are typically much faster than 1.4 MIPS. In the next few sections, we discuss some ways to reduce the average number of cycles per instruction.

CACHE STORAGE

In our example, over 80% of the cycles were required to fetch the instruction and operand from memory. Thus, the first way to reduce the average number of cycles is to reduce the cycles spent accessing memory. Commonly, a cache or buffer is used so that very few processor cycles are needed to access something from storage. (The terms cache and buffer are both used widely; in this paper we use the term cache.)

Cache is high-speed storage located between the CPU and main storage. Cache speeds up memory accesses but is transparent to the programmer and operating system. In most multiple processor systems, each processor has its own cache. The technology for the cache is much faster and more costly than that used for the processor memory. Smith [4] discusses caches in detail.

The cache size of current processors is less than 100 kilobytes or about one-thousandth the size of the main memory on processors. Cache sizes and implementations differ among manufacturers and even among processors. For example, each processor of an Amdahl 5890 [5] has two caches: a 32-kilobyte cache for instructions and a 64-kilobyte cache for operands. Each processor in an IBM 3090 [6] has a cache of 64 kilobytes that is used for both instructions and operands.

Typically, in supervisor state, we can expect about 19 out of 20 memory requests to be found in the cache; thus, a "cache miss" occurs only 1 time out of 20. For problem state, cache misses are even less frequent. If we assume the two memory requests in Figure 1 are found in the cache and a cache access takes only one cycle, then we reduce the number of cycles required for the instruction from 47 to 9. Translating this to MIPS, we have improved the execution rate of the processor from 1.4 to 7.4 MIPS.

PARALLEL OPERATIONS

By adding a cache, we improve the processor's performance by a factor of about five, but we still have a processor that is slow by today's standards. The next design improvement is to execute some of the steps in parallel. The steps we are describing take place in each processor. Figure 2 shows the same steps as Figure 1, only we have arranged them in a diagram that shows the actual order in which the steps must be performed. Figure 2 is similar to a Program Evaluation and Review Technique (PERT) diagram often used in planning a project.

The first two steps must be completed in order: fetch the instruction and decode it to determine what is to be done. Once we have decoded the instruction, we can generate the address of the operand and at the same time prepare to read the register operand. After the operand address is generated, we can perform a number of steps in parallel.

First, the address is a virtual address; thus, we can begin translating the virtual address into a real address. We can also generate the address of the next instruction. Figure 2 shows the storage operand being fetched while the translation is in progress. These two steps can take place concurrently because we assume the cache is accessed using the virtual address.

After the operand fetch is completed, the arithmetic or logical operation is performed. When the operation is completed, the result is written into the register. We have already generated the next address, so the process can begin over immediately. Before determining the improvement that this parallelism achieves, we should discuss the address translation step in more detail.

Generally, when we use the virtual address to access the cache, we fetch the correct bytes. The address translation (or address validation) step goes on in parallel and determines whether or not we accessed the correct cache entry. If the correct bytes were fetched, then execution can begin; otherwise, the proper operand is fetched. The address translation is invisible to the program and the operating system, and, typically, the cycle needed for address translation is eliminated.

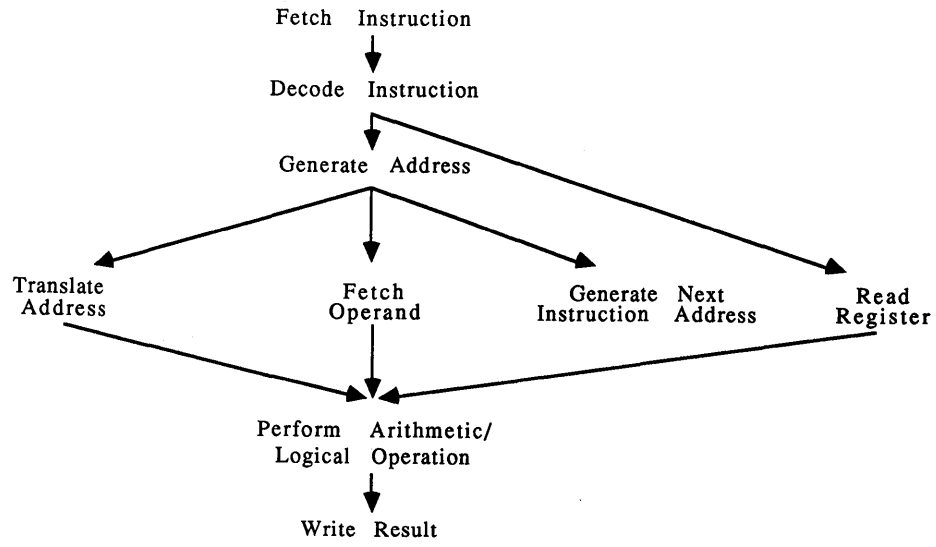

Figure 2: Parallel Operation of Instruction Execution

Thus, by using some parallelism, we effectively eliminate three cycles: the cycles needed to translate the address (1 cycle), read the register operand (1), and compute the address of the next instruction (1). The number of cycles per instruction is down to 6; thus, the execution rate is now about 11.1 MIPS.

INSTRUCTION PIPELINES

The final step in our process is to add another form of parallelism: a pipeline. We should think of a pipeline as an assembly line; for example, a traditional automobile assembly line. As the frame of the car moves along the line, different steps are performed until the car reaches the end. At any point in time, many cars are being worked on; but each is in a different stage of completion. As long as everything functions properly, completed cars should come off the assembly line regularly.

A processor instruction pipeline is very similar. An instruction moves through the pipeline, and at each stage the necessary steps are performed. After every cycle, each instruction moves to the next stage. Thus, if nothing goes wrong, one instruction will complete every cycle. Pipelines are used in large mainframes such as the Amdahl 5890 and IBM 3090 series [5,6]. Again, each processor has its own pipeline.

Figure 3 shows a pipeline with six stages. The six stages correspond to the six crucial phases in Figure 2. Each phase in Figure 2 takes only one cycle; thus, after every cycle, every stage is complete, and all instructions in the pipeline move forward. To explain Figure 3, we can describe the progress of the first few instructions as follows: At the end of cycle 1, instruction 1 has been fetched. At the end of cycle 2, instruction 1 has been decoded and instruction 2 has been fetched. At the end of cycle 5, instruction 1's operation has completed, instruction 2 has its operand, and instruction 5 has just been fetched.

Beginning with cycle 6, an instruction completes every cycle: instruction 1 finishes after cycle 6, instruction 2 after cycle 7, etc. Once the pipeline is "full," the processor can finish one instruction every cycle; thus, the average number of cycles per instruction is just 1. Translating to MIPS, we have a single processor capable of executing almost 67 MIPS!!

PIPELINE DELAYS

Obviously, processors don't achieve 67 MIPS consistently; we discuss some of the reasons in this section. To achieve 67 MIPS (one cycle per instruction) means no pipeline delays can occur; that is, every stage in the pipeline takes only one cycle and nothing "goes wrong."

	Pipeline Stages					
Time	Fetch Instruction	Decode Instruction	Generate Address	Fetch Operand	Perform Operation	Write Result
1	1					
2	2	1				
3	3	2	1			
4	4	3	2	1		
5	5	4	3	2	1	
6	6	5	4	3	2	1
7	7	6	5	4	3	2
8	8	7	6	5	4	3

Figure 3: Instruction Pipelines

The simplest pipeline delay occurs when some instruction cannot be completed in one cycle (e.g., moves, divides). When a delay occurs (e.g., in the *perform operation* step), all instructions following that operation must wait. Again, the analogy to an automobile assembly line is useful: all other stages (workers) are idle until this stage can be completed and the pipeline restarted.

Figure 4 shows the same pipeline as Figure 3; however, now we assume that the execution of instruction 2 takes three cycles. For two cycles, no instructions can move in the pipeline. The effect of this delay is seen at Times 7 and 8, when no instructions finish.

A number of other pipeline delays can also occur. In our example, we assumed that all memory accesses were found in the cache and fetched in one cycle. We also assumed that the virtual address used to access the cache for the storage operand always accessed the right cache entry. If any of these were not true, delays would occur.

The final delay we wish to discuss is commonly called a pipeline interlock. Basically, we are referring to delays in the pipeline caused by other instructions in the instruction stream. Interlocks depend largely on the actual sequence of instructions executed, and not just on the frequency of the instructions. An example of a code sequence causing an interlock follows:

```
A  R1, X
L  R2, 0 (R1)
```

The first instruction adds the contents of location X to Register 1 and writes the result in Register 1; the second instruction uses the contents of Register 1 to determine the address to be loaded in Register 2. MacDougall [2] calls this type of interlock a "generate interlock."

The key is that the second instruction is unable to generate its (operand) address until the first instruction completes. Figure 5 shows the pipeline in this situation. After decoding the second instruction, the instruction cannot proceed to generate the address until the ADD operation is completed. Thus, delays (or holes) appear in the pipeline, and no instruction completes in some subsequent cycles.

Figure 5 actually shows more than just the delays; it also shows a common trick used to reduce the amount of delay. The address generation step begins after the *perform operation* is completed, but before the result is written to Register 1. The processor can recognize that a subsequent step in the pipeline needs the result of the *perform operation* step. Thus, when the operation is completed, a special data path sends the result to the needed step as well as to the result register. This procedure eliminates one cycle from the delay. This type of trick is commonly called a "bypass."

In the design of large processors, saving cycles using pipeline bypasses can greatly affect the performance of a processor. Numerous interlocks have been identified; MacDougall [2] discusses many interlocks and some of the bypasses used to eliminate them or reduce their effects.

	Pipeline Stages					
Time	Fetch Instruction	Decode Instruction	Generate Address	Fetch Operand	Perform Operation	Write Result
1	1					
2	2	1				
3	3	2	1			
4	4	3	2	1		
5	5	4	3	2	1	
6	6	5	4	3	2	1
7					2	
8					2	
9	7	6	5	4	3	2
10	8	7	6	5	4	3

Figure 4: Pipeline Delays - Long Execution Time

8	6	5	4	3	2	
9	7	6	5	4	3	2
10	8	7	6	5	4	3

Figure 5: Pipeline Interlocks

CONCLUSIONS

We began our discussion with a hypothetical processor requiring 47 cycles per instruction, and then, through pipelines, caches, and parallelism, we have shown that it is possible to complete one instruction every cycle. However, processors cannot average one cycle per instruction because of various cache and pipeline delays. Generally for 370 architecture processors, the average value is between three and four cycles. Again, the actual value (that is, the effectiveness of the cache, pipeline, and parallelism) depends on the environment and the application. This fact is clearly shown in LaMaire and White [3], who describe the fluctuation in nanoseconds per instruction (cycles per instruction multiplied by the cycle time) for a production workload over the course of a day.

IMPLEMENTING NETWORK CAPACITY PLANNING

Toby Olberding
US West Advanced Technologies

ABSTRACT

Communication network complexity and size are increasing at a faster rate than any other segment of data processing. During this time of growth, while the per unit cost of the hardware has dropped, the per unit cost of the network has increased. The visibility into the network has also decreased, while the demands have increased.

Corporate plans are carried out with the assumption that the network will successfully provide the service needed to meet the business demand. A network that operates in a degraded mode, or fails completely, causes repercussions throughout the corporation. Degraded network service translates directly into lost productivity and lost business. An unhealthy network means customer service-level objectives are not met, tasks are not competed on time, budgets are overrun, and corporate business plans fail.

This paper is a discussion of how to get started in network measurement and planning. A secondary purpose is to provide a sample project plan to implement the measurement and planning. The topics covered are Workload Characterization, Workload Forecasting, Service-Level Objectives, Integrated Capacity Planning, and Management Reporting.

1.0 INTRODUCTION

One of the success factors for a Management Information Systems (MIS) organization is the proper planning for the MIS data network. To accomplish the planning for the network the following project plan should be followed.

There is need for an increased awareness of what is happening on the network. The need requires that measurement of the network be added to our system measurements to allow us a window into the network.

The MIS organization has an immediate need to strengthen its visibility into the network. This visibility will be used for improved services to the users and provide more realistic service level agreements.

Communication network complexity and size are increasing at a faster rate than any other segment of Data Processing. During this time of growth, while the per unit cost of the hardware has dropped, the per unit cost of the network has increased. The visibility into the network has also decreased There is need for an increased awareness of what is happening on the network. The need requires that additional tools be added to our system to allow us a window into the network.

The expected benefits for the project are:

1. Increased customer service
2. Reduced over expenditures on Network services and hardware
3. Monitoring of Network Workload

1.1 OVERVIEW OF PROJECT

The following is a project plan to carry out Network Capacity Planning for a MIS organization. The need for capacity planning is real if not obvious. We at MIS need to know how the network is growing, who is using the network, and what the future might bring. To answer the questions; the solution is a multiphase approach to Network Capacity Planning.

The phases are:

- Phase 1 -- Workload Characterization
- Phase 2 -- Workload Forecasting
- Phase 3 -- Service-Level Objectives
- Phase 4 -- Integrated Capacity Planning
- Phase 5 -- Management Reporting

The phases are not serial; but have some concurrency.

The need for the network information is important to the success of the MIS organization and the corporation.

1.2 TIME TABLE

The following figure shows the time table for implementing Network Capacity Planning.

Management Approval	Start
Host Software Order	+ 2 Days
Software Delivery	+ 3 Weeks
Software Installation	+ 6 Weeks
Data Collection Start	+ 6 Weeks
Workload Characterization Report	+ 2 Months
Initial Workload Forecast	+ 2 Months
Workload Forecast with Trending	+ 4 Months
Service-Level Objectives	+ 3 Months
Integrated Capacity Planning	+ 6 Months
Management Reporting	+ 2 Months

Figure 1. Network Capacity Planning Time Table

2.0 PHASE 1 -- WORKLOAD CHARACTERIZATION

The first phase of the project will be to collect the information about who is using the network and how they are using the network.

2.1 OVERVIEW

The workload characterization is a process to find out who is using the network, how much is the network used, and for what purpose. The first step in network workload characterization is to gather data about the use of the network. The data can be gathered by using several different types of data collection tools.

The basic concept of workload characterization is that the study of the network can be simplified by the identification of a number of similar "resource patterns," which can be used to statistically represent a network's workload.

Workload characterization is the development of an understanding and a description of today's workload and the service provided. How a workload is characterized depends on the intended use of the characterization. Will the workload characterization be used for benchmarking, management reporting, system modeling, or forecasting?

It is essential that the eventual use of the workload characterization be known before any significant characterization begins.

2.2 SOURCE OF INFORMATION

For this paper the workload characterization will be used for system modeling, management reporting, and forecasting.

The source of the information is the inputs and outputs to the network from the host system. The information is gathered from software monitors that reside in the host and front-end processors.

Software based tools offer the best way to obtain the required information.

2.2.1 REQUIRED MEASUREMENT TOOLS

The required measurement tools are ones that measure the total network constantly. Total network measurements include measurements of all the lines, nodes, and terminals that are attached to the network. The network measurements should be active during the period that the network is active.

Usually software measurement tools provide the best solution by providing consistent measurements.

2.3 EXPECTED RESULTS

The expected results of the data collection will:
characteristic the network workload; determine who is using the network; how much of the network is being used; and what service-levels are being provided to the user community.

The deliverable will be a monthly report detailing how the network is being used. The information that will be provided is shown in the following figure.

1. Availability by: a. Line b. Node 2. Response time by: a. Company b. Line c. Node 3. Usage by: a. Company b. Line c. Node

Figure 2. Phase 1 Deliverable

2.4 TIMETABLE

The following figure shows the time table for implementing the workload characterization phase of the network capacity planning effort.

Management Approval	Start
Host Software Order	+ 2 Days
Software Delivery	+ 3 Weeks
Software Installation	+ 6 Weeks
Data Collection Start	+ 6 Weeks
Workload Characterization Report	+ 2 Months

Figure 3. Phase 1 Time Table

3.0 PHASE 2 -- WORKLOAD REQUIREMENTS FORECASTING

A key part of network capacity planning is to obtain the workload forecast and requirements for users of the network.

3.1 OVERVIEW

Workload forecasting is used to estimate the resources requirements of an application at a future point in time. The estimation techniques range in complexity from simple growth rates evaluation to complex statistical analysis.

The two basic components of workload forecasting are to forecast growth of current applications, and to forecast new applications. Clearly, the planning analyst requires input from users and management to do an acceptable job of forecasting. Without such input the best that can be done is to extrapolate the current applications in a statistical manner based on historical data For new applications the best that can be done is to include a contingency factor in the planning process, which may allow unknown new applications to be acceptably processed.

The management of the network needs to remember the growth of the network. To accomplish this awareness of growth, a capacity planning function needs to be included in network management.

3.2 SOURCE OF INFORMATION

Workload forecasting, like any other planning, must start at the top. In this case, the top means the users' business plan. The business plan must provide the guidelines for preparing the data processing workload forecast.

A recommendation is that users first forecast changes in their applications as an increase or a decrease for services that MIS provides. Then based on business plans, in business-oriented units familiar to the users, the planning process can start. The planning process must then transform these business units, often called "Natural Forecast Units" or "Key Volume Indicators", into input values required by the prediction technique to be used. An important final step is continual tracking of the forecast versus actual workload changes. An understanding of any discrepancies shown by such tracking should lead to more accurate forecasts in the next planning cycle.

Sources of the network workload forecast are the user liaison, the network provider, and trend information from the current network.

3.2.1 USER REPRESENTATIVE

In some MIS organizations User Representatives are the liaison between the users and the MIS organization.

The User Representative is in contact with the users of the MIS systems. In such a position the User Representative have access to the users business plans. The User Representative will know the business plans of the users and will be able to help with the forecasting process.

3.2.2 NETWORK PROVIDER

The network provider with the knowledge of the network and the workload will provide input to the forecasting process.

3.2.3 TREND INFORMATION FROM CURRENT NETWORK

The current network will be analyzed using statistical methods to provide growth trends for input to the forecasting process.

3.3 EXPECTED RESULTS

The expected results for this phase will be a better forecast of the network needs. The forecast will be compared to previous actual data to improve the forecasting process.

The expected deliverable is a monthly report that, with the workload characterization report, details:

1. Actual growth vs. Predicted growth by:
   a. Company
   b. Line
2. Predicted information by:
   a. Network
   b. Company
   c. Line
   d. Node
   e. FEP Hardware
3. Trend information by:
   a. Network
   b. Company
   c. Line
   d. Node

3.4 TIMETABLE

The following figure shows the time table for implementing the workload forecasting phase of network capacity planning.

Management Approval	Start
Initial Workload Forecast	+ 2 Months
Workload Forecast with Trending	+ 4 Months

Figure 5. Phase 2 Time Table

4.0 PHASE 3 -- SERVICE-LEVEL OBJECTIVES

Service level objectives are established with the users. Service levels are threshold values that define acceptable performance to the users. This is a crucial activity since the notion of a system being out capacity is undefined until such objectives are set.

4.1 OVERVIEW

For what service-level measures should objectives be set? Typically they are set for timeliness measures such as response time, system availability, network availability, line availability, and node availability. repeatability of charges.

4.2 SERVICE-LEVEL OBJECTIVES

Service levels are threshold values that are measurable and agreed to by the users and MIS. The capacity of the network is undefined until such objectives are set. Some of the issues to consider when negotiating objectives include:

1. What measures should be used,
   a. Network availability,
   b. Terminal Response time,
   c. Line availability,
   d. System Availability,
   e. Maximum Permitted System Outage,
   f. Repeatability of Charges;
2. Should objectives be met on the,
   a. Average,
   b. 90th percentile,
   c. 95th percentile;
3. Different objectives for different times of day;
4. Dollar differences for different service-levels;
5. Management commitment to honor the service-levels.

4.2.1 ESTABLISH SERVICE-LEVEL OBJECTIVES

Service level objectives are established with the users. Service levels are thresholds values that define acceptable performance to the users. This critical activity can only be set by the customers and the MIS organization.

4.2.2 SERVICE-LEVEL MEASUREMENTS

Objectives can be measured in absolutes, averages, or percentages. Absolute measurements do not allow for varying system workloads. Averages measurements do not lead to consideration of peak loading times. Percentages led to considerations of peak loading times. The service-level measurements should be ones that can be measured and are related to the cost of the service.

4.3 EXPECTED RESULT

The expected result will provide to MIS users and the MIS organization a way of measuring how the network is performing and delivering service.

The deliverable is a monthly report on how the network has met the service-level objectives.

4.4 TIMETABLE

The following figure shows the time table for implementing the service-level objectives phase of network capacity planning.

Management Approval Service-Level Objectives	Start + 3 Months

Figure 6. Phase 3 Time Table

5.0 PHASE 4 -- MODELING AND SERVICE-LEVEL PREDICTION

Once service-levels have been established and workload forecasting has been done, then predictive techniques can be applied to determine the equipment needed.

5.1 OVERVIEW

There are two basic approaches to service-level prediction: benchmarking and modeling. The choice of an approach is influenced by many factors including experience of planning staff, time, cost of prediction, and the amount of data available. Usually, it can be said that modeling is less expensive and less accurate than benchmarking.

5.2 TOOLS AND METHODS

The available tools and methods are: rules of thumb, analytic modeling tools, discrete modeling tools, statistical methods, network simulation, and benchmarking.

The use of the models will help in predicting the service-levels that will be delivered.

Modeling tools and techniques ordered by cost are; rules of thumb, statistical methods, analytic models, and simulation models.

These modeling techniques provide a fast low-cost way of predicting service-levels. The capacity planning group may use any or all the above modeling techniques for predictions.

5.3 EXPECTED RESULT

The expected result will be an equipment forecast based on service-levels and workload forecast. The deliverable will be a quarterly report.

5.4 TIMETABLE

The following figure shows the time table for implementing the modeling and service-level prediction phase of network capacity planning.

Management Approval Integrated Capacity Planning	Start + 6 Months

Figure 7. Phase 4 Time Table

6.0 PHASE 5 -- MANAGEMENT REPORTING

The ultimate success of a planning study depends heavily on the reports which clearly state an justify their recommendations.

6.1 EXPECTED RESULT

The expected result of the management reporting part of the project is better informed management. Management that has better information will make better decisions for the company. The deliverables, of the management reporting project are:

1. Monthly Workload Characterization Report
2. Monthly Workload Forecast Report
3. Monthly Service-Level Report
4. Quarterly Equipment Forecast

6.2 TIMETABLE

The following figure shows the time table for implementing the management report phase of network capacity planning.

11.0 DOCUMENTATION OF THE NETWORK

Documentation of the network is a requirement for a centralized network control and performance measurement of the system. The documentation should include the following:

1. Circuit layout
2. Network map
3. Hardware/software cross-references
4. Network vendor maintenance records
5. software listings by network task
6. software listings by network component
7. All user site telephone numbers
8. All user site individual contacts
9. Interface component maintenance log
10. Circuit control telephone contact, index and log
11. Maintenance history by component
12. Inventory by serial number of all network components
13. Inventory by serial number by site
14. Network redundancy locations and switching circuits.
15. Vendor contracts
16. Tariff commitments
17. Operations manuals by component.
18. Trouble tickets
19. Escalation procedures
20. Preventative maintenance guidelines
21. Diagnostics techniques by component
22. Diagnostics techniques by type of trouble
23. Disaster and recovery procedures.

The Theory and Practice of I/O Tuning

Rich Olcott
Schering-Plough Corp
3022 Jackson
Memphis TN 38151
(901) 320-2867

System performance concerns may center on maximizing throughput or on minimizing turn-around time. For most installations, either concern is addressed most effectively by minimizing time spent waiting for IO completion, especially for online storage. This optimization can only be accomplished if the system tuner can locate and control the performance bottlenecks in the IO subsystem. Different hardware lines and operating systems supply varying kinds and amounts of such performance-related information. This presentation surveys some useful tools and techniques for extracting and using that information. The discussion centers on the MS-DOS and Apple Pascal systems on microcomputers, UNIX V representing the minicomputer level, and the MVS operating systems run on large mainframes.

It's easy to give an inaccurate description of the performance analyst's objective: "Make the machine run faster". But in fact, the running speed of any given computer system is fixed by its hardware designers. Given a specific CPU, there are only two ways to simulate greater speed: either reduce the CPU work per transaction, or reduce the CPU's wait time per transaction. At least half the job is really "Make the machine wait less".

The charts in Figure 1 summarize a typical day in a typical commercial installation running the MVS operating system. Work processed by four major subsystems (TSO, IMS, CICS, and batch work) was analyzed to evaluate the time spent in various defined states. For example, TSO response times were broken down to average time waiting for a swap-in, waiting for a page-in, waiting for a disk input or output operation to complete, ready but waiting for CPU, actually using the CPU, and miscellaneous waits for such things as device allocation and enqueued resources. These subsystems have very different characteristic patterns of operation, but for each subsystem, the waits for disk response comprised 50% or more of the response or turnaround time. If disk response can be improved, every subsystem will show a performance enhancement. The importance of the input and output operations is so pervasive that the acronym I/O has come into common parlance to refer to generic inputting and/or outputting as specific operations, the subsystem that carries out that work, or the data so transmitted.

The moral of these charts is that the disk farm is usually the most fruitful source of performance improvements. This conclusion can safely be extended across operating systems and to all but the most compute-bound processing environments (and there are far fewer of these than is generally thought). A well-tuned I/O subsystem is the first prerequisite for getting the most out of the CPU that drives it.

Performance concerns in general cluster under three headings: response time, throughput, and availability. Throughput is the number of tasks completed per unit time. Response time (also referred to as turnaround time) for an activity request is the elapsed time between request submission and request completion. Tuning actions that increase throughput will usually decrease response time, but not always. Consider, for instance, that an L-1011 carries many more passengers than a 727, but both require 2-1/2 hours to fly from New York to Chicago. With regard to the I/O subsystem, performance is best treated as a response time problem whereas subsystem capacities are often measured in throughput terms.

Availability is often skipped over as a performance concern, but it shouldn't be. The steady improvement in hardware reliability has had two effects. First, we are less ready and more surprised when failures occur. Second, even less sophisticated systems include provision for detection and correction of some classes of recording and transmission errors. Such activity occurs "under the covers" and can be a significant source of slowed device response.

Performance management includes several distinct types of work, most easily categorized by their time-scales. Trouble-shooting is "right now" activity, oriented to locating and addressing problems in real-time. Online performance measurement tools are indispensible here. Capacity planning, at the other end of the spectrum, is concerned with projecting requirements generated by future workloads. Typical capacity planning tools include surveys of user requirement projections, and packages for modeling and trending calculations.

The word "tuning" covers the middle time-scale, from days to weeks. There is some time for analysis and planning, but not enough to solve a problem by bringing in new equipment. The tuner's tools and options overlap those used by trouble-shooters and by capacity planners, with some additions. In particular, the tuner is the one most likely to be involved with designing device cabling configurations and setting operating system tuning parameters.

An effective system tuning activity has a cyclic structure (Figure 2). We must know our desired performance status and our current status. If they don't match, we make a change (only one!) to the system and loop back to status measurement and comparison. Characterization of performance status depends upon the variables that can be measured under the operating system in question. Desirable items include: I/O wait times and request rates for each workload and device, phase or state times for each device, and error rates for each device and path element. (The system-dependant terms "phase", "state", and "path element" will be defined by example below).

There are two basic strategies for selecting the system change to be implemented. The first depends upon "happy values" or rules of thumb (ROT's). These are guideline target values, derived from experience or calculation, that usually lead to acceptible performance. "Device busy should

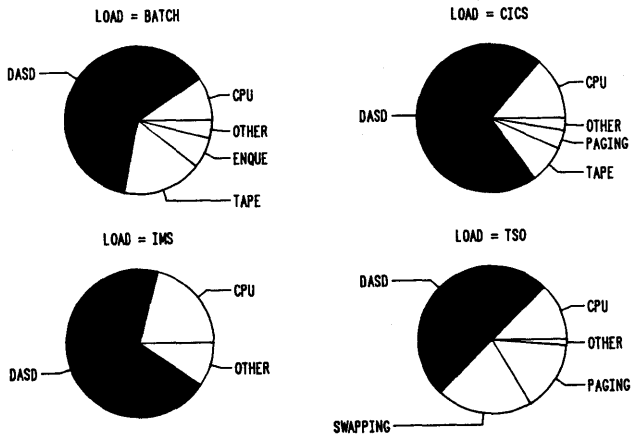

Figure 1. DASD Wait and Response/Turnaround Time

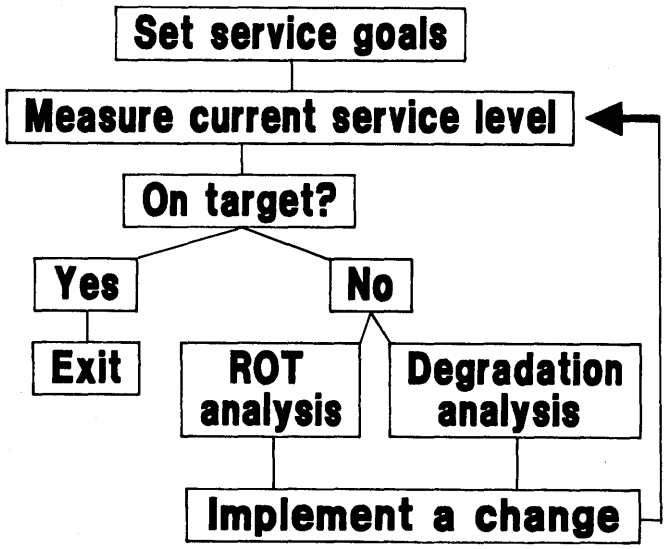

Figure 2. The Structure of the Tuning Process

be less than 30%" is a classic ROT. ROT's are rough averages to be applied to average systems; they do not in general allow for special performace requirements for critical tasks, not do they locate cost savings that could be realized by lowering delivered performance for non-critical work.

The second strategy is more powerful, at the cost of more work in the analysis. Under names such as "degradation analysis", "bottleneck analysis", "time tracking", and "profile analysis", it has been recommended by numerous authors. The heart of the strategy is a structured examination of the life-cycle of a typical or critical transaction. The objective of the examination is to find the system adjustment that will yield the largest reduction of the total response time. The life-cycle is decomposed into wait times and busy times. The times are defined in such a way that each corresponds to a specific tuning action. The longest wait times or busy times are treated first. By concentrating on the most significant components of the life-cycle, one obtains the largest performance improvements early in the process.

The available system adjustments also depend on the system in question. Repair of faulty equipment is always an option. In addition, one can implement operating system tuning options (including buffer allocations), reschedule the work contending for a particular device, rearrange the stored data to minimize contention, and redesign the application.

These general principles apply to computing systems at all levels. To demonstrate this fact and to gain practice at the type of thinking required of a system tuner, we will consider several hardware architectures and operating systems: UCSD Pascal implemented on an Apple II mocrocomputer, MS-DOS on an PClone microcomputer, UNIX V on a minicomputer system, and the IBM MVS/370 and MVS/XA software on a 370-class mainframe [1].

Microcomputer level

The Apple II is a family of microcomputers based on the 6502 chip [2]. USCD Pascal [3] is a single-tasking operating system based on the Pascal language designed by Wirth [4]. The UCSD system includes some language extensions (string operations and a set of I/O procedures), a process control supervisor, and a set of utilities. The Apple implementation of the UCSD system (referred to hereafter as Apple Pascal) contains some additional routines that exploit the Apple II hardware graphics capabilities.

MS-DOS [5] is a single-tasking operating system written by the Microsoft Corporation to run on any of the 8086-based microprocessors ("PClones") that is more or less compatible with the IBM PC family of systems. The Apple and PClone families differ in many respects, but they are sufficiently alike and sufficiently popular that we will use both together as an introduction to I/O tuning in general.

A typical microcomputer system might comprise the CPU chip and memory on a motherboard, a CRT (television or monitor) connected to the system via a display controller card, a disk controller chip on another plug-in card, and one or two floppy-disk drives attached to the controller by a flat cable connector. The essential parts of the disk drive itself are a motor to rotate the disk, a read/write head to interact with the magnetic coating on the disk, and an actuator to move the head radially across the disk.

The data is laid out on the disk in a series of concentric circles, called "tracks". (Numeric data in the next few paragraphs is specific to the Apple system. PClones incorporate drives with somewhat different quantitative characteristics but the same operating principles.) Each track corresponds to a specific radial setting of the head. On Apple II floppy-disk drives compatible with the Pascal system, each of the 35 tracks contains 16 256-byte sectors. Under the Apple Pascal operating system, the unit of file allocation is a 512-byte block comprising a pair of sectors. The internal structure of a file is not defined to the operating system. Although random-access operations are possible, most files are written and read as a sequential byte stream.

The life-cycle of a typical I/O operation starts with a procedure call from the application program. The operating system supplies procedures that read and write a structured record, a delimited line of text, a specified number of bytes, or a full block of data. In all cases, data will be transferred between the disk drive and a block-sized area of main storage known as a "buffer". Many of the input procedure calls can be satisfied by reference to data already in the buffer. In such cases, no physical I/O takes place and there is no delay of the program execution.

Once the system determines that physical I/O is indeed required, the disk controller is instructed to generate the electrical signals that start the disk drive motor. Roughly 500 milliseconds (msec) later [6], the drive is up to rated speed (300 RPM). If the head is not positioned over the proper track, the controller must move it there. This operation, called a "seek", takes a maximum of 400 msec to traverse all 35 tracks. The minimum seek moves the head from one track to the adjacent one. This seek is thus 1/34 of the maximum, or about 12 msec. In fact, delays inherent in head acceleration and deceleration will make the true value a bit more than this. If there is no correlation between one head position and the next, each seek is an "average seek", which can be shown to be one-third of the maximum or about 135 msec on this equipment.

Now the head is over the desired track, but not necessarily over the desired block. The diskette will have to rotate by some angle before that occurs. At 300 RPM, one full rotation takes 200 msec. On the average, one-half a rotation will be required to bring the disk to the proper position. This angular positioning delay, termed "latency", will be 100 msec. With 16 sectors per track, our two-sector block occupies one-eighth of the track; data transfer thus will use up one-eighth of a full rotation, or about 25 msec.

We arrive at the timing data summarized in Table 1. Starting from an arbitrary track on a stopped disk, each request to a random block will require 760 msec.

Suppose our task is to tune an Apple Pascal application to reduce delay to a minimum. Following our tuning cycle strategy, we first ask, "What is the current status?" With

Table 1. I/O Time Constants for a 16-sector Apple II Diskette Drive

Component	Time (msec)
Motor start-up	500
Seek times	
Minimum	15
Average	135
Maximum	400
Latency	100
Data transfer (512-byte block)	25

this hardware and operating system, we have no internally-measured data on application speed or I/O response time. The alternatives are stopwatch measurements, or hardware timing data plus some assumptions. One assumption is that I/O, which runs at mechanical speeds, will always be slower than the CPU work running at electronic speeds. We will proceed on that assumption, after using the stopwatch to measure the initial transaction times.

The largest figure in Table 1 is the motor start-up time. If the drive is given a chance to stop during the compute phase of the work, then the next I/O will be lengthened by half a second. It might be worthwhile to change the application program to do additional I/O, just to keep that motor running. Some system owners have in fact altered their hardware to the same effect. If either change is implemented, we return to our stopwatch study to make sure that there has been an improvement.

Our next recommendation depends upon which is the next largest component of the I/O cycle. That could be either latency or seek time. Both can be affected by manipulating the access pattern across the diskette. Rotation delay would be zero if I/O were timed so that a request always arrived just as the required record came under the head. Several systems (including Apple II and the PClone "standard") have attempted to achieve this ideal for sequential access. The most common technique is to stagger block positions about the track so that block n+1 is two or three blocks past block n. This algorithm succeeds or fails depending on the relative speeds of computation and rotation. If computation runs too long between I/O's, the staggered locations could in fact increase the rotational latency delay.

The key to minimizing seek time is to locate the next block on a track that is close to the current head position. Sequential access minimizes seek time, because all seeks during sequential access are either zero or to an adjacent track. If a file is not to be accessed sequentially, the best tactic is to keep the most popular blocks in the center range of tracks. If multiple files are used simultaneously, it is advisable to dedicate one drive to each file so that a head never has to seek from one to another.

The smallest component of the I/O life cycle is the actual data transfer time. Given a constant blocksize, rotation rate, and data quantity to be moved, the only way to reduce this delay would be to eliminate the I/O altogether. I/O reduction finesses all I/O delays completely. The challenge is to find ways to eliminate I/O activity when, as is often the case, the software requesting the I/O is a purchased program that cannot be altered.

One general strategy is to read often-referenced data once and maintain it in a spare buffer instead of re-reading it. This technique reduces I/O at the expense of main storage and CPU cycles. Both the Apple Pascal system and MS-DOS provide buffer re-read and buffer write defer, in the expectation that the data already in the buffer may still be interesting or may receive yet another update. How many buffers are available for this purpose? Apple Pascal's buffer count (not published) was established when the operating system code was compiled at the factory. MS-DOS is more flexible: the user can optimize the resource trade-off for his/her application by setting the value of a parameter (the BUFFER= command in CONFIG.SYS). The default is 2 or 3, and most users find 10-15 a good compromise between I/O speed and memory encroachment.

The MS-DOS directory system is a good example of an "application" whose I/O can be optimized even though the software itself is beyond the control of the tuner. The directory serves as the table of contents to the files on a floppy or hard disk. No file can be accessed without going through the directory, so slow directory I/O impedes all other work. How should a performance-conscious user treat the directory to minimize wait time?

A single MS-DOS directory on a 360K floppy can contain information on up to 112 files. (The limits vary for other media.) A single disk can contain many times that number of files. MS-DOS addresses the disparity by providing for a hierarchy of directories and sub-directories (Figure 3). Each directory is composed of one or more clusters of 512-byte data blocks. The number of blocks in a cluster varies with the recording medium and operating system level: 1 block per cluster on a floppy, through 16 blocks for a 10 megabyte hard disk and DOS 2.x.

The directory clusters are allocated just like other clusters on an MS-DOS disk, on a first-come-first-served basis starting with the lowest-numbered unused block. For example, the first block of the root directory will automatically be located at the first data block position (following system-specific elements like bootstrap records and a space accounting table). The next block within the first cluster will be immediately adjacent to the first. The next cluster within the directory will not be allocated until after some other files have been built on that disk, so the second directory cluster will be positioned well away from the first. Passing from the first to the second cluster within the root directory generally requires a long seek. Lesson number one: if the cluster size is 2048 (typical but not imperative for a hard disk), you avoid intra-directory seeks by putting no more than (2048 / 32 bytes per directory entry) = 64 files in a directory. (Notice that "file" includes sub-directory pointers as well pointers to commands and data files.)

It should be clear that inter-directory seeks also generate delays. From a performance standpoint, the ideal directory structure is broad, rather than deep. The ideal would be to have a root directory which contains the most often-used commands (to minimize time getting to them) and pointers to sub-directories. No sub-directory would contain a pointer to any lower-level, sub-sub-directory. No directory would span more than one cluster. To bring directory I/O delay to the minimum, all directories would be declared before any other files are built on the disk, because that procedure places all directories together next to the space allocation table.

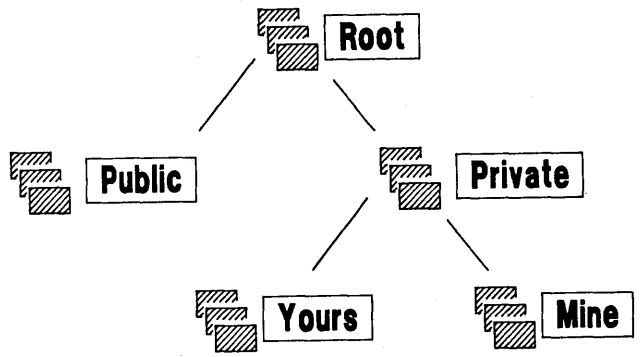

Figure 3. A Sample MS-DOS Directory Structure

UNIX V

The UNIX operating system [7] adds several layers of complexity to our tale. Apple Pascal services a single user at a single terminal, supporting but a single task. UNIX is designed to support multiple users at multiple terminals, with multiple asynchronous tasks running concurrently. Furthermore, the Apple Pascal system was designed to exploit the capabilities of a specific piece of hardware; UNIX has made a virtue of its hardware independance. In fact, the UNIX I/O architecture is so abstract that it would not be worthwhile to describe its interaction with any specific disk device.

A UNIX disk is formatted into 512-byte blocks. A UNIX file is a sequence of blocks linked together by chain pointers. There is no necessary relation between the physical locations of blocks that are logical neighbors within a file. Files written onto a freshly initialized disk may well be placed in contiguous storage. As blocks are used, then given up and reused, the odds increase that successive blocks in any given file will be widely scattered across the recording surface. In general, we can expect that all seeks on a mature UNIX disk will be "average" seeks, taking about 1/3 the time of a maximum seek on the device in question. Furthermore, there is not a reliable way to reduce rotational latency, because (1) there is no regulation of relative block position, and (2) there is no way of predicting compute time between I/O's in the presence of concurrent tasking.

Systems giveth as systems taketh away. The UNIX support of multitasking adds an important source of information to our tuning tool kit. One program can monitor and report on the performance of other programs as well as the system as a whole. UNIX V has several such facilities.

The System Activity Data Collector (command /sadc) maintains several sets of counters in memory. One set of counters records events such as completed I/Os and task switches. These counters are maintained by a portion of /sadc that receives control during system calls. Another set of counters is maintained by a portion of /sadc that records the state of various entities including the processor and I/O devices. This /sadc process wakes up periodically. At each awakening, it scans the system to see if, for instance, a particular device is servicing an I/O. If so, the corresponding counter is incremented. The command also checks to see if other processes are waiting to use the device; the number of waiting tasks (the "queue length") is added to yet another counter assigned to that device.

Performance monitors like /sadc can soak up significant system resources if they attempt to do too much. The UNIX designers wisely chose to limit /sadc to data collection only, reserving data reduction and presentation to other commands. The System Activity Reporter (/sar) and the System Activity Grapher (/sag) are the output side of the /sadc system. Each can generate displays of a wide variety of measured quantities. They differ in mode of operation: /sar produces tabular reports and a binary file; /sag reads that binary file in order to produce its graphs.

The /sadc system measures quantities on a system-wide basis. Two additional commands provide data with a narrower focus. The System Activity Disk Profiler (/sadp command) is a tool for examining the seek pattern on a specific disk. During the measurement interval, each of /sadp's samples yield one observation of the track addressed by that device's read/write head. Over a period of time, these addresses form a picture of the most popular areas of the recording surface. Undesirable patterns, such as widely-separated or very broad peaks, show up readily on the /sadp-generated histograms.

The other major tool is the /timex command, used to investigate the performance characteristics of a specific process. In effect, /timex "wraps around" the selected program, recording for it alone the same set of variables recorded for the entire system by /sadc.

With tools in hand and measurements on the desk in front of us, how do we decide what looks good or bad and what to do next? To begin with, we might use the ROT approach, looking at the system-wide numbers given us by /sar. In general, we'd like to see %busy spread evenly across all disk devices. On the average, %busy for disks should not be greater than 30% (tapes can go much higher). Desirable values for avserv are device dependant, because the service time includes seek, latency, and data transfer times. Numbers for hard disks, for instance, are very much shorter than for floppies. We can get an idea of what to expect by adding together the vendor's specifications for average seek, one-half the rotational period, and (512 divided by the rated data transfer speed). If the observed avserv for a device is consistently more than 1.5 times this sum, it is a good candidate for further investigation.

I/Obuffers are maintained in a region of main memory termed "the cache". A block once read into memory remains in the cache until it is the oldest buffer and some process needs one for a different block. If a block already in memory satisfies an additional data request (read or write), the event is called a "cache hit", representing the avoidance of a physical I/O. The cache is being well-exploited if %rcache is greater than 90% and %wcache is greater than 65%. The latter value is highly application dependant and may not be approached by programs that force physical writes either by direct system calls or by frequently updating large records.

Table 2. Selected UNIX V Measurements

Device activity
- %busy - Device utilization
- avque - Average queue length
- avwait - Average wait time
- avserv - Average service time
- r+w/s - Data transfers / sec
- blks/s - Blocks transfered / sec

Swapping activity
- swpin/s - Swaps in / sec
- swpot/s - Swaps out / sec
- bswin/s - Blocks swapped in / sec
- bswot/s - Blocks swapped out / sec
- pswch/s - Process switches / sec

Directory activity
- iget/s - System path searches / sec
- dirbk/s - Directory READs / sec

System calls
- sread/s - READ calls / sec
- swrit/s - WRITE calls / sec
- rchar/s - Bytes read / sec
- wchar/s - Bytes written / sec

Buffer activity
- bread/s - Physical block READs / sec
- lread/s - Logical block READs / sec
- bwrit/s - Physical block WRITEs / sec
- lwrit/s - Logical block WRITEs / sec
- %rcache - READ hit ratio
- %wcache - WRITE hit ratio

CPU activity
- %usr - % of time in user mode
- %sys - % of time in system mode
- %wio - % of time waiting for I/O
- %idle - % of time idle

System table activity
- text-sz - Text table size
- ov - Number of overflows

On the other hand, hit ratios much higher than these may signal too large a cache size; reducing the number of buffers may speed processing by increasing the amount of main storage available for computation. Such over-commitment of memory will show up in a comparison of swpin/s and swpot/s with pswch/s. Another clue is a high %swpocc value, indicating a large percentage of processes that are swapped out but otherwise ready to run.

Various authors have given ROTs for some of the other /sar variables. For instance, %wio greater than 30% probably indicates excessive I/O delay. However, most of these are critically dependant on the relative speeds of the CPU and the disk equipment.

Degradation analysis begins by asking "Is there pain?" and if so, "Where DOES the time go?" User complaints of slow response time are occasionally valid, but objective measurements leave less room for debate. We could resort to the stopwatch once again, but UNIX gives an alternative. In some installations, tuning effort commences only after the user has presented a log showing the process in question bracketed within a shell procedure between two /date commands. In this way, the start and end of execution are each timestamped and the response time can be calculated to the second.

Assuming that the response time is indeed unacceptably high, the next step is to rerun the process under the control of /timex. Comparison of %usr, %sys, %wio, and %idle quickly shows whether I/O time is a major contributor to the execution time. After all, it is possible that the process is being delayed by contention for the processor or some other resource. The product of %wio and the observed execution time is the maximum amount of time that could be recovered by I/O tuning alone. If %wio promises useful dividends, we turn to %rcache and %wcache to see if I/O waits could be avoided by avoiding I/O. The hit ratios will in general increase if the cache is enlarged, which can be accomplished by adjustment of the NBUF system tunable parameter.

If I/O cannot be avoided, we look next to see where it can most effectively be sped up. The expression (avwait * blks/s / 1000) gives the fraction of the execution time taken up waiting to start an I/O on the reporting device. Similarly, (avserv * blks/s / 1000) is the time fraction during which I/O was in progress on that device. Wait times lengthen if service time is long compared to the arrival rate of new requests. Either service is particularly slow, or the multitasking is allowing significant contention for the device. Thus, if both total wait and total service times are long, it's best to look first at factors affecting service time. If waits are long but service is swift, we must address contention by offloading data from the contended disk or else by rescheduling the contending work.

Long service times are almost always the result of excessive seek activity. The /sadp command will help us locate the busy tracks; other system utilities can then be used to determine which files reside on those tracks, and then to move these busy files to contiguous regions of the surface.

MVS

Because of IBM's dominant position in the mainframe equipment market, its more successful products have become de facto standards for generic device classes. Thus, specifications for recording surface geometry (number, arrangement and size of tracks), timing constants and command protocols for a specific IBM disk drive type actually apply to a class of drives produced by several manufacturers. In what follows, mention of a 3350-type drive, for example, denotes any drive meeting the corresponding geometry and timing specifications. Similarly, the phrase "370-class" denotes equipment (computer systems, disk drives, etc.) that comforms to the IBM 370 architecture specification.

MVS/370 and MVS/XA [8] are the most-used operating systems on 370-class computing systems. Both are primarily throughput oriented (for batch work) but can be optimized for rapid response to interactive transactions. Whereas the Apple system serves a single master and UNIX serves 2 to 20, MVS systems can handle hundreds (under TSO) to thousands (under IMS). Whereas an Apple may be equipped with 1 to 4 disk drives, a mainframe system may contain hundreds of disk drives, each holding up to 9000 times the data of an Apple Pascal floppy disk. Such increased system capacity comes at the price of commensurately increased system complexity.

MVS/XA is descended from MVS/370. There are numerous differences between them, but for our purposes there is only one. In MVS/370, all the work of processing an IO request is done by the CPU. In MVS/XA, much of that work has been offloaded to subsidiary processors located between the CPU and the disk subsystem. There are several implications of this difference. First, of course, more of the power of the CPU is available for application computation. Second, the system gains in flexibility, reliability, and responsiveness, because individual IO requests can be more closely managed (re-routed, clocked, etc.) by the specialized outboard hardware. Third, the CPU is less able to record and report on exactly what is happening outside of its view.

There are two architectures of 370-class disk drives, corresponding roughly to the hard-sector/soft-sector classification of floppy disks. The hard-sector group, defined by the Fixed Block Architecture (FBA), is rarely used in MVS installations and will not be considered here. In the more common architecture the recording unit of data is a block whose length is set by the application. As with the simpler systems, blocks are arranged in concentric tracks on a rotating recording surface. Unlike the simpler systems, a 370-class drive will contain a stack of corotating surfaces, each with its own read/write head. Because there is only a single actuator to move the entire set of heads, an entire stack of tracks will be accessed by a single actuator setting. It is convenient to refer to this track subset as a "cylinder".

In the Apple system, the disk controller chip does the translation of the CPU's disk access commands into electric signals such as "start motor" and "move actuator inward by five steps". The 370-class equivalent to the controller chip is actually a series of complex mechanisms (Figure 4). The disk drive itself contains only the recording surfaces, the motor, the actuator, and the heads. A string of drives is managed by a "head of string" (HOS), which contains electronics for device polling, data transmission, and the lowest level of command translation. One or more strings is cabled to a controller, which does higher level translation and may contain memory (a "cache") of its own. The controller is in turn attached via a "channel" (several different terms may apply, depending on the specific processor in question) to the CPU. The entire series, from channel to device, is called the "path"; each component of the path is a "path element" (PE). During data transfer, each component is dedicated to that particular IO event. Contention for PEs is a major source of IO delay.

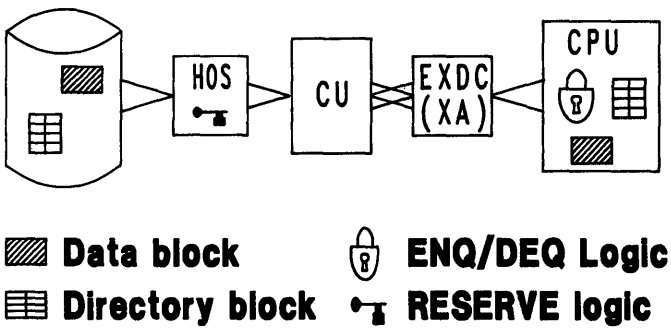

Figure 4. IBM Mainframe DASD Architecture

To exploit the random-access capability of disk hardware, IBM and other vendors have provided a number of "access methods" (AM's). An AM consists of a particular structuring of the data within a block, together with protocols and software to interface application programs with that data. Available modes of access range from simple sequential (forward and backward) through skip sequential and simple keys, to highly sophisticated retrieval strategies based on binary trees or hash techniques. Much of the software is devoted to generating the disk drive commands (the "channel program") that exploit the processing capabilities of the channels and control units. The following discussion will concentrate on the Queued Sequential Access Method (QSAM), which is quite similar to Pascal structured IO. Under QSAM, each block on disk contains one or more records. Records and blocks may be of fixed or variable length, and a record may extend across one or more blocks. It is QSAM's responsibility to keep track of record boundaries.

A typical IO sequence begins when an application issues a GET request to the QSAM software, asking for the next record in a particular file. QSAM owns in-memory buffers dedicated to this file. Because of a previous READ operation, the block containing the next record may already be in a buffer. In that case, the GET request can be satisfied without doing additional IO. If an IO is required, QSAM builds a READ channel program. The program points the channel to the desired device and block, and directs that the block be placed into a specific buffer. The channel program is passed to the IO Supervisor (IOS), which is responsible for overseeing the successful completion of the request.

IOS's first action is to verify that the device in question is free to transmit data. In a multi-programmed, multi-processing system like MVS, many processes may run concurrently so another process may now be engaged in IO with that disk or another one on the same path. Rather than initiate a doomed activity, IOS queues our request until the device and path appear available. At that time, IOS issues a SIO (for MVS/370) or SSCH (for MVS/XA) command to initiate the waiting channel program. Initiation may in fact not succeed, because some element of this path may have been claimed by another IO from this CPU or another that may share the device or path. In MVS/370, our IO request goes back on the IOS queue. In MVS/XA, the request waits in the outboard processor.

Sooner or later, the request is finally able to start. The first command in a QSAM channel program is a SEEK, telling the actuator to move to the appropriate track. The next command is a SET SECTOR, specifying the starting position of the block to be transmitted. The last command is the READ, specifying the number of bytes expected. Notice the device timing constants collected in Table 3.

Rather than tie up PEs during mechanical movements, the IO hardware itself disconnects the path from the drive until the movement operations complete. Now the disk attempts to reconnect to the path in order to receive the next command. (In 3380-type devices, SEEK and SET SECTOR are

Table 3. I/O Time Constants for 370-class Disk Drives

Component	Times (msec)		
Device type	3330	3350	3380
Seek times			
Minimum	10	10	3
Average	30	25	16
Maximum	55	50	30
Latency	8.4	8.4	8.4
Data transfer (4K block)	3.3	3.3	1.3

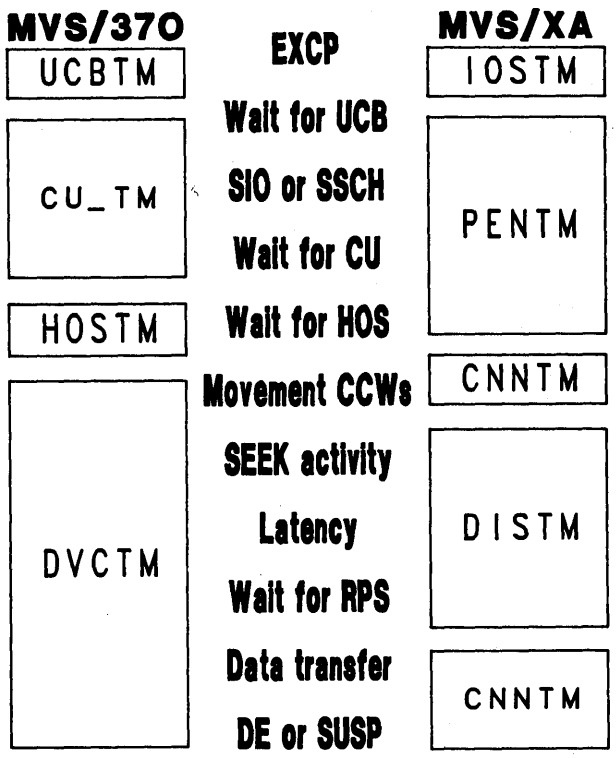

Figure 5. Measuring an MVS I/O Event

transmitted together.) If the path has become busy, the device must wait until the blocking PE is freed. This wait is particularly important at the end of the SET SECTOR operation. At this time, the disk has rotated so that the desired block is about to come under the head. If path reconnection is unsuccessful, then the disk must make a full revolution before reconnection can be attempted again. What had been an 8 msec rotational latency has become a 25 msec delay. The hardware facility that permits the disconnect/reconnect cycle is called Rotational Position Sensing (RPS); the additional rotation because of an unsuccessful reconnect is termed an "RPS miss". If the path is quite busy, a single IO request may suffer multiple RPS misses.

At long last, data moves up the path. However, suppose lightning struck nearby during data transfer. Spurious signals were added to the transmission. 370-class systems have two layers of error detection and error correction capability, residing in the path and in IOS in the CPU. If the error can be corrected in the path, the only evidence is a lengthened apparent transmission time and a "temporary error" entry in the system log. If IOS detects the problem, it attempts to recover by generating a number of retries of the entire channel program. Again, if recovery is successful the only trace of the problem is lengthened times and a log entry for a "temporary error". If recovery is unsuccessful, the application will be abended and the system log will show that a "permanent error" has occurred.

All this complex activity would be unmanageable without appropriate measurement tools. The multi-tasking nature of MVS allows monitors to observe and report on many aspects of system behavior. Several vendors have products to aid the MVS system tuner; we will discuss them in a generic fashion after we have considered the tools that are included in the operating system itself.

The most general of these are the System Management Facility (SMF) and the Resource Measurement Facility (RMF). SMF monitors and records execution times and resource utilizations on a task-by-task basis. One or more records are produced for each batch job, TSO user, and started task in

the system. The records are placed in a special file by a dedicated SMF AM. IBM and other vendors have taken to using the SMF file and AM as a central repository for audit and monitor data for a variety of purposes.

Base RMF consists of a pair of monitors and several reporting mechanisms. The monitors watch over all the system resources: CPU and peripheral devices and several categories of summarized workload resource utilizations. The exact variables differ between MVS/370 and MVS/XA systems. In MVS/370, the CPU is aware of the progress of each IO operation. At any moment, a given PE is known to be in a certain state (busy or not busy, with a certain number of waiting requests) and a given IO request is known to be in a certain phase (waiting for device, waiting for control unit, busy on device, etc.). RMF/370 is a sampling monitor like /sadc, maintaining a set of counters for each device. The system tuner specifies an RMF sampling interval and a recording interval. The monitor routines wake up once each sampling interval to record the state of each device and the phase of any IO request(s) to the device. At the end of each recording interval, RMF builds an SMF-type record containing the current values of all the state and phase counters, which are then reset for the next recording interval.

In MVS/XA, on the other hand, the CPU knows only that an IO request has been passed to the channel. The states of the PEs are not available to it, nor is the current phase of the IO request. On the other hand, the XA hardware is able to measure and report the amount of time spent in each phase at the completion of each request. As a result, RMF/XA device performance data consists of clocks. Figure 5 shows the events of an MVS IO cycle, together with a comparison of the RMF/370 and RMF/XA measured variables.

The first delay is the same in either system: IOS will not attempt to start an IO request against a device when it knows that the device is already busy. Neither system's RMF reports show this delay directly. Both, however, report the IO request rate and the average queue length. The queueing delay can be calculated from Little's Law as:

IOS wait time (sec) =
(Ave queue length) / (IO requests / sec)

RMF/370 reports state percentages rather than wait times. The times can be calculated from these percentages by formulae such as those given in Table 4. RMF/XA reports the times as measured by the outboard hardware. In general, "pending time" is the total path wait time, equivalent to the sum of of the waits for control unit, HOS, and time lost because the device is held by a sharing processor. "Disconnect time" is the total time spent waiting for mechanical motion. "Connect time" is protocol time, data transfer time, and error recovery time. Hardware at and above the IBM 3090 level can measure and report separately on control unit and HOS wait times.

The two RMF monitors differ in time range covered. RMF Monitor I runs whenever RMF itself is running. Monitor I continuously records workload activity and processor loads as well as the IO data we are discussing here. Monitor II is a snapshotting facility, periodically recording instantaneous or short-time utilization levels and counter values. There is a good deal of overlap with the types of data covered by Monitor I, but the time-range difference can itself be useful.

As stated above, RMF has several reporting mechanisms. An online facility queries the Monitor II data collector and can generate any of a set of pre-formatted displays. These displays show current conditions only, and are best used for

Table 4. RMF DASD Performance Fields, RMF/370
Field Names refer to SMF Type 74 (Device Activity) Record

```
DURATION = 60 * FLOOR (SMF74INT/100000) +  MOD (SMF74INT,100000)/1000

SIO Rate:
PSSIO = SMF74SIO / DURATION                    per second

Average queue length:
AVQUE = SMF74QUE / SMF74SAM

Total time (msec) in state xxx during sampling interval:
xxxTM = 1000 * SMF74xxx * (DURATION/SMF74SAM)
         xxx = QUE      Request on IOQ for any reason
         xxx = BUS      Request on IOQ because dvc busy this system
         xxx = ACT      Device busy this system

         xxx = RSV      This system held a RESERVE
         xxx = RDL      Some request held for HOS or external RESERVE
         xxx = DVB      Some request held with dvc busy this system
         xxx = PTH      Some request held with dvc not busy this system
         xxx = CUB      CU busy (any system) on another request

Average queued wait (msec) (Little's Law):
AVQTM = 1000 * SMF74QUE * (DURATION/SMF74SAM) / SMF74SIO

Average service time (msec):
AVSTM = 1000 * SMF74ACT * (DURATION/SMF74SAM) / SMF74SIO

Average response time:
AVRTM = AVQTM + AVSTM

Average wait (msec) at UCB:
UCBTM = 1000 * SMF74BUS * (DURATION/SMF74SAM) / SMF74SIO

Average wait (msec) at CU:
CU_TM = (AVQTM - UCBTM) * SMF74CUD / (SMF74CUD + SMF74RDR)

Average wait (msec) at HOS or RESERVE:
HOSTM = (AVQTM - UCBTM) * SMF74RDR / (SMF74CUD + SMF74RDR)
```

trouble-shooting. In particular, the displays highlight overloaded paths and devices, and provide indications of contentions for critical resources like page datasets and catalogs.

Another RMF reporting system places up to ten different types of records into the SMF file. These records can be used by the RMF post-processing report generator to produce a variety of listings suitable for trend analysis and problem determination. The record formats are described in the vendor's literature, so they can also be read by user programs.

There are several additional sources of performance data in the base operating systems. One of the most important is probably also the most neglected. This is the Error Reporting Program (EREP), a part of IBM's hardware support. This program reads the system log into which the hardware places notations of device malfunctions. Since temporary errors lead to long response times, and permanent errors lead to outages, the EREP reports should be scanned regularly by the tuner as well as by the computer repair technician.

The most useful EREP report is the Trends report. This listing contains a detail line for each peripheral in the system. Shown along each line are the number of permanent and temporary errors suffered by that device for each day in a 30-day period. This "map" layout highlights those devices that should be repaired (permanent errors) or from which at least performance-critical files should be offloaded (temporary errors). There is some controvery about the treatment of temporary errors. Several studies have shown little correlation between temporary and permanent errors. The conclusion is that "weak bits" probably don't "grow" into unusable ones. If that is the case, then one must consider the trade-off between slower disk response versus complete loss of use of the device during repair and adjustment.

MVS actually maintains two system logs. The first, LOGREC, is the one used by EREP and is used mainly for error and malfunction management. The second log, SYSLOG, is essentially a copy of system console traffic. It contains all system operator commands and the system's response to each. It also contains notations of the start and completion of all batch jobs and started tasks. Other information that can be placed in SYSLOG include such items as distress alerts from the telecommunications or other subsystems, status messages from major applications, and indications from task abends. SYSLOG is an important source of answers for the "What else was going on when things went sour?" question.

There are four general classes of performance data sources that do not come along with the MVS operating system: extended monitors, extended post-processors, SEEK analysis systems, and modeling packages. Each addresses a different class of problems. The extended monitors are most useful on the trouble-shooting time-scale. Probably the most sophisticated is the Candle Corporation family of products based on their Omegamon offering. This is basically a system operator's tool. Rather than simply enable an operator to inquire about the current utilization level of a specific resource, Omegamon itself continually monitors all resources. If any utilization goes over a pre-determined threshold, the software displays an alert message on a dedicated terminal. This exception reporting philosophy allows the operator to pay attention to what's wrong rather than having to cope with a flood of data about what's right.

Monitor extensions either add a wider range of managed variables, or lengthen the reporting time-range, or both. One set of new variables is especially important here. The Candle Dexan product and IBM's RMF Monitor III (available only under MVS/XA) both concentrate on workload delay rather than on resource utilization. Each named task in the system is sampled periodically. The task is classified as working, idle, or delayed waiting for some event or resource. Sampled status counts are converted back to percentages over the most recent group of samples. The analyst can then call on the monitor's associated reporting tool to ask for displays of which tasks suffered the most delays, what they were waiting for, and which other tasks were contending for the delaying resource. These products cannot be ignored by an installation seriously interested in effective and efficient solution of day-to-day performance problems.

One of the major shortcomings of the base RMF online reporter is its lack of memory. Many trouble-shooting problems would be most easily solved by comparing the current situation with the one existing 20 minutes ago, say, or maybe yesterday. The Candle Epilog product, Boole and Babbage's CMF system, and the IBM RMF Monitor III all addresss this problem by providing some sort of memory capability, usually extending back only some hours or to the most recent IPL, whichever is less.

These tools are very useful on the trouble-shooting time-scale, but provide little help to the tuner and capacity planner who are more concerned with trends acting over periods of weeks to years. These needs have been addressed by several systems that read records in the SMF file and produce a database that can be maintained to represent the time periods of interest. Examples of such systems include Morino's MICS product family, SAS Institute's MXG system, and a portion of the FastDASD system now being marketed by UCCEL. The Boole and Babbage CMF system also includes a performance database fed from that company's proprietary system monitor. At minimum, these databases allow us to track system performance numbers for exception reporting and management summaries. In fact, their full utility is limited only by the imagination of the people who work with them. We will see some illustrations below.

The third group of software tuning products consists of specialized disk management tools addressing SEEK delay. Another portion of UCCEL's FastDASD product is a SEEK monitor and analysis system, as are Boole and Babbage's DSO product and a free-ware system available from the SHARE user group. Each is fundamentally similar to the UNIX /sadp facility: a monitor routine periodically samples the head position for all or a selected subset of the disk devices attached to the CPU running the software. The motion of the head is assumed to be fairly represented by the samples. These products supply one thing that /sadp doesn't: they also read the subject disk's volume table of contents (VTOC) and so are aware of the location of every file on the disk. Thus, they are able to use the head movement data to make recommendations for file relocation.

The fourth major category of follow-on tools consists of the modeling packages. The oldest generally available system is the Best/1 system from BGS, followed by Boole and Babbages's CMF and Amdahl's MAP. The modeling tools come into the tuning cycle after we've decided what's wrong but before we've decided what to do about it. A model provides no new insight into the currently running system. Rather it permits us to play "what if" games, seeing what effect a given change will produce. A model is used to compare the probable results of alternative solutions to the problem: move this file to that other volume, shorten this string, add cache to that controller. The models help us to rule out solutions that won't solve the problem, and also to put numbers to the inevitable cost-benefit trade-offs to be considered.

Now that we know how the hardware and software operate, let's enter the tuning cycle. We use the measurement tools and obtain a snapshot of the system. Now we need to decide if something's wrong, and if so, what to fix. Let's look first at the ROT approach. Are there any quick indicators of the overall health of the IO subsystem? Yes, and a collection of them appears in Table 5. However, we must keep in mind that a healthy IO subsystem does not necessarily imply that critical work is not being delayed within it. It is risky to rely on ROTs out of the context of service level goals. If critical work is not being delivered in a timely manner, than

Table 5. Rules of Thumb for MVS I/O Tuning

Measurement	Value	Notes
Both systems		
Device busy - batch	40%	
- response	35%	
PE busy	35%	45% for 3380 under XA
Device avg service time	30 msec	3350
	25 msec	3380
Device activity rate	18/sec	3350
	22/sec	3380
Avg queue length	0.10	
% Device RESERVEd	5%	Except JES2 Primary Chkpt
MVS/370		
% Chan Busy & CPU Wait	10%	
Channel avg service time	10 msec	
% Req Deferred - Path	25%	
(%delay) / (dvc busy)	30%	%delay = % reserve delay + % CU delay + 100 * (Avg q len)
MVS/XA		
Average IOS time	5 msec	
Average pending time	2 msec	
Average disconnect time	20 msec	3350
	15 msec	3380

the system needs tuning even if the IO averages are acceptible.

Probably the most famous ROT is the 35% rule for disk devices and PEs. Most tuners try to keep the activity spread out evenly across all drives, and the %busy for each less than 35%. Similarly, the %busy for all controllers and HOSs should be lower than about 35%. However, advancing technology has relaxed some of the constraints that set those limits. For XA systems, the %busy for PEs servicing 3380-type drives (not for the drives themselves!) can go up to 45% before performance starts to suffer significantly. Notice, by the way, that PE %busy is not the sum of %busy for each end device on the path. In XA terms, the path is only busy during connect time, so XA PE %busy can be calculated from the ratio of path total connect time to measurement duration. In MVS/370, on the other hand, explicit PE %busy cannot be calculated. For ROT purposes, we use the Physical Channel %busy from the RMF Physical Channel Activity Report.

There are two other commonly-used ROT's, one measuring load and one measuring stress. The load on a device is roughly proportional to its IO rate. Stress develops when a system component cannot service requests as rapidly as they arrive. That device's average queue length starts to increase, and a length greater than 0.10 is probably a sign of trouble.

The matter of device sharing is a paper unto itself [9]. The 370 architecture allows two or more processing systems to share access to a common disk controller and the device strings attached to it. The arrangement opens numerous exposures in data integrity, security, and performance. The RESERVE is a hardware feature that can be used to preserve integrity. Any processor can issue the RESERVE command as part of a channel program directed to a particular device. The path HOS then blocks IO requests to that device from any processor other than the one holding the RESERVE. The other processors get back only an indication that the device is busy at HOS. This condition lasts until the holding processor issues an RELEASE command. Data integrity is thus bought at the expense of data availability and perceived device performance.

RESERVEs held while the processor does IO to the device are harmless: other processors would be blocked from the device anyway. The MVS code that manages the device storage space, for instance, uses RESERVE during brief periods of intense IO with no ill effects. However, other utilities and applications may not be such good citizens. The 5% ROT serves to alert us to potential abusers of the feature. Note that heavy RESERVE activity is an essential part of normal operation for a JES2 primary checkpoint volume.

ROTs peculiar to MVS/370 IO systems refer to the numbers that appear on or can be calculated from the RMF/370 reports. The most critical to total system throughput is probably the fraction of the time that the CPU is waiting while a channel is completing an IO request. The most telling indicator of structural problems in the IO subsystem is the fraction of all deferred requests that were delayed because of path contention.

ROTs are of much less use in the XA environment, because performance statistics are reported in terms of actual delay times. This reporting convention leads more naturally to a degradation analysis approach than to one depending on ROTs. However, the table does carry a few threshold criteria more suitable for rapid screening than for diagnosis.

As graphics hardware becomes less expensive and more widely available, graphics methods will become more important in system tuning. Figure 6 is an example of the sort of extended ROT technique that can be expected to proliferate in the near future. In this contour plot, time runs along the horizontal axis. The vertical axis has one location for each disk device attached to the reporting system. The z-coordinate, aimed up out of the page, may be any performance statistic. In this example we see the mean path wait time per SSCH. The diagram is thus a depiction of activity or delay across the entire disk farm throughout a week. This sort of display puts an enormous amount of detailed

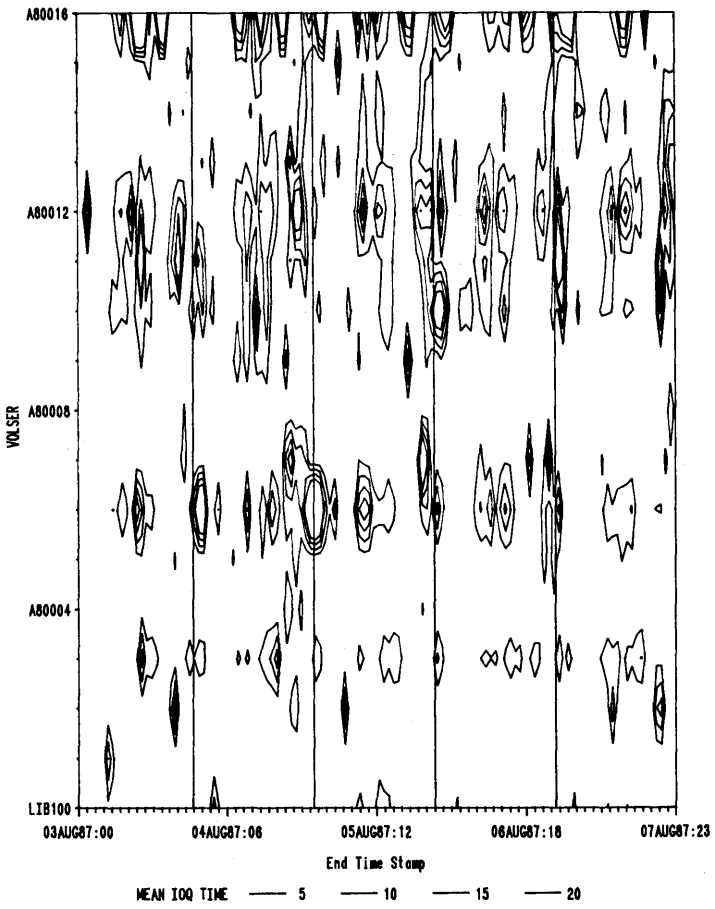

Figure 6. A Sample DASD Delay Map

information into a form especially well-suited to the pattern detection capabilities of the human eye. "Hot spots" show up clearly, as do any time-correlated behaviors.

As we said above, degradation analysis is more readily carried out under MVS/XA than MVS/370. MVS/370 statistics can be used to derive wait times at various queueing points, but most of the arithmetic must be dine by the user. A complete set of formulae has been given elsewhere [9]; a convenient subset is laid out in Table 4. A thorough analysis requires some programming for data reduction and transformation. For convenience, we will state the rest of this discussion in terms of the MVS/XA variables.

As always, the first step is to assay the current state of the system and any critical workloads. The SMF Processing Data record group (types 4, 5, 6, and 26 or else type 30) supply the needed turn-around time data for batch work. Averaged TSO response times can be obtained from the RMF Workload Activity reports or Type 72 records; more sophisticated analyses will require a transaction classification tool such as the Morino TSO-MON product. CICS and IMS transaction times can be obtained from the CICS CMF and IMS DCMON facilities respectively. If all service levels are being met, then the analysis can stop and we can go on to other projects. There are always other projects.

To carry the example further, however, suppose that a critical batch job is running too slowly to meet our service goals. Suppose further that analysis [10] of the relevant SMF data has ruled out delays arising from device allocation, contention for possession of datasets, intensive demands on CPU or memory, and other non-IO waits. We are facing an IO tuning problem.

Now we need data at a lower level of detail. Which entities (devices and files) are the source of how much delay? Probably the easiest route to the answers goes through the SMF Type 30 (Common Address Space Work) record. SMF can be told to generate these records at the end of each job step, and even at stated intervals within a step. Each record contains dozens of measurement fields. We are interested in the EXCP section of the record, holding one set of fields for each file used during each step of a job. The fields include the DDname (used by the running program to reference a specific file), the device accessed, and the number of blocks transferred between file and memory since the file was opened (not since the start of the interval).

So far we know which devices are heavily accessed by the job, but we don't know the nature of the delays. Connect time is only part of the story. We need the total of each type of delay (connect, disconnect, pending, and IOS) if we are to locate the tuning point with the most leverage. The RMF Device Activity Report for the same time interval gives the average delay suffered per IO event for each device in the system. We estimate the job's delays for each file by multiplying the recorded block count times each average delay for the device. The result of that arithmetic will be a matrix of files against delays. We need only scan the matrix to find the largest number, and we can start to think about what to do to reduce that type of delay on that device.

Once we have located this bottleneck in the IO subsystem, what are the tuning options? The first to consider is IO reduction. The systems programmer can take a few actions that will reduce activity to system datasets. The MVS/XA LLA subsystem eliminates traffic against load library directories. JES2 job journalling can be turned off unless the installation uses MVS Checkpoint/Restart. Unused SMF records can be suppressed, as can trace activity of all types. The presence of a performance database, by the way, greatly reduces tape and disk activity by the performance and capacity management staff who are usually among the system's most intensive users. There are a number of software products which use CPU/memory/IO trade-offs to cut back references to load libraries, catalogs, etc.

MVS has an option that interfaces standard AMs to the paging subsystem so that datasets are created and manipulated on "virtual devices" with "virtual IO" (VIO). Because the operating system has control of VIO's buffers and real block sizes, VIO can exploit the "fast-path" code used for MVS paging. If the system is not already paging-

Table 6. Effects of Tuning Actions - MVS/370

Action	Effects

- C Protocol or data transfer time
- U Device RESERVEd but idle
- S Device active time

constrained, VIO offers performance advantages over real IO for small sequential datasets. There can be a large benefit/effort payoff in changing logon PROCs to use VIO datasets for EDIT recovery datasets, for instance. In some environments, users have incentives to convert their datasets to VIO, but beware the job that allocates VIO space for sort work areas!

Physical IO to sequential and VSAM files can usually be reduced at the expense of memory. Larger blocksizes mean the same number of blocks can be sequentially scanned with fewer physical IOs. Consider the timing constants shown in Table 4. If a file of 80-byte records is stored in 80-byte blocks on a 3350-type device, the average delay per GET is 19 msec (assuming minimum SEEKs). If the same file is reblocked to "half-track" (2 9440-byte blocks per track), each physical IO reads in 118 records at an average delay of 0.22 msec, a reduction by a factor of 86. Furthermore, because each block must be bounded by an unused space, the higher blocking fits 3.7 times as much usable data onto each track.

Similar logic applies to VSAM sequential access. VSAM buffer allocations default to one data buffer and two index buffers. If the file is to be accessed sequentially, substantial benefits can be realized by setting the number of data buffers, BUFND, to 10 or more (depending on details of CI size and processing per record).

Non-sequential access is quite another matter, because excess blocksize means excess data movement for no gain. Notice, though, that absolutely random access is surprisingly rare. Patchwise random access is much more widespread, and modest increases in blocksize can often result in a measurable increase in the number of hits per block read in.

Non-sequential access to a VSAM dataset can be sped up through IO reduction of another sort. There may not be much opportunity to cut back on physical IO of data, but the index is neither as volatile nor as bulky as the data. Keeping more index blocks in memory means that fewer will have to be read in a second time. The index buffer count is controlled by the file's BUFNI parameter, defaulted to 2. For keyed access, this value should be at least as large as (n + 1), where "n" is the number of index levels, given in the VSAM catalog listing.

IO reduction is not a panacea, however. It is a general solution that may not fit our problem. Rather than pursue at length the cause and cure of each sort of delay, consider the arrays set out in Tables 6 and 7. Here we see the actions that can be taken during storage tuning, and the type of delay that each will affect (in terms of the relevant RMF descriptor and the corresponding field name in the SMF Type 74 (Device Activity) record for that operating system.

A few words about the action list. The effect of equipment repair will depend, of course, on what part of the path is broken. In our experience, the weakest link is the recording surface and the actuator, both of which have the greatest effect on the "device busy" or "connect time" indicators. However, don't lose sight of the secondary effects that can arise. Error correction activity can dominate a path to the exclusion of all other processing, so a repair of one device can benefit the entire string and others as well.

"Reordering data" applies mostly to pseudo-random files which are accessed sequentially but which contain some data that is much more popular than others. A program load library is a prime example. If the most active programs are loaded physically adjacent to the directory, then head motion between directory and program is minimized.

IO prioritization is taking from Peter to pay Paul. During the IO life-cycle, IOS must be notified when the data movement has completed. This notification takes the form of an "interrupt", in which the current task is stopped so that system control may be transferred to IOS. If several IOs complete simultaneously, IOS must choose which to service. Two disciplines are supported: first-come-first-served and priority. In the latter, each IO interrupt inherits the relative priority of the task that generated the request. Prioritization will help some tasks but hurt others. It is a valuable tool, but requires that the installation make decisions about which class of work to favor.

SUMMARY

From this small survey of operating systems, we can draw several conclusions about the tuning process in general. First, tuning effectiveness depends on the number of dials and the number of knobs. We can't tune what we can't measure, and we can't tune what we can't adjust. Second, tuning responsiveness depends upon ready availability of data and ease of making changes. If measurements can't be made in real time, and adjustments can't be made in real time, neither can improvements.

It is important to treat the tuning process as a cycle, driven by comparison of current status to externally-set service goals. Without constant comparison between the real and the ideal, tuning becomes a pasttime rather than a purposeful activity.

General system tuning works well with a ROT approach, but specific performance problems should be addressed by looking for the significant sources of delay. Averages often hide more than they show, and experience shows that the extreme case is often the (politically or financially) most important one.

Finally, there is no substitute for deep knowledge of the system being tuned. Intuition is a powerful aid in the tuning process, but intuition without knowledge is metaphysics.

ONLINE DATA BASE VS. RAW SYSTEM DATA

Robert H. Denis
Transamerica Information Services

ABSTRACT

For someone who is new to either performance evaluation or ad hoc management reporting, the collection of the necessary system data can be intimidating. This is espcecially true if the analyst has only a basic understanding of the programming language which is used to extract this data. The purpose of this paper is to show how a well structured online data base can help a new analyst develop meaningful and useful reports even with a limited comprehension of the programming language and the raw system data. As a result, the analyst will be able to spend his time performing analysis, rather than sifting through data. For illustrative purposes, the MICS Data Base and SAS language will be used.

INTRODUCTION

Every performance analyst or programmer has to go through the awkward stages of being new in that particular field. If SAS was the main language used, the analyst was probably sent to a basic class and given manuals to look through. He would obtain a good understanding of these basic skills and be of the opinion that he could handle most projects that came his way. However, he learns that the System Management Facility (SMF) is the main source from which most of the reporting will be done. The first examination of the layout of this data reveals that the SMF record is not the simple straightforward record that he had worked with previously. This paper will illustrate how this situation can be handled so that the analyst can respond to an SMF request even with just a basic understanding of the SAS language. The answer is the online data base. Before the data base is described, it is necessary to understand the general format of the SMF record.

THE RAW SMF RECORD

The SMF record is the means by which several computer functions can be monitored. Performance analysts and capacity planners use this record to measure such functions as throughput and resource usage. While SMF records are not overly complicated, they do not follow a fixed format. That is, the data is not in a format where each line contains fields in exactly the same columns for every record. The SMF record is a variable length record. It always starts with a header which contains among other things the numeric identification of the record. For example a type 5 record is created at the termination of a job in the system. Next there is a header unique to the record type which contains such information as entry length, number of entries on the record, and a record subtype identification if applicable. The remaining part of the record contains the data unique to that record type. This part of the record is an entry. There is usually more than one entry on a record. At the end of one entry a new entry starts on the same line. It is at this point that the analyst realizes that he is not dealing with a simple basic record. He must be able to hold data so that the entire record can be read. Then the offset of the fields in each entry must be considered because of the variability of the entry length. As a result the column numbers are not constant. In addition the numeric fields in the SMF record are not just plain numbers. Some of these fields are in integer binary and packed decimal formats. Time fields are in such formats as integer binary, time, and smfstamp formats. Some time measurements are made not in seconds, but in microseconds (tenths of seconds). Often these time fields must be manipulated requiring conversions to SAS time and back again when printed out. A well organized online data base can simplify this data extraction process significantly. Morino Associates' MICS Data Base shall be used to illustrate this point.

ONLINE DATA BASE

In order to have a workable online data base for SMF records, it must be able to provide the same data while simplifying the coding required. The MICS Data Base takes a giant step toward this goal. The logic needed to access the raw records is built into the source code. Each field of data is given its own unique name. Since each field name is unique, the analyst does not need to know in what columns the piece of data resides. The data base does that for him. The data is not in several different formats. All fields are either character, numeric, SAS time, or SAS timestamp. These formats are also part of the source code. If these fields are going to be printed on a report, no FORMAT statement is needed as the data base automatically prints them using the proper format.

Now that we have all of these handy fields, the question is how can they be organized for easy access. Related pieces of data are put into information areas such as Batch Utilization, Hardware Utilization, and so on. Each information area contains files. These files are given their own unique names. It is in these files that the various fields reside. Data from several SMF record types can be stored in the same database file.

In addition to data taken directly from the raw SMF records, additional fields can be created which contain computations from other fields on the data base. These fields can hold minimum values, maximum values, averages, percentages, and so on. This extra computed data can assist in reducing SAS code even further.

Another coding time saver is to have the data summarized by convenient units of time. This can be done in timespans such as DAYS, WEEKS, MONTHS, and YEARS. Within each timespan the data can be summarized to a level of time such as hour, day, week, month, or work shift. For this latter option MICS has a field called ZONE which allows the specification of unit of time other than hour, day, week, and so on. This time measurement could be work shift, peak and offpeak periods, or any period of time desired. A timespan can also be used to represent unsummarized data. This data would have the same granularity as the raw record. For example, a raw RMF record is created every fifteen minutes. In the data base an observation would be available which covers this fifteen minute period. MICS does this in a timespan called the DETAIL timespan. This is a daily timespan, but the difference between DETAIL and DAYS is that DETAIL data is unsummarized and DAYS data is summarized by hour. So now we have all this data nicely organized into fields, files, and timespans, but how does the analyst know what each field on the data base means? This is accomplished with a data dictionary.

The data dictionary gives an explanation of exactly what each piece of data represents. In the case of the MICS Data Base various pieces of information are

included. Of course a clear definition of the field should be the first item mentioned. The derivation of this field from the raw SMF record is included either as part of the definition or as a separate item. Next is the SAS format of the data. Then an explanation of how this field is handled in summarization is given. As an aid to the analyst a brief explanation of how this field can be used is present. Finally, a list of related fields that give similar information can also be included. The data dictionary can also have explanations on general topics which might be of interest to the analyst. These topics can be things like the effect of a new release on data collected, how various measurements are done, or anything related to the data base which can be explained fairly briefly. A data base has now been created which has all of the data well organized and a data dictionary to provide explanations of what the fields are. To make it easier to obtain data for a certain period of time MICS uses the concept of aging. For example, using the DAYS timespan, the first days data becomes cycle 01. The next example, using the DAYS timespan, the first days data becomes cycle 01. The next run moves this data into cycle 02 and the new day's data is put in cycle 01. On the third day, cycle 02 becomes cycle 03, 01 becomes 02, and the new data goes into cycle 01. This process continues each day. Let's say that 14 cycles are being kept online. The data in the 14th cycle will drop off the data base on the next run. Tapes can be created to supplement the online data base. These tapes allow longer retention of data without taking up disk space. MICS also provides a cycle 00 for WEEKS, MONTHS, and YEARS. This allows for either week-to-date, month-to-date, or year-to-date data to be kept. Now that we have a well organized data base it is necessary to take an additional step which is to minimize Job Control Language.

A Job Control Language Library should be created to hold various procedures needed for execution. Having these procedures as part of the data base reduces the amount of JCL required for the analyst to have in his application. In the case of MICS several procedures exist for various purposes. For brevity the MICSSHR procedure shall be used as an example since this is the procedure most commonly used by analysts. MICSSHR allows read only access to a single MICS data base unit. A unit is simply an organization of related data. For example, SMF data can be one unit, IMS data another unit, and so forth. Among other data sets, this procedure contains the data set names of each timespan with DDnames corresponding to the name of the desired timespan. Thus when this procedure is specified in the EXEC statement of the JCL, all of the JCL is generated.

For a simple example let's assume that a request has been made to list all executions of job A1234567 for the previous day. This report is to include the system and time the job ran. Upon looking at the MICS files, it is discovered that the data we need is part of a file called BATJOB. Since this file is part of the SMF data base unit, the single character ID for that unit is the letter S. This ID varies from one installation to another. Since the data requested is for the previous day we want cycle 01 on the DETAIL timespan. This file does not have a DAYS timespan and if it did we would need unsummarized data anyway. The specific fields required would be JOB for the jobname, SYSID for the system name, STARTTS for the time the job started running, and ENDTS for the time the job ended. Since a data base unit is being accessed the MICSSHR procedure shall be used. The code needed to do this is as follows:

```
// job card
//STEP1 EXEC MICSSHRS
//SYSIN DD *
DATA JOBS(KEEP=JOB SYSID STARTTS ENDTS);
  SET DETAIL.BATJOB01;
  IF JOB='A1234567';
PROC PRINT DATA=JOBS;
  ID SYSID;
  VAR STARTTS ENDTS;
TITLE EXECUTIONS OF JOB A1234567;
```

The data base unit identifier "S" is added to the end of the MICSSHR procedure name in the JCL. Note the absence of an INPUT statement. MICS is accessed using a SET statement. The first part of the SET statement indicates the timespan desired. DETAIL is a DDname in the MICSSHR procedure. Then after the period the name of the file, BATJOB, is indicated. The next two positions indicate the desired cycle. Since the previous day's data is needed, cycle 01 is given. A KEEP statement shows what fields are desired from the BATJOB file. Remember that no formats are needed since MICS handles that automatically. An IF statement is present because only those observations with jobname A1234567 are required. Next a report is created with a PROC PRINT. In the PROC PRINT illustrated the observation line numbers are being suppressed and the system id is the left most column. The ID statement performs these two functions. The VAR statement then indicates that the next two fields to be shown on the report are STARTTS and ENDTS in that order. Because these two values are MICS fields there is no need to have a FORMAT statement. They will automatically be printed using the DATETIME format. Finally a TITLE statement for the name of the report concludes the program.

If a new analyst had to write this same program directly from the raw SMF record, he would need to find the location of each field. As mentioned earlier, this is not as straightforward in SMF. The location of a field is usually the result of a calculation rather than an actual column number. He would need to be aware of the format of each piece of data as well. In other words, the analyst would be spending extra time figuring out what the INPUT statement should be. The program would also need FORMAT statements for the time fields so they are printed in a readable format. In MICS all that would be needed would be to look up the proper file and find the names of the needed fields without worrying about where the field is located. In a more involved program calculations may be needed on some time fields. These fields are already in a SASTIME format in MICS. The conversion has already been done in the source code. Another common SAS statement may isolate parts of DATETIME field such as month, day, and so on. MICS has fields such as MONTH, DAY, YEAR, HOUR, etc. which makes most of these statements unnecessary. As a result time is freed up for doing analysis rather than sifting through data and extra SAS code. Unfortunately the many benefits provided by an online data base do not come free. The next section discusses both the advantages and disadvantages of the data base approach.

ADVANTAGES/DISADVANTAGES

In this section the main advantages and disadvantages of the online data base are summarized. The main advantages are as follows:

1. The new analyst is able to produce practical reports sooner with a limited amount of SAS knowledge due to the simpler record format.

2. A large volume of data is available online, with tapes used for long term data.

3. Several fields are summarized in higher timespans. As a result fewer observations are needed to retrieve data covering various periods of time. To illustrate, four RMF records would be needed to cover an hour. In MICS only one record would be required in the DAYS timespan. Summarization in this timespan is done to the hour.

4. More than one type of data is available on a single data base. For example, SMF and IMS data can be collected in one program by using a procedure that provides read only access to more than one data base unit.

As good as the online data base is, it does have a couple disadvantages which are as follows:

1. The data base is not available during updating. In other words programs cannot be executed against the data base while data is being reformatted from the raw record.

2. A data base of this type tends to use a large amount of disk space. In the case of MICS not all timespans are activated for all files. Various value judgements were required to best produce a data base which is practical while using a minimum amount of space. Disk space will vary depending on the amount of data the user desires to keep online.

3. People and machine resources are required to establish, maintain, monitor, and update the data base itself and the data base system.

4. Fields and summarizations may not always be in the desired form.

5. By using data that is "one step removed" from the originally recorded data, one always runs the risk of making mistakes of interpretation or misunderstanding.

CONCLUSION

Any new analyst faces the responsibility of bringing himself up to speed as efficiently and quickly as he can. This task is done through training and on the job experience. If part of his duties is the accessing of SMF data, then an online data base can make this learning process go a little faster. In using the MICS Data Base as an example, it has been shown how a well organized collection of SAS files can simplify SMF data extraction. As a result the new analyst feels a little less awkward and gains confidence that he can do his new job well.

METHODOLOGY TO DEVELOP A TOOL FOR MONITORING CPU USAGE BY APPLICATIONS RUNNING UNDER VM

Robert D. Deese
Hossein H. Ghannad
IBM Corp.

ABSTRACT

In CMG 86 at Los Vegas, Nevada a need for a tool that would report different applications CPU usage running under VM was mentioned more than once. This is very important information for a capacity planner who has to determine in a timely fashion whether a larger processor is needed. A given VM installation may run several different applications. The CPU resource requirement of these applications are usually different and when a user growth projection is made, they are made for each and every application. The combination of knowing the average CPU resource requirement for each application and the projected usage growth for that application allows the capacity planner to accurately project the size of the CPU to be obtained.

In this paper we will describe a step by step methodology to build a simple tool using existing VM capabilities (REXX and CP internal timer facility) to monitor CPU application usage by one or more users.

1. INTRODUCTION

One of the most important function that a capacity planner performs is to order and procure a higher capacity central processing unit (CPU) before the existing one becomes over loaded. This is important for two reasons. First, it usually takes between three to twelve months from the time the determination for a larger processor is made and the time the processor is actually installed. Secondly, as the utilization of any computer resource, including CPU, approaches its threshold, usually 90-95 percent for CPU, the response time passes the knee (or elbow) of the throughput/response time curve (see figure 1) and becomes excessively large. This is not a desirable situation to be in for a capacity planner unless he/she likes to spend a lot of time, usually on the telephone, explaining long response times to users who in many cases have to interface with customers who may be even less patient.

One of the ways capacity planning is usually done, as far as CPU is concerned, is by determining CPU consumption for an 'average' user for an 'average' session. The projection of increase in the number of users is usually obtained from other departments in an organization. Simple arithmetic yields the amount of more processing power which would be needed if the increase in the number of users projection is realized.

One of the problems that many capacity planners run into is determining resource consumption, in this case CPU, by the 'average' user. For some systems this is not difficult because all users of that system interface with the same application and basically use the system for the same type of activities.

VM/CMS, is an interactive system which is used for many purposes such as program development, numerically intensive computing, document development, office management system by the same or different users. The CPU requirements of these activities may be considerably different. A good example of this is the difference between CPU resources requirements of a physicist, who mostly runs numerically intensive routines that are precompiled and stored on a system, versus an executive or secretary that may deal mostly with office communication and scheduling. If the projected growth in user population will have a different distribution than the present one or the character of the user population is to change, that is, same group of users using the system differently than before, then the capacity planner needs to know the CPU requirement of an 'average' user for a given type of activity or how much CPU is consumed by an application per user. In the sections that follow we introduce a methodology which uses existing VM/CMS capabilities and functions provided by the system to answer the questions needed by capacity planner to make a more accurate projection of the size and time of CPU upgrade.

It is also our intention to show that this tool can be easily built within ones own shop with little or no additional skills. As is true with any programming tool, there is more than one way of obtaining the same solution, including the use of other programming language. We used the Restructured Extended Executor(REXX) language, which is processed by the System Product Interpreter, and the Control Program (CP) internal timer facility. It is the authors opinion that learning the REXX language is easier or as easy as learning any other 'high level' programming language. The use of timer facility is very trivial and is matter of executing a system provided command (Query TIME). The objective is to implement a monitoring tool which will be virtually transparent to the user. This tool will calculate the total CPU time (virtual and overhead) and the virtual CPU time used per application and also keep track of the total elapsed time while using these applications. A running tally must be kept which can be either directly used or reduced and used by the capacity planner for his or her user growth projections.

2. SELECTING USERS

The number and type of users to be selected for monitoring depends on several factors. First, the capacity planner needs to obtain the user and/or application usage growth projection from other departments based on the establishments future activities and growth. Secondly, the capacity planner needs to determine the type of users and their computer system activities. For example, there may be a projection of thirty percent increase in office management system usage, ten percent in data base management application usage, and three percent in numerically intensive computing type usage.

The actual number of users to be monitored depends on the variability of resource usage by the users. This may be statistically determined with a high confidence level if statistics (means and variance) for the processor usage is available. The rule of thumb is the larger the variation, the more users should be selected. If there are no statistics available, a few users of the applications under study may have to be monitored before one can determine how many users of each application should be included in the study to project the future CPU capacity need. We should point out that sometimes additional sessions from the same user may be substituted for more users. This can be done if users engage in different types of activities from day to day.

Once the user selection for monitoring has been made and the number of sessions determined, the tool and an introduction to it should be sent to the selected users. The introduction should include a brief description of the tools purpose, similar to an abbreviated version of our introduction, and a brief description of the tool and its function.

Once the tool has been stored on the users disk, they simply include its invocation in their user profile. From there the tool will run transparently.

3. THE TOOL DEVELOPMENT METHODOLOGY

The first step to collecting the needed data is to create a CMS input file. This is easily achieved in REXX by using the System Product Editor (XEDIT). Before the file is actually created, two commands are needed, which are put in the command queue. These are the commands to write the current data to the file and to store the file on the users disk for further update. The data is used for two purposes. First, is for tracking and recognition of the trace, and second, to enable storing the file on the disk (the system will not store an empty file on the disk). Once these commands are in the queue, the file is created by issuing an XEDIT command in the REXX program. The date inserted, the file is stored on the users disk for further data input over the monitoring period.

Once the above action is completed, the user is prompted with a ready message to start his work with the tool running transparently. From this point until exiting the tool, commands entered will be read into a template (a special variable to store strings). A 'while' loop is used to read every command that issued by the user. If the command issued by the user is not the 'LOGoff' command, the code block that holds the bulk of the program is entered via a subroutine call.

This subroutine will issue a query of the CP internal timer facility and assign the returned information to a variable called STARTCOMMAND. The command who was stored in the template is then issued for execution by the system. The execution of the command is carried out as usual without any interference by the tool. Upon completion of the command, the CP internal timer facility is again queried and the returned information assigned to another variable called FINISHCOMMAND.

To convert the times which are in string form to real time in seconds three function calls are made to two different functions. The Querying of the time supplies the STARTCOMMAND and FINISHCOMMAND variables with time and date information, from which, the tool uses the following: the actual clock time spent in the current terminal session, the virtual processor time and the total processor time used in the current session terminal. The actual clock times were in hours, minutes, and seconds which were converted to seconds in the functions, before total elapsed times were calculated. The other two times (VTIME, TTIME) are given in minutes and seconds. Therefore, we used a different function to convert and calculate the VTIME and TTIME. The functions started by parsing the string stored in STARTCOMMAND variable to isolate the processor times or actual clock time. This substring is then converted into seconds and put into STARTTIME variable (the actual clock time also contains a hour variable which also needs additional conversion). Upon completion of the command stored in the template, this process is repeated with the FINISHCOMMAND variable by calling the same functions. This time the functions return the converted values in FINISHTIME variable. Then STARTTIME variable is simply subtracted from the FINISHTIME variable to generate the processing and/or elapsed time per command.

Many commands are truncated to give a shorted version of the command word for ease of use. Many users also do this for their own use in a synonym file. The truncated commands and synonyms are compared with the full command word and all truncated commands and synonyms are then converted to the full command word. This is done to make the reduction of the data and calculating total times per session for a given command easier.

With the needed times calculated and the command words in suitable form, they are gathered together and formatted into one variable. A command which allows for I/O operations to VM/CMS files is now issued to write the formatted variable containing the required data to the monitoring file.

The user is now prompted for their next command. If the entered command is not the 'LOGoff' command, the loop is reentered and the above process repeated. However, if the user is logging off their machine, the loop and the program is exited. The monitoring file is then sent to the capacity planner or other person responsible for monitoring the data. The monitoring file is erased from the user minidisk and the user is logged off.

4. DATA REDUCTION

As we mentioned earlier, the monitor program writes the command, the total processing times (VTIME and TTIME), and elapsed time for each command into a CMS file. We wrote a simple PASCAL program to reduce the data. The program first reads the command, whose total processing time during the session is desired, from a CMS file. This file is created using XEDIT and includes a list of one or more commands. Then the reduction program searches the monitor file for all the occurrences of that command and adds the three above mentioned times together and writes the command and totals into a third file for later inspection. We used an appended function of CMS to create one file from several sessions of the same user or from several users whenever we wanted to look at accumulative CPU consumption of each command for more than one user or session.

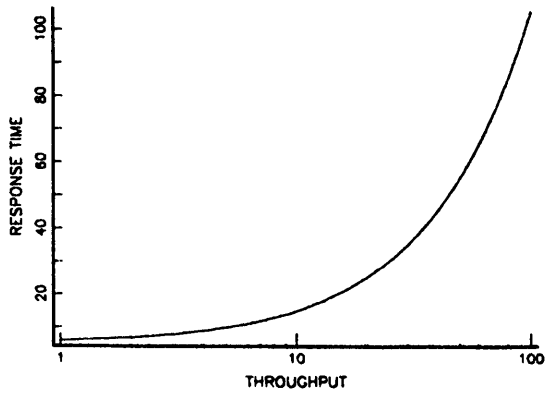
5. SUMMARY

In this tutorial paper we restated the need to develop a tool to monitor and report the CPU consumption of applications running under VM/CMS. We introduced a methodology to develop such a tool using existing VM/CMS facilities. We also presented a high level algorithm which we coded in REXX, and described a simple data reduction program to provide the results for analysis or further reduction. It is the authors opinion that a tool built using our description would be of great help to capacity planners of VM systems in determining their future processing needs.

HIGHLEVEL DESIGN OF OUR ALGORITHM:

```
Create a Monitor File
Enter Desired Command or Application
While the Entered Command is Not LOGoff DO
  Call a Subroutine to:
    Query the Time
    Execute the Command or Application
    Query the Time
    Call a Function to Calculate Total CPU Usage
    Call a Function to Calculate Virtual CPU Usage
    Call a Function to Calculate Total Elapsed Time
    Format the Collected Data
    Write the Formatted Data to the Monitoring File
    Return
  Enter Next Command or Application
End or Repeat the Loop
Send the Monitor File to Persons responsible for
  Data Collection
Erase the Monitor File
Log off
Exit
```

FIGURE 1– A TYPICAL RESPONSE TIME/THROUGHPUT CURVE



CICS PERFORMANCE AND WORKLOAD REPORTS

Chuck Comstock
Hallmark Cards, Inc.

ABSTRACT

Reporting the "health" of CICS systems was once a problem of lack of sufficient performance data. In today's world of RMF, CMF, TMON, and other performance monitors, the converse is more often the case. Reducing hundreds of thousands, or perhaps even millions of detail performance records into meaningful performance and workload reports is a significant challenge.

This paper will examine some of the more important performance and workload indicators and appropriate statistical measures, summary levels and trend analysis, and issues that should be kept in mind when creating or analyzing CICS performance and workload reports.

Introduction

Today there is a profusion of CICS information available from a variety of monitors and data collectors. Reducing this mass of data to to something meaningful and useful requires some understanding of what is available and what is needed. Regardless of the specific performance monitor being used, however, two broad categories of system metrics should be collected and reported: performance data and workload data.

Performance measures indicate how well the system satisfied requests for service. Performance indicators consist primarily of response time, or how long before a request was completed, and throughput, or how many requests were processed. Unfortunately there are several different ways of reporting these metrics. Considerations will be covered in more detail in the sections on Simple Descriptive Statistics and Summary Levels and Trend Reports.

Workload statistics show the demand for system service. Some workload measures are: transaction input rates, CPU utilization, data access request rates, and memory requirements.

Of course some measures fall into both categories. Transaction rates are primarily a measure of workload but, depending on availability of resources, they can also be a measure of performance.

Simple Descriptive Statistics

Simple descriptive statistics should be just that: simple, descriptive measures of performance and workload. Most of the classical statistical measures are useful when reporting one or another of the performance and workload indicators. Some forms are more appropriate with certain metrics and considerations will be covered with each statistic below.

Some of the most frequently used statistics and metrics are:

- Averages
- Sums (totals)
- Minimums/maximums (range)
- Percentages/percentiles
- Rates

Averages

Perhaps the most frequently used and, therefore, abused statistic is the average. "Average" response time is often the performance analyst's cop-out, particularly when it represents goodness.

Our obsession with the average is probably due in large part to the fact that it is something easily related to. For example, most can easily tell the difference between half second response and five second response, or, as an old saying has it, if you notice response, it is too long.

The problems with averages that most of us have experienced fall into two categories: (1) outliers that ***skew*** the average up, e.g., the presence of a few very long running transactions, and (2) outliers that ***skew*** the average down. While the latter may usually be dismissed, the former is hard to ignore.

One solution to the problem of a few outliers skewing an average is to use a ***percentile*** or ***percentage distribution*** approach. For example, instead of reporting average response time, express response in terms of a percent of the total completing in less than some arbitrary time, say, three seconds.

The disadvantage of the percentile approach is that it may be difficult to relate to. The obvious advantage is that a few extreme observations will not skew it. An excellent discussion of the percentile/distribution technique may be found in the *Morino Associates Technical Tips, Volume II.*

Another solution to the average skew problem is to discard, or at least ignore, the outliers. Since most long running transactions are doing "background" work anyway, their elimination from the reported response time is justified. Our view of response time is that what we should report is what the true ***interactive*** user is experiencing, not some non-terminal attached "batch" transaction.

One technique of determining if a transaction should be ignored when calculating the average is to set thresholds for resource consumptions. Transactions that exceed the thresholds become candidates for exclusion from the average response time calculation. A transaction that performs several thousand data base calls, for example, can hardly be expected to execute with subsecond response time, at least with most of today's software and hardware.

Fortunately, most performance monitors and post-processors allow some degree of control over the transactions used for reporting. Morino's MICS system, for example, provides a ***relative longevity*** exit (CICRLRT) that allows for ***typing*** CICS transactions based on any user developed algorithm. Transaction typing has existed in the TSO world for some time as a real-time prioritizing technique (are you listening, Hursley?), and while not available to us in real time, at least the concept is useful after the fact.

In reality it may be appropriate to report both averages and percentiles, understanding the limitations of each. If the average exceeds the bounds of good taste we at least can refer to the percentile to gauge what the appropriate level of crisis reaction should be.

The following are candidates for reporting as averages or percentage distributions:

- Response Time (Internal)
- Wait Time (VSAM, DBMS, Journal, Terminal)
- Suspend Time
- CPU Time

Sums (Totals)

Our delight in small numbers for response time is equalled only by our joy in large numbers for total transactions processed.

While a one-million transaction day may be impressive to the casual observer, to the performance and workload concerned individual this total is only interesting in so far as it relates to yesterday, or last week, or last month, or last year. Summary levels and historical trends will be discussed in more detail later; suffice to say that totals may be a useful measure of not only workload but also performance.

Some measures that may be reported as totals are:

- Transactions
- Data Access Requests (VSAM, DBMS, Journal, Terminal)
- Availability (Up Time/Down Time)

Minimums/Maximums

Minimums and maximums may be considered a high level view of variability, a measure easier to understand than standard deviation or coefficient of variation. In reality, it has been our experience that maximums seem to be more helpful than minimums and minimums can safely be ignored in most cases.

A maximum, taken along with an average, can be informative. If the variance between the two is large we know the possibility exists that the average has been skewed up to a significant degree. Also, particularly when analyzing several transactions, the presence of similar large maximums may be an indication of a common problem such as file string contention, enqueues, or even hardware problems.

The most useful indicators to report as maximums seem to be:

- Response Time (Or Wait Times)
- CPU Utilization

Rates and Percentages

Rates, such as transactions per second or data base calls per transaction, are useful because they take a sum or total and make it into a more easily understood number and make comparisons easier. For example, isn't it easier to relate to 4 transactions per second than 345,600 per day?

Likewise for percentages. Knowing that a CICS system consumed 28,800 seconds is not very revealing. Understanding that this is 80% of the system may raise a few eyebrows.

The following are good indicators to report as rates and percentages:

- Transactions Per Second (Minute/Hour)
- CPU Utilization
- Data Access Requests Per Second (VSAM, DBMS, Journal)
- Data Access Requests Per Transaction
- Page Ins Per Second
- Page Ins Per CPU Second
- CPU Per Data Access Request
- Terminal Characters Per Transaction

Summary Levels And Trend Reports

From detail, transaction by transaction reports to the annual summary, there are many different levels of summarization possible. Consider:

- Detail (1 observation per transaction)
- Interval (5-60 minutes)
- Hourly
- Shift (zone)
- Daily
- Weekly
- Monthly
- Quarterly
- Yearly

Each summary level is appropriate for different levels of management, from the performance analyst to the MIS Director or the executive board.

The sample report shown at the back of this paper is a daily report that reflects daily totals, some shift breakdowns, an hour by hour summary, and some trend reports in the form of daily averages and summaries.

It has been our experience that this report works well from middle management down to the performance analyst. The first page (daily summary and averages) is often the only page referenced. Anyone with experience using this report has a fair idea of what is "good" and what is "bad." If the first page reflects goodness, then that is it. On the other hand. . . .

When an element of evil creeps into the daily summary we would like to have as many answers as possible contained within the report without having to refer to other data or run additional reports.

The hourly reports provide some insight into the distribution of the "badness" and, if the problem is isolated to a small portion of the day, the approximate time of the difficulty. Of course, if the whole day looks bad, that tells us something as well.

Finally, the trend reports, charts or significant performance statistics by day for the last week or so, can reveal just how bad the situation has become and whether or not the problems have occurred recently.

Almost identical reports are also produced on a weekly and monthly basis.

Closing Comments

One of the significant performance software developments of the last 5-10 years has been that of the Performance Data Base (PDB) management systems such as Morino's MVS Integrated Control System (MICS), BGS Systems Info-Base, and Merrill's MXG.

These systems build data bases of performance data summarized to the individual user's needs (and availability of DASD to store it!).

Several of these systems use SAS Institute's SAS as the base language and data management system, or provide interfaces to SAS. The power and flexibility of SAS in conjunction with a PDB was a major factor in our ability to provide a variety of reports at various summarization levels.

While Artificial Intelligence and Expert System technology will address the issues discussed in this paper, there may always be a need for reports similar to those outlined here. The challenge will always be to provide the most amount of required information in the most meaningful manner in the least amount of space.

The author gratefully acknowledges the assistance and advice provided by Shawn Wikle, Joe Bell, Irwin Kraus, Nathan Walsh, and technical support personnel from Morino Associates.

AN INTRODUCTION TO PROGRAM-TO-PROGRAM COMMUNICATION AND PEER-TO-PEER NETWORKING IN AN IBM SNA ENVIRONMENT

Thomas W. McDonald
MGT Technology Group
Natick, MA

ABSTRACT

Systems Network Architecture (SNA), IBM's communications architecture, is currently undergoing major enhancements which allow for the support of distributed transaction processing, program-to-program communication, and peer-to-peer networking. This paper looks at the developments which precipitated the new communications requirements, and the major architectures and products that facilitate these enhancements, including Logical Unit 6.2(Advanced Program-to-Program Communication), Physical Unit 2.1(Low-Entry-Network), APPN(Advanced Peer-to-Peer Networking), and related office systems applications.

1. INTRODUCTION

Historically, users of information systems have submitted specific transactions to be executed on centrally located mainframe computers. Today, as the nature of both the business and technological environments becomes more complex, users look toward the submission of business problems (rather than simple transactions) to dispersed information systems and resources. The challenge facing data processing and networking is to leverage all of the various resources or systems to provide integrated business solutions to the user.

This paper discusses the changes in the network services environment that are necessary for the information system to meet these user needs.

Since 1974 when IBM first announced SNA, the architecture has evolved to meet the needs of the user of traditional hierarchical SNA networks. In this traditional network, a user located at an unintelligent workstation communicates in a master/slave relationship with a centralized processor and information source. A typical SNA network has consisted of one or multiple mainframe processors, centralized databases, and a large number of dispersed terminal users (e.g. users stationed at 3270 CRT's or printers). These terminals are typically located at unintelligent workstations, (e.g. 3174 or 3274 cluster control nodes). (See figure A.)

The user of a terminal at an unintelligent, or **limited function work station** (**LFWS**), is heavily reliant on a central processor for application processing, message route determination, and management control functions such as component activation and deactivation. This hierarchical master/slave relationship between mainframe processors and LFWS's adequately serves the needs of users conducting inquiry/response work to centralized points of information.

However, the traditional 3270 user who wishes to step beyond the master/slave, inquiry/response profile and into the realm of distributed transaction processing and peer-to-peer communications, finds him or herself limited by the incompatibility of communication protocols between different products and the nonexistence of local processing and local network management.

2.0 FORCES DRIVING THE NEW ARCHITECTURE

The end-user's demand for the network to provide services beyond the traditional boundaries of the master/slave relationship has been primarily fueled by two forces: the replacement of the LFWS by intelligent workstations, and corporate and MIS management's perception of the network as a strategic tool. These two forces have come together to breed new access to information for the network end user.

2.1 The Intelligent Workstation

While the 3270 remains the mainstream terminal product populating SNA networks, recent changes in end user requirements outreach the abilities of the 3270, its datastream, and the architecture which supports it. The limitations of the 3270, coupled with breakthroughs in microprocessor technology have caused the replacement of many 3270's by stand-alone microprocessors such as personal computers(PC`s), and by multi-user departmental systems such as the IBM System/36, System/38, 9370, 5520, 8100, the DEC VAX and other minicomputers. This paper will generically refer to stand-alone microprocessors and multi-user departmental systems as **intelligent work stations** (**IWS**).

The IWS brought processing power and data storage and retrieval capabilities to the departmental and desktop level of operations. As the IWS began to populate SNA networks, users became aware of the potential for greater flexibility and for the desire for interconnection between systems. For example, a user of a personal computer may wish to have the independence of a stand-alone processor but at the same time have the ability to share files with other PC's and to access departmental systems, as well as maintain the mainframe access he or she experienced as a 3270 user. A departmental system such as a System/38 may wish to have access to other departmental systems for resource and database sharing, have access to a centralized mainframe database for periodic information updates, as well as serve as a departmental processor for its directly attached devices.

The SNA architecture provides services to network users in the areas of applications support, logical services support and physical services support. As the IWS begins to take a predominant place in SNA networks, the profile of network usage changes. This support of applications and physical and logical services had to be expanded to support the users at these intelligent stations.

2.2 CORPORATE MANAGEMENT'S MOTIVATION

The second force that drove the need for major enhancements to the network architecture was management's growing perception of the network as a strategic tool within the corporation. Corporate management recognized a competitive edge in providing "any-to-any" functionality by incorporating the separate and specialized networks into a single homogeneous corporate network, while at the same time retaining departmental autonomy. This motivation to produce an integrated, homogeneous environment was propelled further with the perception of the "extended corporate environment", i.e. the idea that for maximum competitive edge, the corporate network should reach out to include the company's suppliers, sellers, and customers.

As the view of the network as an integrator which ties together disperse groups throughout the company and extended enterprise grows, the ability to provide accessibility to corporate wide resources for any user across a homogeneous network becomes a central deliverable of network services. This means that a user at a terminal or an IWS must be presented with a single window to data, corporate-wide.

3.0 A NEW NETWORKING ENVIRONMENT

The local availability of processing power and data retrieval capability that the IWS brought to SNA, along with the new requirements for end user flexibility which resulted from it, came together with management's perception of the network as a strategic resource to breed new distributed applications and service needs. These include: decision support systems and office system applications, such as message delivery, document exchange, and distributed library functions; the need for centralized network management; and the ability to take advantage of the cost savings inherent in the integration of separate networks, especially voice and data integration.

These new applications and service needs spelled trouble for an architecture that was designed to support communications in a hierarchical fashion. In a network which includes IWS's, intelligence is no longer located at a central serving point but is distributed among IWS's.

An IWS looks much more like an equal to a mainframe processor than a slave. It contains a processor, an operating system and data storage capability. A network architecture that provides for a master/slave relationship only, will either not allow the IWS to exercise all of it's capabilities, or force the end user to write their own communication support services. In the integrated network, both hierarchical as well as peer to peer communication must be supported. (See figure B.) As a peer, the IWS would be able to independently initiate and terminate communication with another user, as well as control processes such as error recovery.

3.1 DISTRIBUTED TRANSACTION PROCESSING

To take advantage of the power of the IWS, processing power and information banks are distributed away from a centrally located processor to IWS's that are local to the end user and which may be targeted for specific departmental functions. This use of IWS's and the related ability to distribute intelligence between nodes leads to the ability to execute distributed transaction processes. The new application requirements stated above execute by **distributed transaction processing.** It is the need to support distributed transaction processing that is the driving force behind the changes in SNA's logical and physical services and applications support.

Distributed transaction processing involves two or more transaction programs, cooperating via program intercommunication to share each other's resources such as processor cycles and data bases. Distributed transaction processing takes place when a business transaction, generated on an IWS or a mainframe computer, can be broken into components and separate components can be executed on separate targeted machines. A machine may be targeted because of processor function, data handling or retrieval abilities, or physical location. These independent executions are brought back together at an IWS or a mainframe and a single presentation image is presented to the end user.

3.1.1 AN EXAMPLE OF DISTRIBUTED TRANSACTION PROCESSING

Figure C shows a possible network configuration for an insurance company. Remote field personnel use a personal computer to communicate with a regional departmental System/38 for regional customer information, a System/36 for price quote information, and a System/370 for policy forms and issuance.

In this example, the field worker needs to respond to a request from a potential client for an automobile policy. An application in the PC responds to the field worker's query by initiating multiple transactions.

The PC initiates a transaction with the System/38 requesting customer history information; a second transaction is

A HIERARCHICAL SNA NETWORK

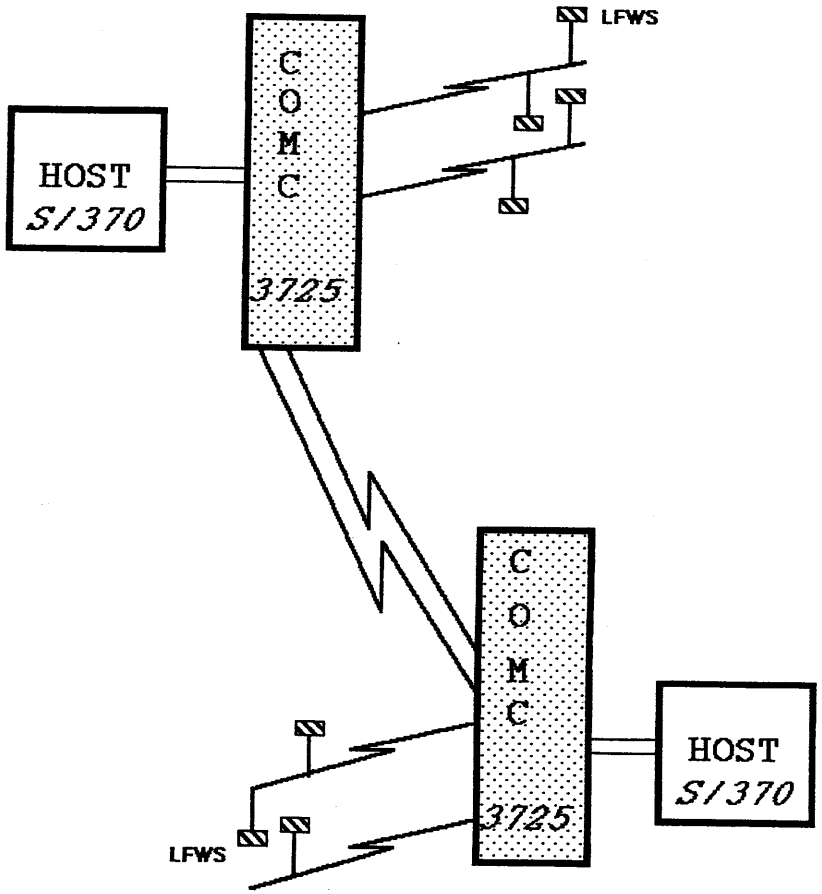

FIGURE A

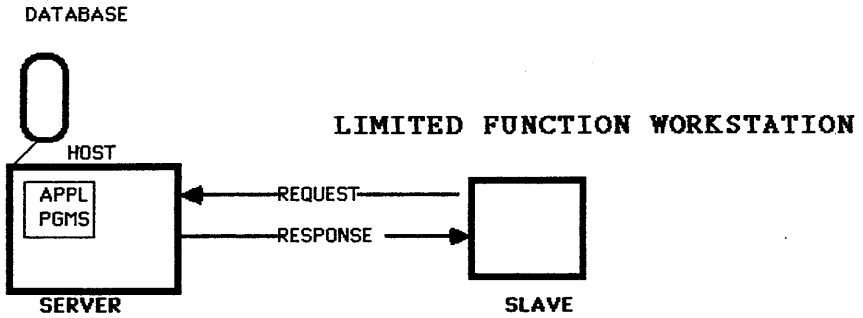
MASTER/SLAVE



PEER-TO-PEER

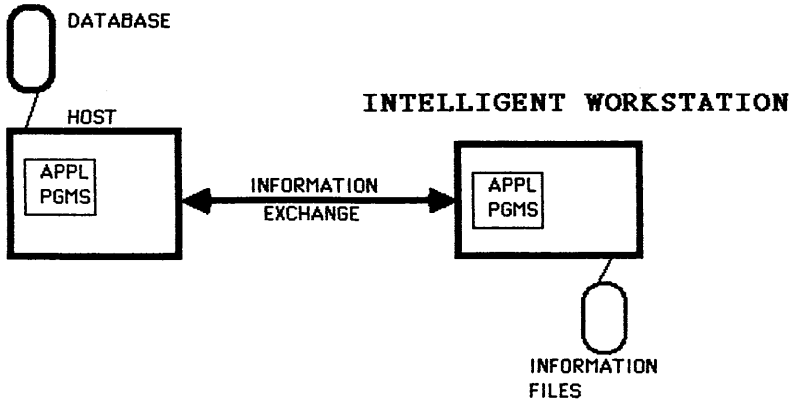


Figure B

DISTRIBUTED TRANSACTION PROCESSING

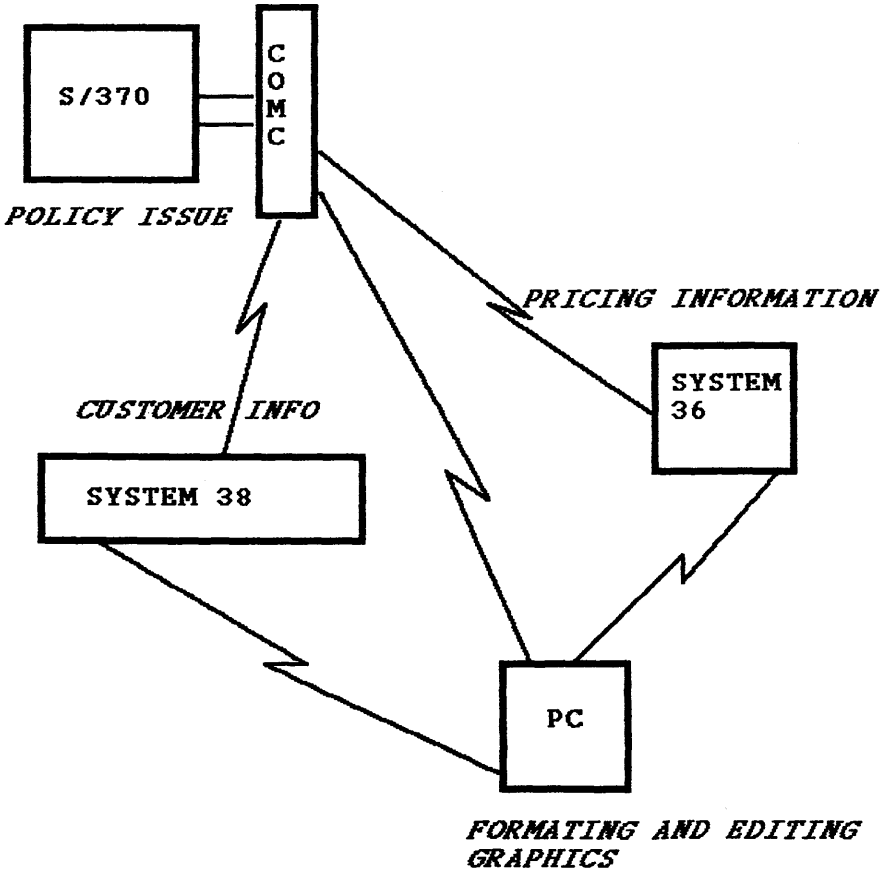

Figure C

CONVERSATIONS AND SESSIONS

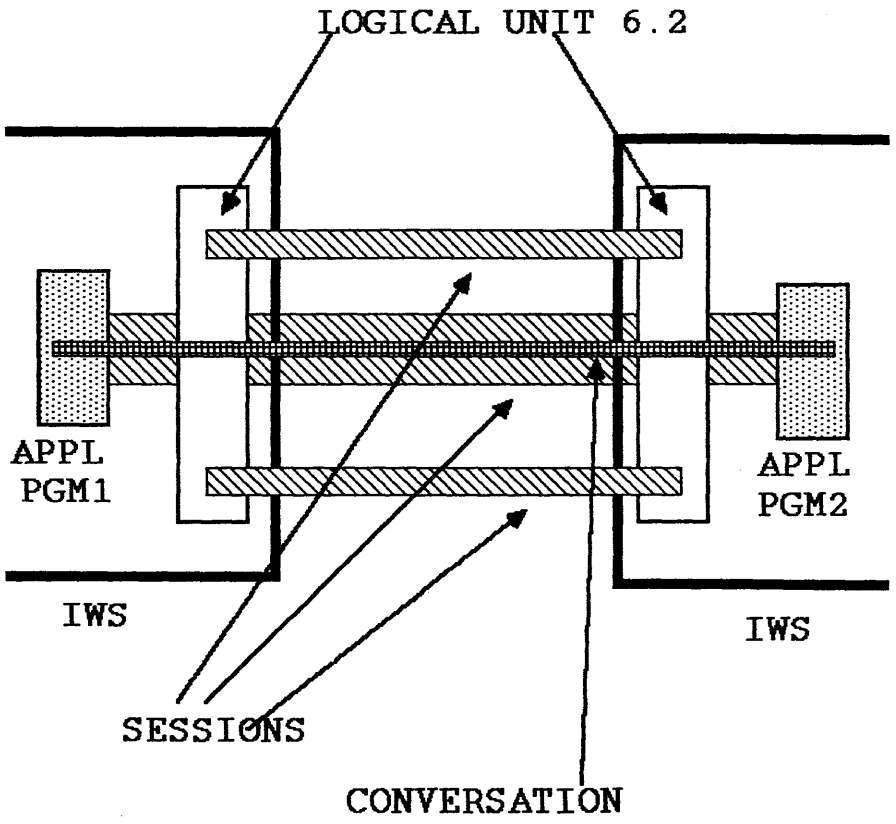

Figure D

initiated to the System/36 for price quotes. (The System/36 may respond with a request for the customer information that the PC has received from the System/38 before it responds with the pricing information.)

Once the PC has received the pricing and customer information, it forwards it to the System/370 for policy issuance. The System/370 issues the policy and sends the information to a printer. The System/370 sends notification to the PC that the policy has been written and indicates the location of the printer.

In a distributed transaction processing environment the concept of an end-user has changed from the traditional sense. In a distributed transaction, the end user is often represented by an application transaction program rather than by a user at a terminal as it is in a hierarchical network. The interchange of information is between application transaction programs on distributed processors.

3.2 NEW SUPPORT NEEDS

The SNA communications needs that exist for a network which supports IWS's as distributed processors are dramatically different than those between mainframe application and LFWS. A communication architecture which provides physical, logical, and application services to meet these needs must provide for the following:

1) Support of peer-to-peer communications between distributed processors. This allows communication to take place within SNA between intelligent stations without the intercession of a mainframe computer.

2) Support of common communications protocols between intelligent stations. This allows users at mainframes, departmental processors, and PC's to readily communicate with one another.

3) Standard application program interfaces to network services. This allows applications developed across different processors and products to readily communicate with one another across a common network.

4.0 MEETING THE NEEDS OF THE NEW NETWORK ENVIRONMENT

These three major needs are answered in SNA by the definition of new logical unit and physical unit types. Brief definitions follow:

Logical Unit - A port through which an end user accesses the SNA network in order to communicate with another end user. Communications services are accessed by the end user via the logical unit.

The SNA logical unit provides the port between the transaction programs and the communication path which ties them together. It allows a transaction program to invoke remote programs and to exchange data between them.

Physical Unit - The SNA resource in each node responsible for managing and monitoring the subordinate resources attached to the node. Examples of nodes are a host processor, 3725 COMC, 3274 terminal controller.

4.1 LOGICAL UNIT 6.2

It is **logical unit 6.2** that provides the common communications protocols which facilitate the coordination of processing between distributed transaction applications and the transfer of data between users of different systems. Logical unit 6.2 was designed specifically to support communication between distributed applications programs. It defines communication protocol for moving data between users and provides services that coordinate data exchange and flow between distributed applications.

IBM markets this facility under the name of **Advanced Program-To-Program Communication (APPC)**. Logical unit 6.2 and APPC are used interchangeably in current literature.

4.1.1 STANDARD INTERFACE BETWEEN THE APPLICATION AND THE LOGICAL UNIT

One of the attributes which makes logical unit 6.2 unique against previously defined logical unit types is its support of an architectured verb interface. A transaction program uses logical unit 6.2 to communicate with other transaction programs by issuing transaction program verbs.

This verb interface provides a common way for applications to request services of logical unit 6.2. It allows a transaction application written on one distributed system to use logical unit 6.2 protocols and to operate compatibly with an application on another distributed system or on a mainframe which also uses logical unit 6.2. For example, an application which wishes to establish communication with a second remote application would issue an **Allocate** verb to logical unit 6.2. The logical unit would then establish communication with the second application by the initiation of a conversation between the two users.

The capabilities within logical unit 6.2 can be broken into subsets of a base set of functions and optional sets. All products which support logical unit 6.2 must support the base set of protocols. This insures a common communications protocol between logical unit 6.2 stations. (A list of the basic set of verbs can be found in Table one. Each verb maintains a parameter set).

Additional functions such as advanced recovery procedures, specialized error detection, and security routines are implemented on an individual product basis

by the issuing of optional verbs. The use of base or option sets is communicated by the distributed transaction applications who wish to transfer information by an information exchange that takes place at SNA session initiation. This insures compatibility of protocols between the conversing applications.

4.1.2 ESTABLISHING COMMUNICATION VIA LU6.2

Another important aspect of logical unit 6.2 is its ability to support:

1) Multiple sessions between logical units.
2) Multiple conversations over a single SNA session.

A **session** can be defined as an exclusive logical connection between users in an SNA network. In order to communicate, users must be "in session". In hierarchical SNA networks, end users can support a maximum of one session at any one time. When a user wishes to break communication with one user and start communication with another, the session with the first user must be brought to an end, and a new session initiated with the second user.

As end users add function, this single-session limit becomes restrictive to smooth operations. As the terminal user is replaced by an IWS, the restrictions seriously limit the practical application of the IWS.

To illustrate this problem consider an example in which an end user is an application on a System/36 supporting multiple terminals. Multiple users may be requesting that the System/36 application be transferring data between a local application and other remote applications. If only one communication could be occurring at a time, and if communication had to be broken and reestablished for each transfer of information for a different user, a performance bottleneck would likely occur.

To prevent such a bottleneck from occurring, logical unit 6.2 allows multiple sessions to exist concurrently between users. Users use the session as a resource. They establish communications across that session by establishing a **conversation.** Conversations may be interleaved over a single session without breaking and reestablishing communication.

A conversation can be thought of as a session within a session. It gives the end users exclusive use of the session for the duration of the conversation. It is a conversation that the logical unit initiates in response to the Allocate verb from the application. When a deallocation takes place, the conversation is terminated and another conversation may be established by the same users or other users on this session. This allows communication to be established and broken without session binding and unbinding overhead.

The exclusive relationship which tied a particular session to specific users no longer exists. The logical unit 6.2 session is now a shared resource. (Figure D illustrates the uses of sessions and conversations between users of logical unit 6.2.)

Logical Unit 6.2 is transparent to the protocol of the communications link. It is therefore compatible with IBM's Synchronous Data Link Control(SDLC), X.25, and local area network(LAN) and private branch exchange(PBX) protocols.

4.1.3 SUMMARY OF LU 6.2 CAPABILITIES

Logical unit 6.2 facilitates communication between users of the integrated network by:

1) providing a standard verb interface between transaction application programs and the logical unit services. This provides access to communication services that establish and coordinate data exchange between distributed applications.

2) providing common sets of communication attributes between distributed users. This allows communication to take place between users in disimiliar environments.

3) facilitating interleaved conversations and multi-sessioning.

4.2 PHYSICAL UNIT 2.1

Physical unit 2.1 allows peer-to-peer communications to take place. It does this by :

1) providing connectivity enhancements

2) facilitating local network management and control

4.2.1 CONNECTIVITY ENHANCEMENTS THROUGH PU2.1

Physical unit 2.1 allows remote IWS's to directly link-attach to one another and provides multiple link support for the IWS.

To carry out peer-to-peer communications it is necessary to have the ability to directly connect IWS's to one another and to have the ability to connect to more than one station at a time.

The most common SNA control units, the IBM 3174 and 3270 family of cluster controller nodes, are SNA physical unit 2.0's. The PU 2.0 supports only one link attachment and this attachment must be to a more intelligent device such as an IBM 3725 communications processor, or an SNA host. The physical unit 2.1 incorporates multi-link support into the workstation, as well as provides for the ability to connect with another physical unit 2.1, or with a communications processor or SNA host.

4.2.2 NETWORK MANAGEMENT/CONTROL ENHANCEMENTS WITH PU2.1

Physical unit 2.1 provides network management and control capabilities local to the IWS.

Traditionally, the SNA host has been the center of the network. It is from here that the hierarchical network is defined, operated, and managed. The component in the SNA host that handles these tasks is the **System Service Control Point (SSCP)**, which is resident in the host access method.

A subset of the SSCP functions has been moved into the physical unit 2.1 as the **Single Node Control Point (SNCP)**. (In some manuals this is referred to as the Network Node Control Point.)

The SNCP provides the distributed node with the ability to provide network management control such as activation and deactivation of network resources and the ability to resolve network addresses and conduct session establishment in a peer to peer context. This frees the distributed processor from dependence on the mainframe and the SSCP for communication management functions.

The implementation of physical unit 2.1 with logical unit 6.2 (also called **Low-Entry-Networking(LEN)**), puts in place a mechanism which allows IWS's to communicate within a full-function SNA network, in a peer-to-peer and application-to-application fashion without a mainframe processor.

An IWS using logical unit 6.2 has the option of communicating with a mainframe or with a peer workstation. To communicate with a mainframe, a logical unit 6.2 workstation does not need to implement physical unit 2.1. Currently, when a physical unit 2.1 communicates with a mainframe, it does so under control of the SSCP, and in a traditional master/slave manner (see figures E and F). The logical unit 6.2 capabilities in the host may reside in a VTAM application subsystem (currently CICS is the only subsystem offering this support), or as the following section discusses, this support will soon reside in VTAM.

4.2.3 VTAM SUPPORT FOR LU6.2

IBM recently announced logical unit 6.2 support within ACF/VTAM. VTAM is the communications access method resident in a mainframe computer. The SSCP resides in VTAM. This support means that all VTAM based application subsystems (e.g. IMS, CICS, TSO) will have logical unit 6.2 support through VTAM. Previously, only CICS maintained support. This support is scheduled to be implemented in the third quarter of 1988.

One important benefit of this support is that users at an IWS may now look upon their counterparts in a System/370 as peers. The IWS may behave as a primary or secondary logical unit in its communication with the S/370 and may maintain multiple sessions. This breaks the master/slave relationship between the S/370 and its users. The user may now view the S/370 as just another IWS. With this implementaion, the communication depicted in Figure B will become a reality.

4.2.4 SUPPORT FOR 3270 APPLICATIONS

As logical unit 6.2 applications are developed, 3270 applications will continue to serve as the dominant sources of information for network users for the near future. Logical unit 6.2 software does not block the users at the IWS from communicating with the 3270 applications in the mainframe. Without such dual capability, the user would be forced to choose between being able to access the "old" 3270 applications, or those of the new logical unit 6.2.

4.3 APPN

Logical unit 6.2 and physical unit 2.1 make no accommodations for communication between nodes not directly adjacent to one another. For users in a limited geographic region, one solution to allowing the integration of multiple nodes is the implementation of a local area network. For more dispersed networks, this function is provided by **Advanced Peer-to-Peer Networking (APPN)**.

In traditional SNA networks, network routing and topology changes are implemented in a rigid fashion. Hierarchical SNA networks route data along pre-fixed routes. Intermediate nodes do not route based upon a real-time best path available scheme. In a traditional SNA network, changes to the topology of the network (i.e. adding a new node, or reconfiguring existing nodes), can only take place when the entire network is in an inactive state.

An analogy is often made comparing this restriction to the phone company requiring every user of the phone service to hang-up each time the phone company added a new phone to the system.

In an integrated environment, networks may consist of users who are in non-related departments or companies. These units may be isolated from one another both geographically and organizationally, and they may not maintain high levels of technical support locally. In this environment it is unreasonable to expect that changes to a single user's environment must be considered by all users of an integrated network.

Advanced Peer-to-Peer Networking (APPN) brings dynamic routing and dynamic topology updating capabilities to SNA logical unit 6.2 networks. APPN maintains directories of users and locations and topology databases which allow for dynamic configuration of the network and dynamic routing of data to its destination by the most expeditious route. With APPN new

APPC WITH PHYSICAL UNIT 2.0

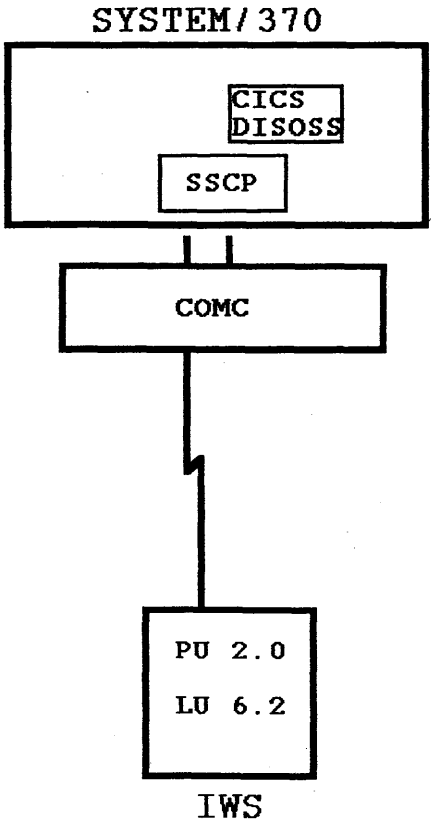

Figure E

APPC WITH PHYSICAL UNIT 2.1 PEER-TO-PEER NETWORKING

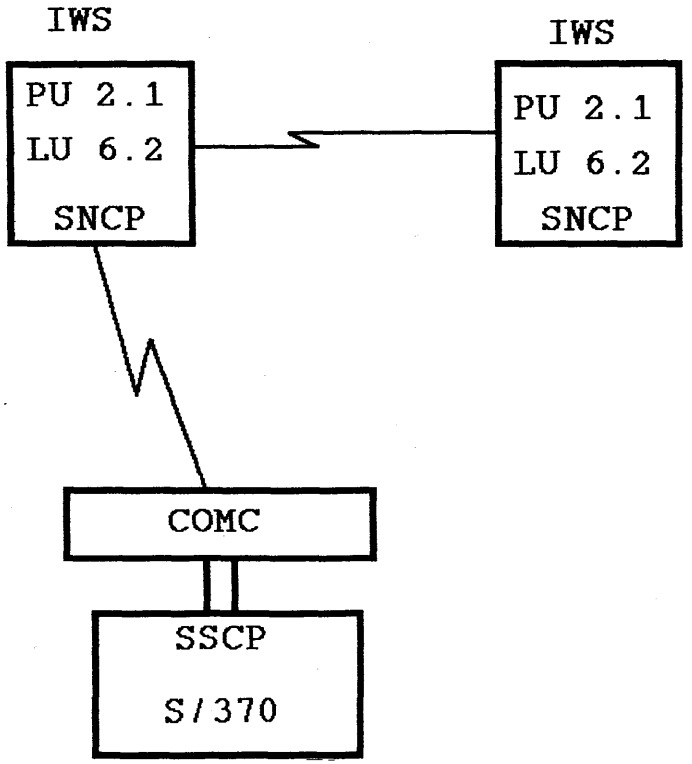

Figure F

users can be brought on-line transparently to the functioning network.

APPN is not an architecture. It is a feature of the System/36. It is an extension of physical unit 2.1. Only System/36's with physical unit 2.1 capabilities support APPN. See figure G.

System/36's which house APPN are termed "network nodes". They may support multiple "end nodes" or "peripheral nodes." (See figure H). Each network node maintains a table of its peripheral node entries. This information is not distributed throughout the network to other network nodes.

4.3.1 EXAMPLE OF DYNAMIC ROUTING WITH APPN

When a peripheral node requests its owning network node to communicate with a second peripheral node on a second network node, an undirected search takes place (see figure H). In this example peripheral node Jan T. is trying to establish communication with peripheral node Chris F. After Chris F. is located, an entry is made of its location and that of network node 3 in the cache of network node 6. Network node 6 sends the data to network node 3 via network node 5 (network node 5 has been resolved by APPN in network node 6 as the next node on the best route available to network node 3). Intermediate network nodes dynamically route data across the most expeditious route until the information arrives at the desired destination network node.

An alternative to an undirected search is to dedicate a network node as a directory node. All searches are then directed to the directory node. Cache entries are made in both the directory node and the node requesting the connection.

4.3.2 TOPOLOGY DATABASE AND DYNAMIC ROUTING WITH APPN

An example of how APPN allows topological changes to take place to the network without interrupting network operation follows. (See figure I).

Each network node maintains a topological database of the network. When a network node is added, the new node sends out a topological database unit (TDU) to all adjacent network nodes. The TDU contains information on the new nodes configuration attributes. The adjacent nodes reciprocate by returning TDU's of the existing network nodes. This TDU exchange ensures that all network nodes in an APPN network maintain a complete and current topology database.

APPN eliminates the need to pre-define routes between all users in a network. Each network node uses its knowledge of the network's topology to ensure that the most expeditious route will be taken by the data it is routing.

One consequence of maintaining this knowledge is a functional limit to the number of nodes that can realistically be supported in an APPN network. The limit is considered to be about one hundred nodes. This limitation indicates that APPN will not cause hierarchical networks to become extinct. They will coexist with them, operating as satellites, alternating between independent and integrated operations.

4.4 LU6.2, PU2.1, AND APPN WORKING TOGETHER

Logical Unit 6.2, Physical Unit 2.1, and APPN allow for the transparent interchange of corporate information irrespective of the location of the end users and of their hardware or software environments.

These new features allow:
1) The accommodation of distributed application processing.
2) Flexible and robust use of the IWS.
3) The corporate network to be viewed as a uniform resource capable of being used as a strategic tool.

5.0 APPLICATION SUPPORT

The majority of software available on logical unit 6.2 networks today consists of office systems software. These software tools work together to provide the ability to easily create, process, store , and distribute data, text, and video files. This paper will discuss : **Document Content Architecture(DCA)**, **Document Interchange Architecture(DIA)**, and **SNA Distribution Services(SNADS)**.

5.1 DOCUMENT CONTENT ARCHITECTURE

DCA defines a uniform formatting of documents that are to be interchanged in an office systems environment. DCA delineates the guidelines for formatting functions such as paginating, highlighting, centering,etc, for documents to be exchanged between office systems.

5.2 DOCUMENT INTERCHANGE ARCHITECTURE

DIA is a set of conventions that allows the distribution of office systems functions across diverse systems. It is an architected application that allows the exchange of files between office systems in a network. It carries out local document distribution, storage, retrieval, and transfer. It defines the data stream constructs for the exchange of information between two DIA users. Transaction programs are the "users" of DIA.

It is DIA which allows different IWS's such as the System/36, System/38, Series/1, 5520, Displaywriter, and DISOSS/370 to exchange office documents among one another when operating as office systems nodes.

DIA transaction programs communicate by establishing conversations over logical unit 6.2, since DIA has no facilities for delivering data between DIA users. In order to deliver the data between remote DIA users, DIA employs SNADS.

ADVANCED PEER-TO-PEER NETWORKING

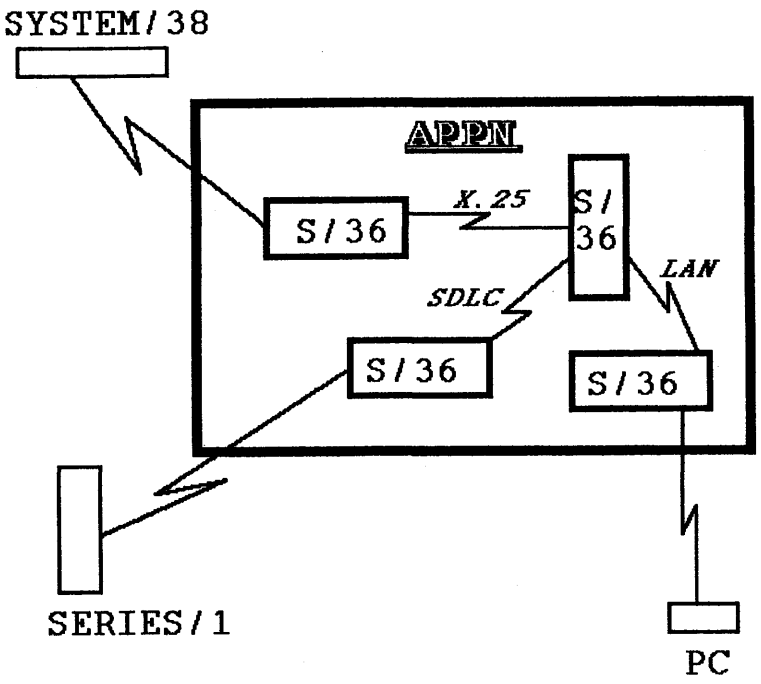

Figure G

APPN NETWORK UNDIRECTED SEARCH

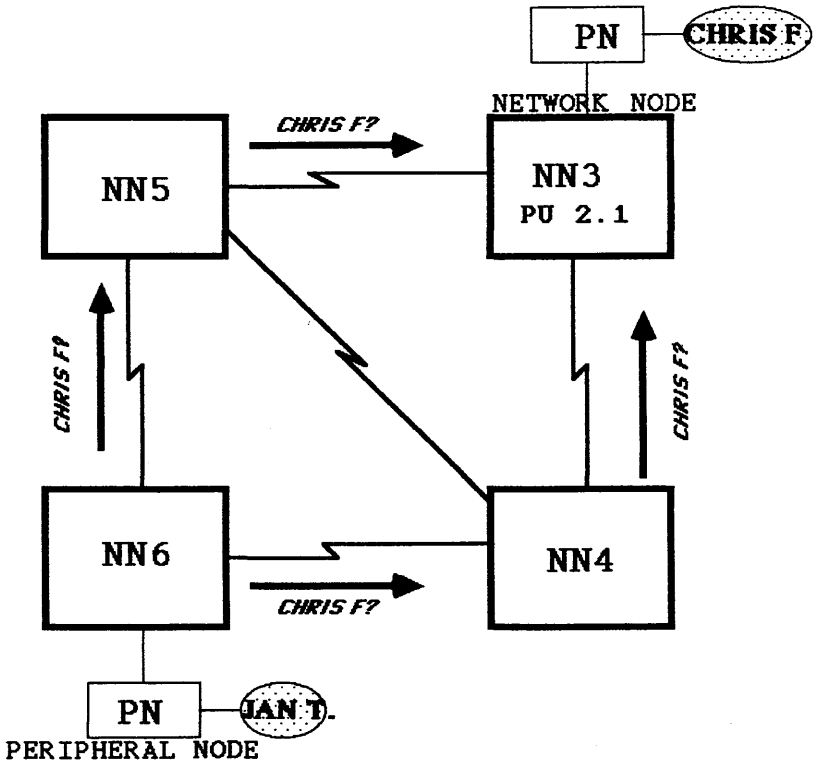

Figure H

APPN
DYNAMIC TOPOLOGY UPDATE

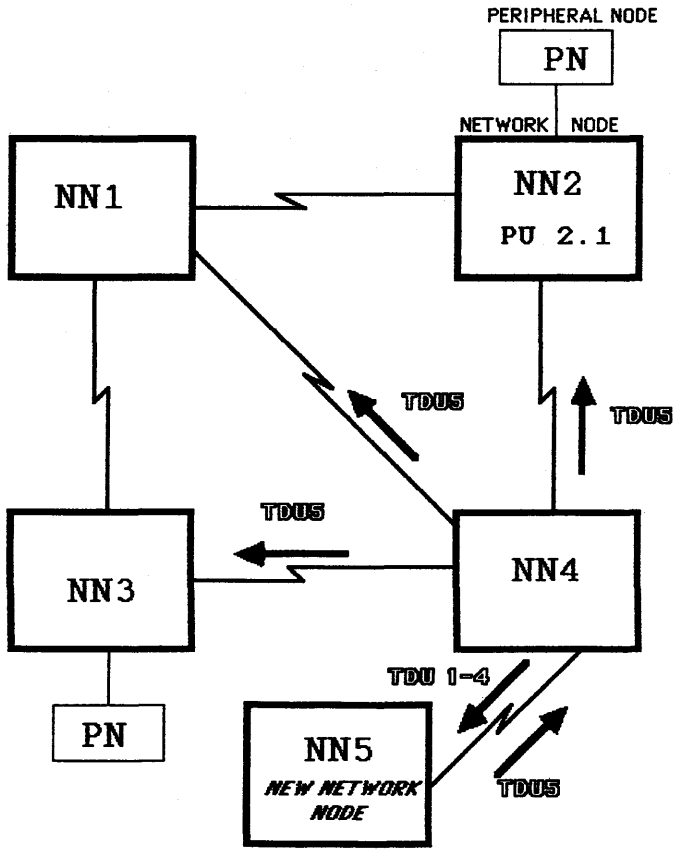

Figure I

SNADS NETWORKING

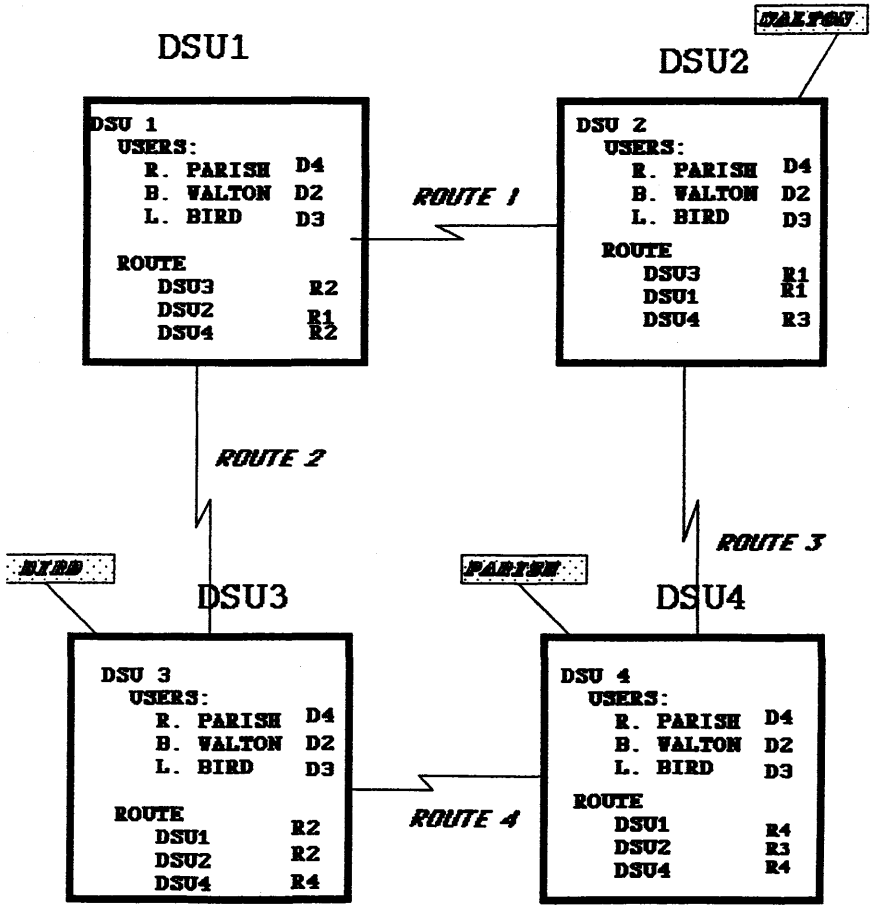

Figure J

DIA communicates with both logical unit 6.2 and SNADS by protocol boundary interfaces verbs. DIA documents follow DCA specifications.

5.3 SNA DISTRIBUTED SERVICES

SNADS is an architecture for the asynchronous distribution of information between network users. It provides a delivery system between IWS's serving as office system nodes. It accepts and delivers documents which are in DIA/DCA format.

Previous to SNADS, SNA supported the delivery of data in a synchronous fashion only. This means that the sender of the information, the receiver, and the components making up the path between them must be simultaneously active. (An example of "synchronous" communication is a telephone conversation.) For traditional hierarchical inquiry/response work this was adequate support. Distributed application programs, especially office systems programs, led to the need for support of an asynchronous system of delivery. Asynchronous delivery allows a sender or requester of information to do so without knowledge of the activity state of the receiver or the path between sender and receiver.

The SNADS function used with logical unit 6.2 and supporting software allows a user to interchange office systems documents to remote users without an awareness of the receiving users location, software environment, or the activity states of the receiving user or the components which make up the path between sending and receiving users. (An example of an "asynchronous" communication is the post office mail delivery system.)

SNADS consists of a set of transaction programs that run in a logical unit 6.2 environment. The SNADS "network" consists of interconnected distributed transaction programs that communicate synchronously via logical unit 6.2. This set of programs and individual synchronous communications form an asynchronous end to end delivery service.

A SNADS user is an addressable entity that can serve as the origin or destination of a file. They are termed "distribution users". Distribution users transfer data in the form of "distribution interchange units" (DIU's).

The requester of a file is termed the "originator user". The receiver of a file is termed the "destination user". Most products which implement SNADS have both originator and destination user ability.

Each distribution user has a unique name. The name is divided into two parts. The distribution group name (DGN) is unique to the SNADS network and the distribution element name (DEN) is unique to a group. These names map directly to the DIA assigned user names to facilitate transfer between SNADS and DIA.

The collection of transaction programs and data structures at a location that provides SNADS services are termed the Distribution Service Unit (DSU). Each DSU has a unique name. The routing group name (RGN) is unique to the SNADS network and the routing entry name (REN) is unique to a group.

Each DSU maintains a directory of entries of local and remote users. The DGN and DEN are resolved to their attached RGN and REN for routing. For large networks, it may be impractical for each DSU to maintain entries for all end users network wide. A practical subset of users could be maintained, with default routings listed for those that fall outside this subset.

5.3.1 SNADS EXAMPLE

An example of data transfer via a SNADS network follows. (See figure J.)

A user Bird at DSU3 wishes to send a memo to Walton in inventory control, and Parish in marketing services. DSU3 searches its directory and finds that the two targeted resources are in DSU2 and DSU4 respectively. It checks its route table to see what routes connect DSU3 with those remote DSU's.

A copy of the office document file is shipped across each of the routes to the destination DSU's. Any intermediate node goes through the same look up and routing procedure until the documents arrive at their destination DSU. The destination DSU hands the file to DIA for local delivery of the information or storage on local media if the targeted end user is currently inactive or unable to receive the data. An intermediate DSU may store the information in memory or on disk if the receiving or next DSU is unable to accept delivery. The intermediate DSU will attempt delivery when the receiving DSU becomes active.

In this example SNADS has conducted data delivery functions similar to those described for APPN. It should be noted that this ability is written specifically for users of a SNADS/office system environment. This service is carried out at the application level of the architecture. It is not a generic routing capability as is that provided by APPN, nor does it allow the dynamic reconfiguration that APPN does.

These office systems applications give us a good indication of how other data processing applications will be executed across the new architectures.

6.0 Summary

The networking environment and the services required to support the environment continue to change at a rapid pace. The addition of logical unit 6.2, physical unit 2.1, APPN, and associated supporting software to SNA completes the architectural framework for a communication environment

that will allow users of SNA networks transparent "any-to-any" access to information, irrespective of data location, communication protocol, or operating system environment.

This new architecture which allows for the coexistence and integration of users communicating in peer-to-peer and hierarchical fashions will allow the network to fulfill its role in providing solutions in a transparent manner to business problems posed by the information system user.

TABLE ONE
THE BASE SET OF LOGICAL UNIT 6.2 VERBS

ALLOCATE	Allocates a conversation with a remote logical unit
CONFIRM	Requests that the remote logical unit confirm receipt of data
CONFIRMED	Sends a confirmation of receipt to remote logical unit
DEALLOCATE	Releases the conversation between users at completion of transaction
GET_ATTRIBUTES	Retrieves SNA session parameters for a conversation establishment
RECEIVE_AND_WAIT	Waits for information to arrive on a conversation and then reads the data
REQUEST_TO_SEND	Notifies the remote application program that the local program wants to send data
SEND_DATA	Sends data to the remote application program
SEND_ERROR	Informs the remote logical unit 6.2 application program that an error has been detected

A Real-Life "How-to-do-it" Guide to Modelling

Michael Taylor

Orinda, CA 94563

Abstract

In this tutorial emphasis will be placed on the practical aspects of modelling from the user's perspective rather than that of the vendor or product developer. A straightforward "how-to" approach will be taken. Collection, summary and "shaping" of data will be emphasized so that the inputs to a model yield results that "make sense."

The authors feel that pragmatism and experience with the modelling process are the cornerstones of success. This tutorial is intended for those who have little or no actual modelling experience, who expect to become (more) involved in modelling, and who would like some of the mystery and esoterica associated with modelling dispelled.

We think that many of you are like us. We do not have advanced degrees in mathematics or statistics. We learned how to handle system measurements and models while on the job. Skills were acquired as needed in response to work assignments. Pragmatic application of those skills paid off. The ends justified the means; we utilized whatever tools and techniques were available to get the job done. In many respects this has been a process of trial and error.

For this reason we have adopted a pragmatic not a mathematical approach to the modelling process. We deal with queueing theory only to the extent that it is required to make informed judgments when selecting data and building the model. This tutorial attempts to give the flavor of a modelling study as it was created. The results are presented "warts and all" to give you a feel for the modelling process as a whole as it unfolds.

So, if you have yet to go through the process of modelling a system, or if you have a little experience and want to know if all the things that happened to you are "normal," then this presentation may be of some value to you. Our emphasis will be on creating and running models using software packages and on presenting results. Lots of formulas will not be presented. Little's Law will not be explained here.

By the way, copies of the foils are available. They were not included in the CMG '86 Proceedings because we felt that they were not sufficiently self-explanatory and that their content might be misconstrued. In addition, don't be upset if this presentation does not follow the write-up in the Proceedings word for word. Some of that is blather, anyway. All the good stuff is here, plus a great deal more.

We view modelling as a process. Since learning about a process is not the same as experiencing it, we have divided this tutorial into two parts, each with the same subdivisions. They are:

I. FIRST PASS: BACKGROUND AND BACKGROUND
II. SECOND PASS: THE REAL THING

In the first part we will talk about the modelling process. We will then make a second pass with a real model, warts and all.
Our modelling process has six subdivisions.

1. Tool selection.
2. Data collection.
3. Data formation.
4. Shaping the model.
5. Evaluating the model.
6. Interpreting the model.

The first item on our list affects the modelling process as a whole. Items 2 and 3 deal with creating the model, while items 4 and 5 have more to do with running and refining it. You will spend more time working with your data than you will with the model, especially the first time out. Later efforts will balance out differently. The final entry in our list considers how to present results to management and how management will evaluate the model. Sometimes there are surprises here - not all of them pleasant!

FIRST PASS: BACKGROUND & GROUNDWORK

Tool selection

Tool selection can affect the modelling process as a whole. There are several alternatives available. Mainframe-based products seem to be the most expensive, but offer the largest number of features. PC-based products are less expensive and have the advantage of offloading the host. They generally impose a data entry or transmission burden, however. You can program your model yourself using APL or SAS or some other language. Finally, you can do it by

hand with a good calculator and a pencil. which we believe to be normally distributed. We recommend mainframe or PC products designed to model your operating system environment(s). They provide much greater support for your efforts. The study presented in this tutorial was created from a commercially available PC-based modelling package.

Data collection

This is usually the toughest part of modelling, particularly the first time. There are a few rules and cautions in this area:

1. Know your system. You must be able to describe your system in terms of workloads and their servers, customers and queues.
2. Don't confuse detail with understanding. It is necessary to identify those phenomena in the system which are of interest. We need meaningful information not a mountain of facts.
3. Spend a lot of time choosing a good interval for the study. The purpose of the model is to examine the potential behavior of your system under particular conditions.
4. Decide how to distribute portions of shared servers to the workloads that you have some inkling about defining.

Data formation

This is where you formulate the workloads in your system. This is also where you must choose data from a particular time period as your starting point. The choice of interval is very important. The main problem that you will experience here is the nonexistence of a perfectly "representative" period during which time all of your workloads are in a steady state. You may find it advisable to choose to summarize several measurement periods into one for modelling purposes, or you may find it easier to find one small interval that works for most of your workloads. In the latter case, you know up front that you are going to have to "tweak" the model, a fact we all learn sooner or later anyway.

Remember that a model is merely a representation of reality - and an approximate one at that. So, it is important that workloads be defined so that they are reasonably homogeneous. A workload with a high degree of variation built int› its resource consumption patterns will not behave as predictably as one with less internal variability. In other words, take those "Jaws"-type transactions and make a separate workload out of them. We will have more to say about this in the second part of this tutorial.

Shaping the model

Here's where the real fun begins! A valid model should produce results that are within five percent of measured resource usage. Reported throughput and response times should be within ten percent at the outside of actual measurements. A well tuned model will reduce the throughput and response time margins to within five percent with concomitant reduction of resource usage variances. This, of course, is our mean opinion based on our experiences

If one or more of your workloads just doesn't look right, you should feel free to "fix" it so that it works. This may sound crude, but it really is not. The polite term for this activity of punching workloads where they hurt is **calibration**. A model that doesn't reproduce known results within reasonable bounds is not worth the keystrokes required to purge its output. As you will see, we forcibly calibrated a batch workload in our own model, and we are completely unrepentant.

Evaluating the model

This phase represents the bottom of a loop that may take you back to any of the preceding stages. If you have been careful, however, most of the time you won't go back past the shaping stage.

Your primary aim here is to be a beneficiary of the 80/20 Rule by finding the point at which the model is "good enough" as quickly as possible. That point is indicated when you have satisfactory answers to questions such as "Does the model answer the question(s) that made me build it?", and "Are the results within reasonable bounds?" When the yesses begin to pile up, quit fooling around and get to the last phase.

Interpreting the model

A model is a technical thing. A lot of expertise and insight go into its construction and ongoing use. You just can't take the output from a complex mechanism such as this and hand it over to a manager without a lot of explanation.

So, save yourself some trouble. Translate the results of your labors into a simple document that refers to the model as if it were a shrine worthy of veneration, but dismisses almost all of your work as a mere support effort dedicated to answering management's Great Question. Then provide information that can be used to back up a decision that involves spending a fair amount of money. For that is what management is concerned about most of the time.

SECOND PASS: THE REAL THING

Very little text is given here for this part of the tutorial, since the use of foils is critical and explanations of the foils' content is not practical.

Tool selection

Our choice of tool was dictated by cost and environmental considerations. There were pros and cons that affected our work.

Data collection

Data came from two main sources: RMF and Living Memory.

Data formation

39 servers, 6 workloads and a short interval were developed.

Shaping the model

Here we show what we changed and why in calibrating the model.

Evaluating the model

We looped a couple of times until it worked properly.

Interpreting the model

We succeeded. Management's views will be revealed.

ANALYTIC MODELING
FOR THE NON-ANALYTIC MODELER

Barbara Sannerud
Boole & Babbage

ABSTRACT

The objective of this tutorial is to provide a fundamental introduction to queueing flow problems. By relating to real world examples, this paper covers the basic laws of queueing theory including Little's law, response time law, forced flow law, and Markovian models. The development of queueing networks and multi-class models is also discussed.

Queueing theory, as a mathematical discipline, has its practical origins in the study of flow, such as traffic problems, network communications, assembly line problems, and so on. On a daily basis, we all encounter queueing theory when analyzing our time spent waiting in line at tollbooths, or when we get service at a gas station. Though not always evident, most large scale human endeavors are queueing flow problems. Queueing theory is also at the heart of capacity planning and is embodied in many of the basic rules for performance management.

Although capacity planning products use many of the mathematical models available, all are concerned with similar metrics and answer the same types of questions. The methodology used may involve simulation studies, benchmarking or analytic modeling. Analytic modeling is the technology used in many commercial capacity planning tools.

In spite of the fact that explanations of performance problems do not always neatly fit into existing analytic models, models are a basis on top of which refinements can be made. Unlike the science of programming, analytic modeling is not an exact science. Nevertheless, an understanding of queueing theory will help the analyst make more informed decisions and will help explain system performance.

Basic Queueing Theory

Regardless of where it is used, queueing theory addresses parameters such as arrival rates of customers, time a customer spends on line for service, and the service time the customer obtains. When relating queueing theory to practical problems such as transaction response time, think of transactions as customers arriving from either a finite or infinite source population. They may wait on a queue for service, or reneg, then they obtain service, and eventually they exit that server . The server may be an I/O device or the CPU or memory. They then move onto another queue or exit the system.

Example:

Take a stand alone environment with IMS transactions as the only customer and the CPU as the only server. If 100 transactions arrive over 10 seconds the transaction arrival rate is 10 per second; if 50 complete, the throughput is 5 per second. In the same 10 second interval, if the CPU is busy for 3 seconds then each transaction uses 3/50 or .06 seconds of CPU time. Given that the throughput is 5 transactions per second and that the average service requirements are .06 seconds, the utilization is 5x.06 or 30%. This relationship between throughput and service is the Utilization Law. Some of the basic formulae expressing these relationships are:

$\lambda = A/t$ A=arrivals t=Time λ =Arrival Rate
$X = C/t$ C=completions X=throughput
S=Service at the resource μ =utilization
$\mu = XS$

The Utilization of a resource is the product of the throughput of that resource and the service at that resource. This is known as the utilization law.

In a steady state environment, the product of the throughput of the system and the average time spent in that system by a request yields the number of requests present in the system at any given point in time. The same relationship holds true for customers in a queue awaiting service. This law known as **Little's law** is simply a modification of the utilization law and finds its way into many performance applications.

$N=XR$ or **$N_q=XR_q$** **N=number in the system X=throughput R=response time**

Where q denotes customers in the queue not receiving service.

TSO

There are times when Little's Law does not empirically hold true. In a TSO environment or in a lightly loaded batch environment, we might find discrepancies between actual and calculated results using these laws. What should response time be if there are 10 TSO users and TSO transactions are processed at a rate of 5/second? Since N=XR and 10=5R implies R=2, means response time should be only 2 seconds. This is internal time only, which does not consider think time. Little's Law is modified in this case for think time:

$N=X(R+Z)$ where **Z** is the average think time.This law is known as the **Response Time Law.**

While the Utilization and Little's law focus on a particular resource, the **Forced Flow** Law considers throughput and service across many different servers such as DASD and CPU. Essentially, it states that for all components in a system throughput rates remain proportional to one another. The visit count at a service resource equals the number of transactions completed at that particular resource compared with the total number of system transactions.

Example
If a typical IMS transaction does 10 reads and the DASD device services 20 I/O's per second attributable to IMS, then throughput is 20/10 or 2 transactions per second. If, at the same time, there are 8 buffers accessed per second from IMS, then each transaction requires 8/2 or 4 buffer accesses. The forced flow law can be used to determine throughputs at various servers. Throughput and residency at different service centers can be equated. Different servers in the same system tend to do proportional amounts of work in any given time interval.
The **Forced Flow Law** is expressed as:

$X_k=V_kX$ **X=throughput**
V=visits to a server
k=a particular resource

The throughput at resource 'k' is the product of the average number of visits a request makes to resource 'k', and the system throughput.

Example:

How can these laws be tied together to estimate response time? Take the following example given a system where there are:

•25 transactions in the system
•DASD utilization =35%
•service requirements at the device is 70ms. per request
•there are 10 visits to the DASD device per transaction:
What is response time?

Calculate response time:

•Utilization Law	$\mu=sx$	DASD throughput $x=\mu/s$ x=35%/70ms = 5 requests/second
•Forced Flow Law	$x_k=V_kx$	System throughput $x= x_k/V_k$ x=5 /10 =.5 interactions / second
•Little's Law	n=xr	Response time r=n/x r=25 / .5 or 50 sec.

Response time=50 seconds

The Queueing Network Model

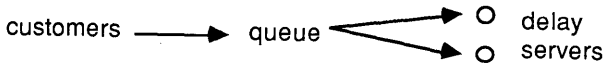
The previous discussions are useful for calculating response time on a small scale. But how do models predict response time in large computer systems? Essentially, one must identify the major bottlenecks or contention points from the universe of all possible service centers in the system. For example, I/O can be analyzed on a microscopic level, from the perspective of seek delays, set sector, wait for channel program, blocking factors, and so on. However, one must examine the major service centers or resources, and queues which have significant effect on your system.

The modeling approach which examines the entire set of queues, service centers, customers and system resource contention is known as a *queueing network model.* The model becomes more complicated when you consider shared DASD since this involves contention from outside the system. A service center can be either a queueing center or a delay center.

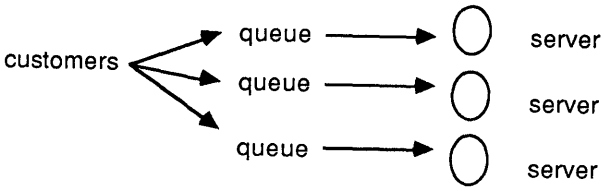
The following diagrams illustrate three possible service configurations in a queueing network model.

(1) A single server such as a UP processor

(2) A delay server such as think time for TSO



(3) Multiple servers such as tape or DASD devices



There are two major types of service centers in this model: a queueing center and a delay server. A delay server can be thought of as a constant or delay added to service. The time a transaction spends at a delay center is equal to its service requirements there. Customers each have their own dedicated server avoiding competition for service. There may be single service center (one cpu) or multiple service centers (DASD). Customers either receive service or queue for service; the two are mutually exclusive.Some of the parameters of queueing network models include :

(1) customers - described by arrival rate, population and delay service time
(2) service centers- described as queueing centers or delay centers
(3) service demands- resources consumed by customers at each center

•There are 3 types of customers: Open or transaction workloads like IMS, have variable size infinite source populations. Once a transaction receives service, it leaves the system. Batch or closed workloads have fixed populations and there is recirculation. Customers that leave the system are immediately replaced, i.e. job initiators service backlogs of requests. Terminal or TSO workloads are similar to both of the above, in that they have variable populations bounded by the number of active terminals but have think time and a variable number of transactions.

• Service centers were previously described as queue or delay centers.

•The service demands at each center are summed up for a customer. At each center, k, the customer demand is $D_k=V_kS_k$. The product of the number of visits to that server and the service requested at that service center, yield the service demand for that center.

Multiple Classes

The only major distinction between multiple classes and single class systems is the inclusion of a scheduling algorithm. A scheduling algorithm is a set of rules which determine which customers get serviced next and their duration of service. In a single class system, only 2 possibilities exist: queueing servers or delay servers. Multiple class systems exhibit many behaviors:

Scheduling Disciplines:

FCFS-first come first served. In FCFS, the first customer to arrive is served. The assumption is made that all classes have similar service requirements. There is no preemption of service.

LCFS-last come first served-preemptive. This is used to model high priority, frequently dispatched jobs. The arriving job preempts the current job until it has completed its service requirements. CPU's handle this algorithm by resuming preempted jobs. This algorithm is rarely used for DASD.

RR - round robin-time slicing. Jobs are served FCFS until their service time exceeds a threshold. Then the job is preempted and placed at the end of the queue. The algorithm insures that the processor is equally shared by all its customers. It is an efficient algorithm providing that the overhead of managing the algorithm is not excessive.

STRF-shortest time remaining first. This optimal scheduling algorithm serves the customers with the smallest remaining outstanding service requirements. It is used often with drum devices. Over the long run, it tends to optimize the mean response time of all customers.

These scheduling algorithms are studied with respect to UP vs. MP processors. Many studies have proven limited differences in the performance of the various algorithms. Generally, FCFS is the easiest approach and has the least overhead.

What are the outputs of a model?

The outputs of a model are familiar performance metrics: response time, utilization, throughput, residency, average number of users in the system, to name a few. The outputs can be calculated by the queueing laws described earlier in this paper. Utilization means percent busy, system response time is the sum of residency time at each service center, R_k,

$R = \Sigma R_k$ where $k=1,..n$. Throughput is calculated through the forced flow law, and queue length can be derived from Little's law, or from the Response time law for TSO. By summing up all the constituent queue times you have the population of your entire system.

When a model has multiple service classes, they are parameterized on a class by class basis. All inputs and outputs are identical to that of the single class with the exception that metrics are assigned to that service class. Total response time for the system is weighted by throughput for each class.

Markovian Model

There are many popular mathematical models used in practical capacity management. The most prevalent of all queueing models is the so-called Markovian or memoryless model. The Markovian process, is also known as the M/M/1 Birth and Death process, where births equate to arrivals of customers (transactions or jobs) and deaths equate to customers exiting the system.

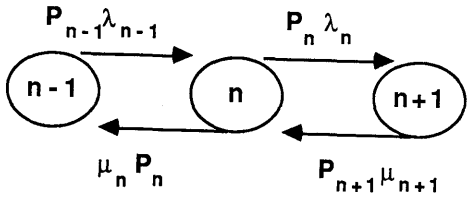
The Markovian model is used to accurately represent a computer system without including either too much detail or too little detail about past events which might influence the current state of the system. The first position of the M/M/1 model refers to interarrival time; the second to service time, and the third to the number of servers. Here we have exponential interarrival times and exponential service times with one server. (The M designates Markovian). In this model, the arriving transactions has 2 choices, it either receives service if the server is idle, or it must wait if there is a queue for service.

A queueing network can be represented by a Markovian process as follows. Each service center is represented by a Markovian state, or node, and there is a set of probabilities to identify transitions from one state to the next. When a customer completes service at the i^{th} node, he proceeds to the j^{th} node for service with probability P_{ij}. Each i^{th} node receives requests from outside the system as well as requests internal to the system.

A state transition diagram helps explain what Markovian process looks like. Each node represents a state Ei. The flow of requests into the node is

$E_n = (\lambda_{n-1})(P_{n-1}) + (\mu_{n+1})(P_{n+1})$ and the flow out is

$E_n = (\lambda_n)(P_n) + (\mu_n)(P_n)$. The flow out equals the flow in; the number of births equals the number of deaths.



Example

A system has one terminal at a branch sales office available 18 hours daily. The time spent at the terminal is on average 30 minutes-1/2 hour- for inquiries. There is only one terminal for 20 salesmen. The terminal is utilized 20x1/2 or 10. out of 18 hours per day. Let ρ be the utilization, then $\rho = 5/9$.

•What is the average wait time for the terminal?
W=expected service time/ $(1-\rho)$ = 30/(1-5/9)
= 67.5 minutes avg wait time

•What is the average number of salesmen in the queue?
The number in the queue $L_q = \rho^2/(1-\rho) =$
$(5/9)^2 / (1-5/9) = .7$ people waiting at any time

Two important practical capacity planning outgrowths of the M/M/1 model are:

(1) Expected time in the system for a customer = expected avg service time/ 1 - server's utilization

(2) Number of customers in the queue = server utilization^2/(1- utilization)

As the utilization increases, we see an increase in queue length and response time, similar to the traditional response time curve. As arrival rates of transactions linearly increase, residence time in the system grows exponentially. With utilization growth, a small increase in utilization corresponds to a significant increase in total time in the system. So overloaded systems operating at the 80-90% utilization level are much more sensitive to workload increases than those operating at the 60% busy level. If throughput is increased so that servers are busy for a shorter period of time, response time decreases.

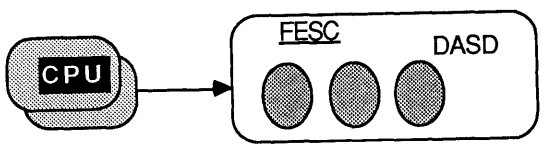
FESC's

We have covered techniques used to solve simple models so far. In particular, the Markovian technique is used to evaluate a small number of states. In large environments, where huge I/O and network systems are involved, there is a need to decompose the large super structure into more manageable systems. This process is known as *hierarchical* modeling and uses a concept called *FESC* or *Flow Equivalent Service Centers*. In constructing the FESC model, you first partition off the major subsystems, i.e. network, I/O subsystem and processors. Each component piece is analyzed as an individual entity, namely an FESC.

An FESC is a single, service center that exhibits delays and throughput characteristics on a large scale equivalent to the behavior of the detailed components of which it is comprised. After the decomposition process, you have a hierarchy of FESC's which are then evaluated from the lowest level of the hierarchy up. The result of this process, is the creation of many single service centers which are equivalent from a modeling perspective and smaller in scope than the original subsystems. The reduced model can be evaluated by a variety of mathematical techniques beyond the scope of this paper.

It is assumed that the subsystem is in equilibrium with the larger or macro system, of which it is a part. This occurs when the service centers in the subsystem can handle the influx of activity from outside,i.e. from the macro system.

FESC's are analyzed using "load dependent service centers" where the service rate depends on the actual number of customers in the queue. The FESC is considered to have a service rate equal to the throughput for all customers and classes that it serves, and the number of customers depends on the customers already in the macro system.

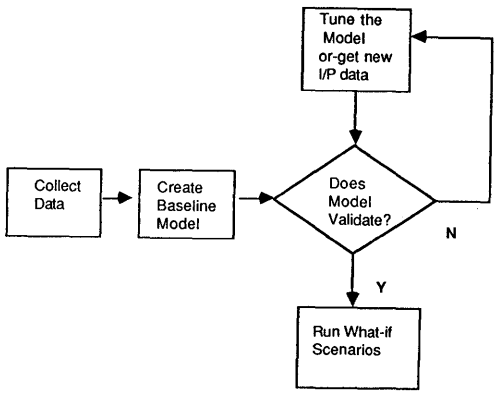


Practical Modeling

How do these theories and models relate to a pragmatic approach to modeling? To parameterize your current system, you must have on hand valid information about your customers, your service centers and your service requirements. The version of the operating system, the processor and I/O configuration, scheduling schemes, MPL levels and resource consumption by workload are some of the key inputs. Workloads must be characterized and grouped by function or by resource usage, i.e. by performance groups. Then the system and workload specific data is gathered through sampling techniques, i.e. through RMF. There are often other supplemental model inputs such as IMS transaction data from various vendor monitoring packages, since IMS workload metrics are not captured by RMF. The period of time chosen for the sample must be representative of the system's peak processing window, since most capacity studies are based upon maximum levels of activity.

Customer data (transactions, jobs) are decomposed into workloads of key concern to the organization. They correspond to performance groups and transaction groups for IMS and CICS. Service center data consists of the major queueing bottlenecks in the system, such as the processor, the DASD, or memory. Service requirements of each customer at each service center are identified through software monitors and samplers. System metrics such as CPU time, storage requirements, I/O activity by workloads are inputs to the model. However, measurement becomes complicated by the apportionment of system wide overhead attributable to MVS. This includes CPU burst activity, scheduling overhead, dispatching overhead and paging.

After the inputs are fed into the model, the model is validated for reasonableness. If the model validates, the modeled estimates do not differ dramatically from the measurements for an interval. Validating the model is not an easy process even though a small margin of error of 10-25% deviation is tolerated in the various measurements. When the model fails to validate, it is often due to some irregularity in the interval, such as the presence of an unusual job, lack of detail in the model definitions, or incorrect common system measurements such as poor distribution of paging overhead by workload. Validation implies either capturing a new set of more representative data, or changing metrics in the model, such as CPU burst, to alter the model to reflect the real system. Once the model validates, it can be used to pose what-if questions or to plan for different hardware and software scenarios.



Summary

This paper attempts to provide a general background covering analytic modeling fundamentals which are applicable to both formal and informal capacity planning. Hopefully, mysteries behind some of the commercially available packages begin to become clarified. In any aspect of performance and capacity management, a basic knowledge of queueing theory always adds to the decision making process.

Though real computer systems deviate from mathematical formulae, queueing theory serves as a foundation for performance estimates. If the analyst is willing to accept a broad range of accuracy, analytic modeling can be used to understand and explain performance results. This brief survey provides a glimpse into the behavior exhibited by many of the more complex queueing models implemented in capacity planning tools.

VM/HPO PERFORMANCE MEASUREMENTS

Mark S. Streger
Computer Sciences Corporation

ABSTRACT

Measuring the VM/HPO environment can be a challenging and difficult task. This tutorial will introduce those measures that quantify the different components of a VM/HPO system including CPU utilization, workload activity, user throughput and swapping. The focus will be on those measures that are both easily interpreted and are significant to performance analysis of a VM/HPO system.

1. INTRODUCTION

It is essential to realize that VM users are just like users of any other interactive time sharing system. Typical applications include fourth generation languages program development, information center packages and electronic office systems. Additional usage can include guest operating systems such as MVS or UNIX. VM systems typically provide the users with good responsiveness, but as I will describe, there are no good measures to inform either the performance analyst or the users of how the system is responding.

2. TRANSACTION TYPING

Performance analysts of other operating systems have developed over the years very concrete ideas of how to classify the workload and the service received. An excellent example is IMS response analysis with short, medium and long transaction average response times. Another example is TSO which prohibits a user from entering data at the terminal until the system is ready to accept it. This allows reporting service with command grouping. VM is much different. A VM system will allow a user to enter many commands in succession until the input buffer has filled up. The monitor data provided by the system does not characterize the workload, nor does it present data so that this can be accomplished. The monitor data does provide data that can be very useful, provided it is interpreted correctly.

3. THE VM MONITOR

VM provides the analyst with an integral data collection facility, the Monitor. This facility provides the analyst with two distinct types of data; interval data which quantifies activity over time and event data which is generated by specific activity. For most analysis the interval data is sufficient and the load generated is low enough to allow continuous collection. Event data may be necessary for analyzing obscure problems. Interval data has a default sampling interval of one minute which is typically used. The data itself originates from counters embedded throughout VM control blocks. It is worth noting that these counters are generally cumulative since the previous IPL, so that the analyst has to detect supurious data due to counter overflows. Monitor data needs to be reduced before it can be used for performance analysis with packages such as VMMAP or MICS/VM.

4. SYSTEM PERFORMANCE

Significant data describing system activity, subsystem utilization and numerous system counters can be obtained by collecting class 0 monitor data. This is interval driven data and the default one minute interval is typically used. Class 0 performance data provides an excellent overall view of the system so that current performance problems can be analyzed, as well as enabling the analyst to study the effect of changes upon the system. Some areas of interest include:

- Utilization: What the system was doing during the measurement interval.
- Workload : How many users were logged on the system and what portion of these were truly active.
- Storage : What the utilization was and what problems were affecting the storage manager.
- Swapping : How effective the swapping subsystem was. Are logically swapped users able to reclaim their pages.
- Throughput : How much user work was performed. Did users perform more work this week than last.
- Response : A comparitive measure of system responsiveness.

5. USER DATA

Collecting class 4 monitor data will generate a record for each logged on user during an interval. This data quantifies by user activity, resource consumption and delays incurred. Some of the measures need to be examined cautiously, as they can be skewed by a user who was logged on for only a few intervals. Some of the useful information provided by the user records include:

- Delays : What delays are most users experiencing. Are some users consistantly experiencing the same delays.
- CPU : Who are the largest CPU consumers.
- Storage : Which users have the large working sets.
- I/O : How much I/O the user performed.
- Response : No good measures at the user level.

6. I/O SUBSYSTEM

Collecting class 6 monitor data generates a wealth of data quantifying the I/O subsystem for disk and tape devices for each interval. This data allows analysis to be performed at the device, control unit and channel levels. Some of the useful information provided by the class 6 records include:

- Queueing : How often did a queue exist at this portion of the I/O path and what was the average queue depth.
- Utilization: How busy was the device, control unit or channel.
- I/O counts : How many I/O operations were issued to this path component.
- Response : No true measure, but can be approximated.

7. EVENT DATA

Collecting monitor event driven data can generate significant quantities of data depending on the event frequency. These classes are collected when the interval data does not provide sufficient granularity to analyze a situation. Some of the event data classes implemented provide information that is more suited to the VM developer when implementing an algorithm change, than to the performance analyst. The more interesting of the event data classes are:

Schedule : Exhaustive information is provided on the manipulation and activity to the dispatcher queues. This can be used to learn exactly how a user is serviced.

Seeks : This data provides information on DASD arm movement and is typically used as the basis for disk reorganizations.

Swap : This data class quantifies both logical and physical swapping. The information is presented on a user basis so that the effect of swapping on important users can be determined.

8. SUMMARY

This tutorial has examined the prime measurement data source of VM/HPO performance management and capacity planning. This discussion has focused on those mea ures that are important to basic performance analysis. The two distinct types of monitor data; event driven and interval driven have been contrasted, as well as the basic analysis that each type of data can provide. The basic and small set of measures discussed are sufficiently robust for basic VM performance analysis. As in depth knowledge of VM is developed, the additional measures that can be obtained can provide more insight to VM performance and aid in solving obscure problems.

CAPACITY PLANNING BY THE KISS METHOD

LARRY KAYSER
BGS SYSTEMS, INC.

Since the advent of formal capacity planning functions, more and more tools and techniques have been made available to the practitioner. Unfortunately more tools and techniques do not always lead to a successful process. Sometimes it is better to step back and look at the process in a more simplistic light. This tutorial will try to re-establish such a frame of reference.

A BIT OF HISTORY

In the early days of data processing, the environments were considerably less complicated. Capacity planning was geared to a few fundamental areas like the CPU and "when do I get my printout back." The rule of thumb in those early days might be likened to "if you don't care where you are, you ain't lost." Capacity planning, if attempted at all, most likely took some form of linear projection, based solely on CPU usage against time. The results were often like "The First Law of Evolving System Dynamics," "Once you open a can of worms, the only way to re-can them is to use a larger can."

A LITTLE CLOSER TO HOME

W ith the increase in computer technology and its uses, the demands placed on capacity planners have increased dramatically. The tools currently available to the capacity planner are far superior, but in my view at least one problem remains . . . **Understanding**.

Gone are the days of "Buy a bigger box." No longer is capacity planning just a function of CPU, but rather a complex interaction that crosses many boundaries. As more and more environments replace batch oriented systems with real-time, on-line systems, response time becomes the critical issue. Basic relationships exist within response time but they are a bit more complex than the sum of the parts.

A UNIQUE RELATIONSHIP

A relationship that I liken to a Rubics Cube. As with the Rubic's Cube, hindsight is great. With every twist of the cube you may be closer or further away from a successful solution. Capacity planning is like the cube. You know where you have been; you were balanced in the performance and cost of your DP environment. But how you get back to it is another question. The effects of changes now may be seen in problems further down the road. Especially if you rush into a solution.

WHAT IS CAPACITY PLANNING

So in a generic sense, what is capacity planning and how does one get started ? The objective of a capacity planning project is to maintain a fine balance between performance and cost effectiveness. This equilibrium is constantly stressed by several major factors.

Corporate management's view of DP is as a consumer of capital that may be better spent on other projects.

An increased DP exposure that comes from the use of on-line system.

More sophisticated users demanding:

- improved service
- better price performance
- new functionality

THE PROCESS

Capacity planning is a systematic process that:

- Forecasts User Workloads
- Determines Capacity Requirements to Support Those Workloads
- Manages Resources to Meet Defined Objectives

An observation from a number of years experience is that capacity planning and performance management are basically one and the same. A change in capacity can have an effect on the performance of an environment. And a change in demand can have an effect on capacity. Hence a "Catch-22". The effects from one must be weighed against the other to achieve the fine balance demanded in today's aggressive environments.

TECHNIQUES

There are numerous techniques for doing capacity planning/performance management. The basis of the process I present here is one of common sense. What I suggest are my ideas for having a reasonable chance at a successful capacity planning project.

First, my basic definitions.

Usable Capacity of a Resource -

The utilization beyond which the resource response is degraded to the point performance objectives are missed.

Performance Objectives/Service Requirements -

The ability to deliver a resource with a specific time frame.

GETTING STARTED

So how does one get started in capacity planning/performance management? My suggestions are based more on experience and common sense than on my formal training. They have been derived from a number of years of first hand exposure, both as a planner and as a vendor specializing in performance and capacity planning.

I believe there are eight essential points to a successful capacity planning process.

START SIMPLE

Practice the KISS principal and don't bite off more than you can handle. All that results from such attempts is frustration and failure. Tackle a piece at a time and use each as a building block to the next. The various pieces may include, among others :

- Tuning
- Costing and Charging
- Data Collection
- Workload Characterization
- Modeling

UNDERSTAND YOUR ENVIRONMENT

Each environment is unique and I promise you that if you are to be successful at capacity planning you will get to know your environment from CPU to terminal, from actuator to application. Get to know your users. Try to understand their problems and needs. Try to relate to them in terms they understand, not some obscure DP jargon. You will make your job a bit easier and possibly make some friends in the process. REMEMBER TO KISS.

PICK MANAGEABLE OBJECTIVES

Don't try to report everything in your system. Not only will you confuse yourself, but those you are reporting to as well. Try such things as CPU and response time by workload. Also track DASD usage in terms of volume. REMEMBER TO KISS.

TRACK YOUR OBJECTIVES

We all know that our projections are correct; but does reality reflect that as well? Remember, "If we don't care where we are, we can't possibly be lost." How well does reality track against your projections. This is why I stress KISS. If you are trying to manage to too many objectives when starting out, you might find that you are not meeting any of them.

REPORT ON YOUR OBJECTIVES

You don't need a book, when a memo will do. And conversely, when a major presentation is due, it is easier to have to deal with a few well managed objectives early on. Report only what is needed to make your environment understood. Basic CPU against current capacity, current response time against user requirements, projected CPU usage against capacity, and projected response time against user requirements. These are a few good ones to start with. REMEMBER TO KISS.

AVOID THE FLASHY

Too many times I have seen good management presentations get lost in the desire to be fancy and flashy. Somehow facts get lost in the process. KISSing is best. Avoid glitter and rely on substance. It works well. Spend the time working on the content and preparing alternatives for management.

PLAN PLAN PLAN

"A good plan today is better than a perfect plan tomorrow." Provide options and cost benefits to each. Most management I have dealt with prefer options. A few well thought out options are better than trying to razzle dazzle them. Try to anticipate what the future may hold and plan for alternatives, so you can reply quickly to management requests. But don't go overboard, REMEMBER TO KISS.

EDUCATION

Stay on top of technology. This business is one of the most dramatic in terms of changes, past or present. Be on top of options, hardware, software, or operational. It will make your job easier.

Diagram *#1* is the outline for a basic capacity planning process that was developed for a previous employer. I believe it represents a very sound structure to use as a guideline for establishing your own capacity planning process. Notice that it entails an understanding of all the areas I mentioned above and requires a great deal of interaction between the major components. It is also designed to be implemented in phases. By adhering to the KISS principle it becomes a manageable task that can and should evolve over time. Rome wasn't built in a day and neither is a good capacity planning project.

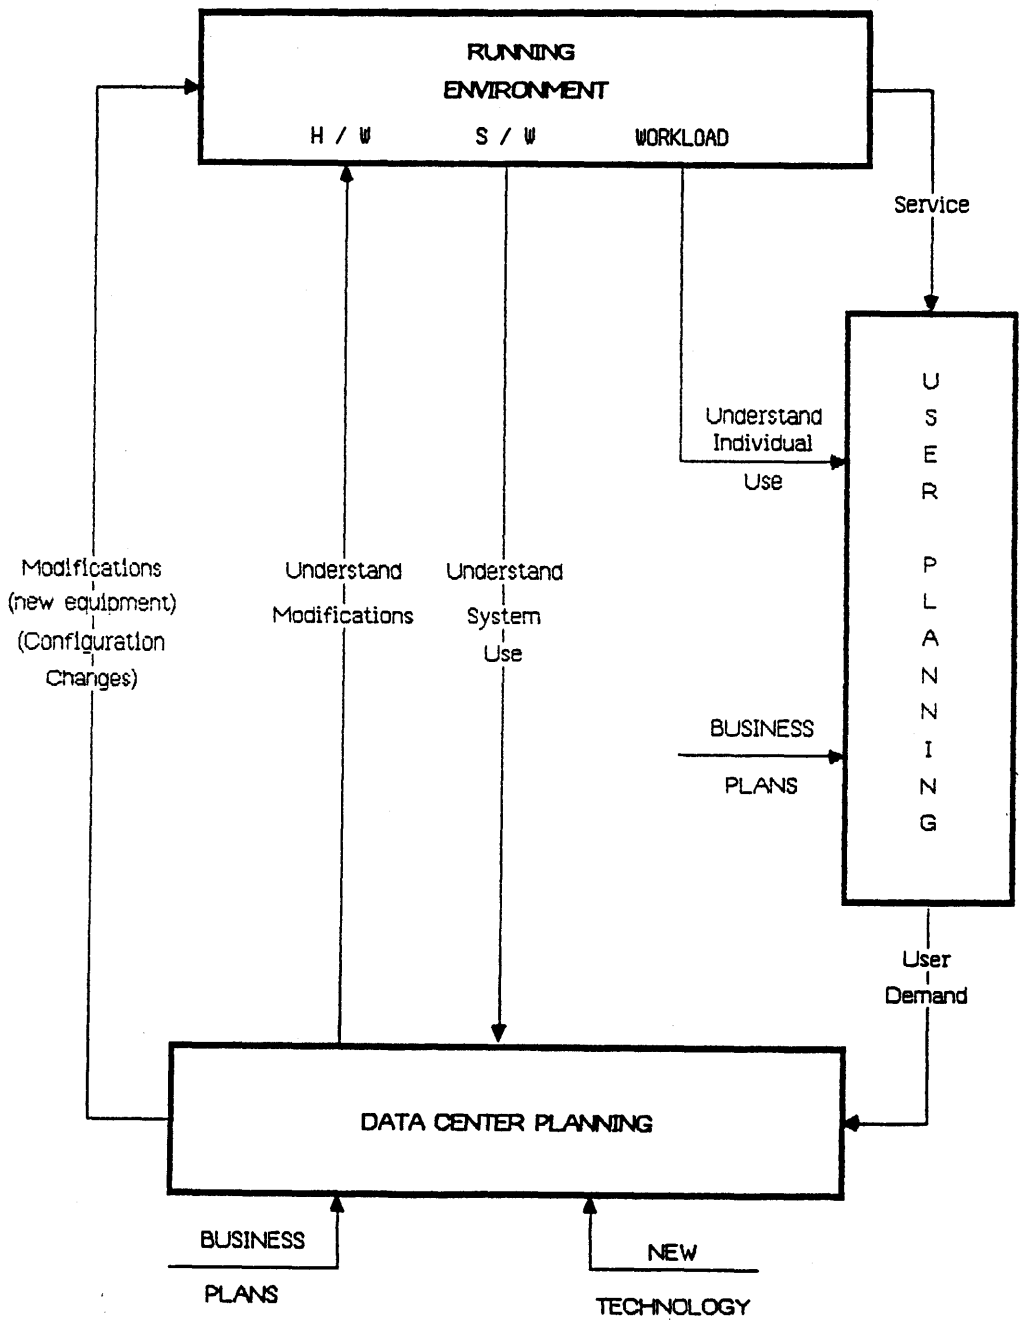

Diagram #2 is an example of an expanded process that was implemented at the same company. It will give you additional insight how the same capacity planning project grew. This particular one evolved into as many as seven full time people managing four major processing environments and several smaller support environments.

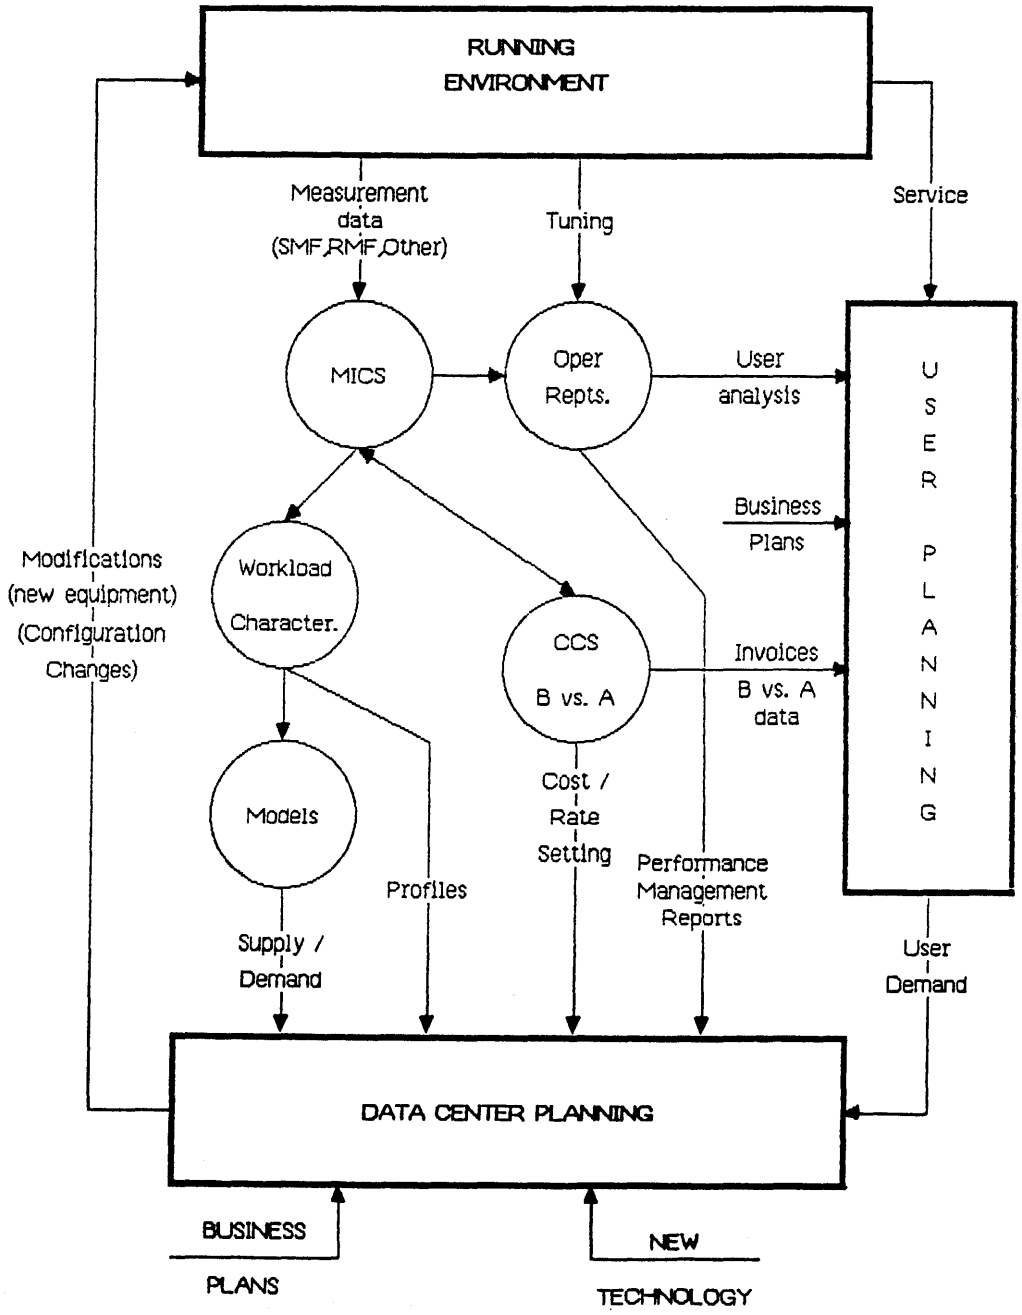


Finally, I would like to add a few footnotes. Capacity planners must be "a jack of all trades." They also need to be diplomats because they must deal with a number of areas within an organization, and corporate politics being what they are . . . enough said.

They need to be a promoter. They must understand and believe in their recommendations and be prepared to defend them. Many times management will question a recommendation, not so much in doubt of its value, but rather to test how well you have done your homework.

A capacity planner must be a technical ambassador, working between the various organizations promoting new technologies and better techniques to improve service and performance.

And last, for manager's of capacity planning projects, remember:

"*Nothing is impossible for the person who doesn't have to do it themselves*"

Give a new capacity planning function a chance to develop and don't push for the world when a small home in the country will do.

REPORTING AVAILABILITY AT THE JOB STEP LEVEL

Jim Scott
Virginia Department of Information Technology

ABSTRACT

Availability of a scheduled application can be defined as the percentage of scheduled time that the job step representing that application was executing. Using this definition, availability can be reported by a program whose input consists of a schedule table and step execution data from SMF or MICS. Relevant issues include these: What are the advantages and disadvantages of availability by job step? How should regular and irregular schedule variations be provided for? How can missing information (e.g., a missing step termination record) be accounted for? Is SMF interval accounting necessary? How can the availability report be presented online? How is the report used?

INTRODUCTION

The customers and managers of the Virginia Department of Information Technology (DIT) need daily information on the availability of scheduled applications. They use this information primarily as one measurement of how well DIT is doing its job. This information was originally calculated manually, but now the daily reports are generated quickly by a program. The program compares step execution start and stop times with the schedule. It then calculates and reports, for each application, the percentage of the scheduled time that the application was executing.

The key concepts are:

- The idea of basing availability on the execution of certain job steps, relative to a schedule;
- The particular method used by DIT to implement this idea.

These concepts are applicable to any installation that has scheduled applications implemented as job steps. It is advantageous, but not essential, that the schedules be reasonably stable.

AVAILABILITY BY JOB STEP

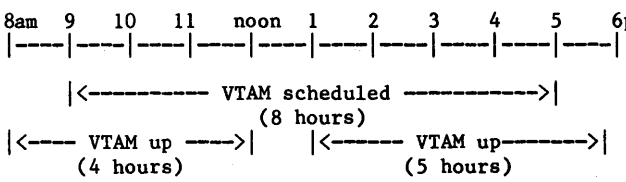
An application can be defined as a job that is scheduled to be up during certain periods of the day. It provides a service, usually in the form of online access to data, which is supposed to be available to customers in accordance with an announced schedule. When the application is up, the service is available.

For example, here are some of DIT's applications:

- JES2
- VTAM
- IMS control region
- CICS (two)
- Adabas (several)
- Division of Motor Vehicles (DMV) driver inquiry (daytime and nighttime versions)
- DMV vehicle update
- Legislature Quick Draft

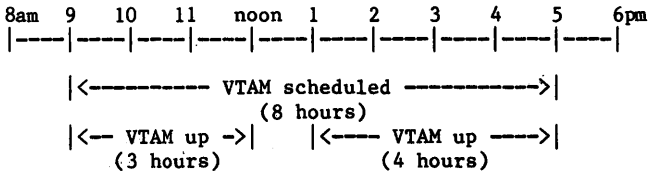
The job that supports an application may have several steps. There may be auxiliary steps that set up access to the data base, for example, or that do some kind of clean-up at the end of the job. Invariably, however, there is one main step that actually provides the scheduled service. Typically, the auxiliary steps run quickly, whereas the main step runs for hours and doesn't stop executing until operator action or a mishap causes it to stop. It's reasonable to equate availability of an application with the execution of the main job step for that application.

Thus, we say that an application is up between the time when its main step starts execution and the time when the main step ends execution. But in reporting availability, we only care about those periods when the application is **scheduled** to be up. It would be misleading to include execution time outside the schedule when calculating availability. Therefore, execution time outside the schedule is excluded. Consider the following example:



This diagram indicates that VTAM was scheduled to be up for a period of eight hours, from 9:00 a.m. to 5:00 p.m. VTAM actually came up an hour early at 8:00 a.m., and came down (because of some problem) at noon. It was down for an hour until the problem was fixed. Then it came up again at 1:00 p.m. and wasn't brought down by the operator until 6:00 p.m.

For the purpose of calculating availability, the diagram looks like this:



Here, the execution time outside the schedule has been ignored. The fact that VTAM was up early and stayed up an hour late may have been useful to some customers, and may even have compensated somewhat for the fact that it was down for an hour at noon. But there is no good way to measure that usefulness. The best we can do is to say that, outside the schedule, there is no such thing as availability.

In this example, then, the availability of VTAM is

$$\frac{\text{7 hours execution time}}{\text{8 hours scheduled time}} = 87.5\%$$

The advantages of measuring availability by job step are:

- It is well-defined:
- It is based on readily available data:
- It is a reasonable indicator of computer center performance.

The operating system provides reasonably accurate data for step start and stop times, and Operations policy provides official schedule start and stop times. Job step availability indicates how well the schedule is being adhered to.

The disadvantage of this method is that it may not measure "real" availability, in at least two senses:

- The service may not be really available the whole time the main step of an application is executing. For example, the main step may take a few minutes to do its initialization. In this case, the service isn't really available until a few minutes after the step begins execution.
- A much more fundamental problem is that job step availability is not the same as "end-user" availability. If an IMS message processing region is up and the IMS control region is down, then the user of the message processing region sees the service as being unavailable. The same would be true if both job steps were up but the front end processor that handled IMS customers' terminals was down. (Job step availability doesn't reflect network hardware availability at all.) In other words, job step availability is not a particularly accurate measure of availability as the customer perceives it. However, it is a good comparative measure of how well the computer center is handling one major aspect of its duty.

MANUAL REPORTING OF AVAILABILITY

In the past, availability was calculated by hand. Each morning, an operations analyst would go over an incident report filled in by operators over the previous day. For each application to be tracked, down times and up times would be noted and compared to the schedule. Availability percentages were calculated with a hand calculator.

There were two problems with this method:

- The times in the incident log were not particularly accurate. When a job or the system crashes, the operators' primary concern is to get it back up again. Recording the exact times involved would be of secondary importance.
- The manual effort was a waste of person-hours, and undoubtedly introduced occasional calculation errors.

INPUT DATA

DIT's availability report program requires three sets of input:

1. Execution data
2. A schedule table
3. Auxiliary tables

EXECUTION DATA

System Management Facilities (SMF) of the MVS operating system provides step execution data in the Type 30 (Common Address Space Work) record. DIT uses the MVS Integrated Control System (MICS) from Morino Associates, Inc., which makes SMF and other data available in a data base which is much easier to use than SMF files. In the MICS data base, step execution data are available in the Batch User Program Activity (BATPGM) file and the System Task Program Activity (BAT_ST) file.

DIT's fundamental cycle for reporting availability is a 24-hour period, midnight to midnight. Since we dump SMF data to tape once a day, at about 3:00 a.m., our SMF input would have to be two consecutive SMF tapes, covering from 3:00 a.m. the day before to 3:00 a.m. the day after the date to be processed. Each MICS "cycle" covers the same period as the SMF tape it's based on, so we use two consecutive cycles of each of the two MICS files mentioned above.

Even so, some steps run for days, so an application that's still up at the end of the day may not produce any step termination data until way after the 3:00 a.m. end of the input data. To account for this fact, we turned on SMF "interval accounting", with an interval of one hour. This causes each long-running step to produce step execution data in an SMF Type 30 record every hour starting one hour after the step begins execution. MICS then provides the same information. As long as SMF doesn't get dumped before 1:00 a.m., the input data can be assumed to reflect each step that was up as of midnight.

So the execution data to be used as input to an availability report can be SMF Type 30 records or MICS records: DIT uses MICS. Either way, SMF interval accounting is required, unless every scheduled application is brought down at least once a day.

SCHEDULE TABLE

A schedule table defines which applications are to be tracked; how to identify the execution data that corresponds to each application; and the schedule times for each application. It resides in a partitioned data set member maintained by Operations. Here's an example of a schedule table:

```
COMPONENT SCHEDULE
SMTWTFS DDMMMYY-DDMMMYY
 XXXXX  08JAN86 31DEC99
CICS PRD CICP2    DCSSIP   DFHSIP    0730 1715
CICS VEC CICP1    DCSSIP   DFHSIP    0730 1715
DRV INQD DMVPT02* T02DAY   DMVT02**  0650 2200
DRV INQN DMVT02NC T02NITE  DMVT02**  0000 0640 2205 2400
IMS CTL  IMSPCU   IEFPROC  DFSMVRC0  0615 1900
IMS MPP1 COMMPP1  COMMPP1  DFSRRC00  0620 1900
JES2     JES2     IEFPROC  HASJES20  0000 2400
LEG QD   LEGQDCU  QD       QDDRAFT   0735 2400
VEH UPDT DMVPT51C DMVT51** DMVT51**  0650 2200
VTAM     NET***** NET***** ISTINM01  0000 2400
```

The first three lines are used to identify the member and to specify to which dates and to which days of the week the schedule applies. In the rest of the table, each line is an entry containing the following items:

Name An eight-character name for the application: long enough to be recognizable, but short enough to save space in intermediate files

Job name The job name always associated with this application

Step name The name of the main step

Program name The program executed by the main step

Schedule period 1 Schedule start and stop times

Schedule period 2 Start and stop times for second schedule period, if any

The job name, step name, and program name fields define which execution data records represent a particular application. Note that wild-card characters are allowed in these fields.

In the example above, the application with name "DRV INQN" is scheduled to be up from midnight to 6:40 a.m. and from 10:05 p.m. to midnight (i.e., its actual schedule is 10:05 p.m. to 6:40 a.m.). It has job name DMVT02NC, step name T02NITE, and any program name beginning with DMVT02.

There can be several schedule tables with different member names. DIT maintains separate tables for:

- Sunday
- Monday
- Tuesday-Friday
- Saturday
- Holidays (two types)

AUXILIARY TABLES

The three auxiliary tables are the description table, the holiday table, and the window table. They're not essential to the concept of job step availability; they just facilitate the process. Like the schedule tables, they are partitioned data set members.

DESCRIPTION TABLE. The description table equates each short application name (as used in the schedule table and in intermediate files) with a longer application description, to be used in reports. Here's an example:

```
COMPONENT DESCRIPTIONS
SMTWTFS DDMMMYY-DDMMMYY
XXXXXXX 09JUL85 31DEC99
CICS PRD CICS PRODUCTION
CICS VEC CICS - VEC
DRV INQD DMV DRIVER INQUIRY (DAY)
DRV INQN DMV DRIVER INQUIRY (NIGHT)
IMS CTL  IMS CONTROL REGION
IMS MPP1 IMS MSG PROC REGION 1
JES2     JES2
LEG QD   LEGISLATURE QUICK DRAFT
VEH UPDT DMV VEHICLE UPDATE
VTAM     VTAM
```

HOLIDAY TABLE. The holiday table identifies which dates are holidays, so selection of a schedule table can be done without manual intervention:

```
HOLIDAY TABLE
SMTWTFS DDMMMYY-DDMMMYY
XXXXXXX 01JAN85 31DEC88
2 %% 01 01 NEW YEAR'S DAY
2 87 01 02 NEW YEAR'S EXTRA DAY 87
1 85 10 14 COLUMBUS DAY 85
1 86 10 13 COLUMBUS DAY 86
1 87 10 12 COLUMBUS DAY 87
1 88 10 10 COLUMBUS DAY 88
```

The items in each entry, from left to right are:

Type The type of holiday, 1 or 2. A type 1 holiday is a minor holiday on which many businesses stay open. A type 2 holiday is a major holiday. DIT has a different schedule for each type of holiday.

Year The year that this entry applies to, or '%%' if the holiday has the same date every year.

Month The month of the holiday

Day The day of the month

Description The name of the holiday

WINDOW TABLE. A window table defines two time periods:

- The start and stop times of a scheduled maintenance window, if any; and
- The start and stop times of the period of the day, if any, considered to be "prime time".

A **maintenance window** is a period of a few hours reserved for preventive maintenance, repairs, or testing, on a particular day of the week. **By definition**, nothing is scheduled during a maintenance window, regardless of what the schedule table says. Any execution time and any schedule time that would overlap a maintenance window are ignored. Of course, windows could be reflected in the schedule tables, but then more schedule tables would have to be maintained.

The concept of **prime time** is used to report availability, not only over a 24-hour period, but also for the prime time period of the day. Prime time availability ignores any execution time or schedule time outside of prime time. Prime time availability can be useful, for example, in the following way: Suppose that on a particular day the availability of JES2 was 84%, but prime time availability of JES2 was 98%. Management may want to say that this was not as bad as a day when availability of JES2 was 90% and prime time availability was 92%.

There are two window tables, one for regular work days and one for holidays and weekends. Here are both tables:

```
SCHEDULED WINDOWS - MONDAY THROUGH FRIDAY, NON-HOLIDAYS
SMTWTFS DDMMMYY-DDMMMYY  WINDOW    PRIMETIME
 XXX X  22JAN86 31DEC99            0700 1730
    X   22JAN86 31DEC99 0250 0505  0700 1730

SCHEDULED WINDOWS - HOLIDAYS AND WEEKENDS
SMTWTFS DDMMMYY-DDMMMYY  WINDOW    PRIMETIME
X       22JAN86 31DEC99  0750 1205
 XXX X  22JAN86 31DEC99
    X   22JAN86 31DEC99  0250 0505
      X 22JAN86 31DEC99
```

One of these tables is selected, based on the day of the week and on whether the day is a holiday (according to the holiday table). Then, an entry from the table is selected, based again on the day of the week (and possibly on the date range). For example, on Thursday, December 10, 1987, which is not a holiday, there is a maintenance window from 2:50 a.m. to 5:05 a.m., and prime time is defined as 7:00 a.m. to 5:30 p.m.

Note that there is no prime time on weekends and holidays. On these days, prime time availability is undefined.

OVERVIEW OF PROGRAM

The program that calculates and reports availability is written in SAS (from SAS Institute, Inc.). It's executed each day by a scheduled job that runs after SMF has been dumped and MICS has been updated. The operations analyst who is responsible for the job must make sure that the schedule tables and auxiliary tables are kept up to date. When the job is submitted, a date parameter may be used to specify the date to be processed; the default is yesterday (the day before the date the job is being executed).

The program, knowing the date to be processed, then goes to work:

1. The day of the week is determined.

2. The holiday table is used to determine whether the day is a holiday, and if so, which type.

3. The proper schedule table and window table are selected and read in. The description table is also read in.

4. The MICS cycle numbers (generations) to be used are determined. If the date to be processed is yesterday, the cycle numbers used are 1 (the latest day's worth of data) and 2 (the next-to-latest). If an earlier date is being processed, the cycle numbers will be higher (for older data). This may occur if a previous run needs to be rerun. See "Handling Bad Data", below. Since a limited number of cycles of MICS detail data are kept, there is a limit to how far back a rerun can be done.

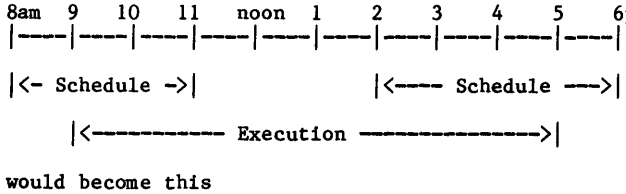
5. The execution records are read in and summarized to produce one record per job step execution (by combining all the interval records for each step).

6. Execution records are discarded for steps that did not overlap the date being processed, and for steps that lasted less than one minute.

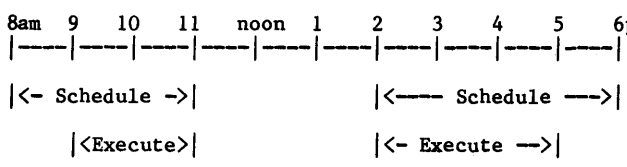
7. The remaining execution records are merged with the schedule table, based on job name, step name, and program name (and taking any wild-card characters into account). This process eliminates most of the execution data, leaving only the records for job steps whose availability is to be reported, i.e., those mentioned in the schedule table. It also associates a set of schedule times with each surviving execution record. A schedule entry with no matching execution data becomes a record of an application with no execution time.

8. Execution time outside the process date is excluded. For example, a step which started the day before and ran until 4:00 a.m. of the date being processed is considered to have run from midnight (the beginning of the day) to 4:00 a.m. (A SAS time constant of '00:00'T indicates midnight at the beginning of the day, and '24:00'T indicates midnight at the end of the day.)

9. Any execution which overlaps two scheduled periods is broken up into two executions by excluding the non-scheduled period in between. For example, this



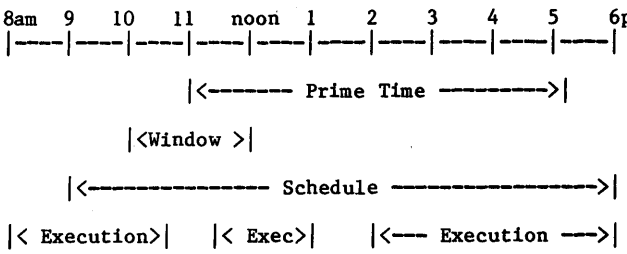
would become this



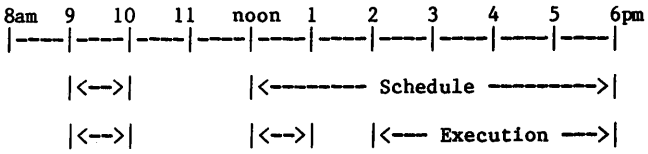
10. Overlapping executions are de-overlapped. The start time of one is moved later, or the end time of the other is moved earlier, or an execution totally contained by another is dropped entirely, so that the overlap is removed. An arbitrary minimum down time of one minute is imposed.

(There are various ways that two executions with the same job name can overlap. A batch job and a started task with the same name can execute at the same time. Also, the use of wild-card characters in the job name field of the schedule table can result in apparent duplicate execution.)

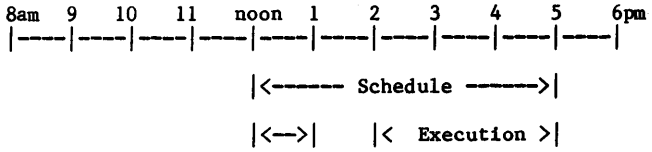
11. The data are "normalized". Schedule time during a maintenance window is excluded. Execution time outside the schedule is excluded. An execution which spans a maintenance window (probably meaning that the CE didn't take the machine down after all) is broken into two pieces, as above. A second set of data is also kept for prime time availability, by excluding all execution and schedule time outside prime time (if any). For example, suppose the input data for an application looked like this:



For the purposes of 24-hour availability, the schedule and execution data would be converted to this:



For prime time availability, they would look like this:



12. Availability is calculated for each application by computing the ratio of total execution time to total schedule time. For the application in the example above, availability is

$$\frac{\text{6 hours execution time}}{\text{7 hours scheduled time}} = 85.7\ \%$$

13. Likewise, prime time availability is calculated for each application by computing the ratio of total prime time execution time to total prime time schedule time. In the example above, prime time availability is

$$\frac{\text{4 hours execution time}}{\text{5 hours scheduled time}} = 80.0\ \%$$

14. The number of "hits" or interrupts is also calculated. A hit is an incident in which an application's job step does one of the following:

    - Comes up later than scheduled;
    - Goes down earlier than scheduled;
    - Goes down and comes back up during the schedule;

o Isn't up at all during a schedule period.

In the example above, the application had **one** hit, the down from 1:00 p.m. to 2:00 p.m. The down at 11:00 a.m. was completely within the window, and therefore was not counted as a hit because it was considered to have been outside the schedule.

This definition of a hit is probably the most practical one for computation by a program, but it isn't always fair. For example, a nighttime application may go down at 11:30 p.m. and come back up at 12:30 a.m.; this one down would be reported as two hits, one on each day.

15. The daily availability report is printed, and stored in a partitioned data set for online access.

16. The month-to-date availability report is calculated, reported, and stored. For each application, the day's total execution time is added to the total execution time for the preceding days in the calendar month, and likewise for schedule time. Then the month-to-date availability is calculated by dividing month-to-date execution time by month-to-date schedule time. The month-to-date data are stored in a SAS data base for use in the next day's calculations.

    After the month ends, the month-to-date report for the last day of the month is then considered the "monthly report" for that month.

17. If the date being processed is a Saturday, the weekly availability report is calculated, reported, and stored. The calculations are similar to those for the month-to-date report, but the weekly period is always Sunday to Saturday.

THE REPORT

The daily availability report looks like this:

DEPARTMENT OF INFORMATION TECHNOLOGY
MVS SYSTEM
DAILY AVAILABILITY REPORT
FOR THE DATE OF: WEDNESDAY, DECEMBER 9, 1987
COMPUTED ON: 10DEC87:08:41:03

APPLICATION DESCRIPTION	EXECUTION TIME	SCHEDULE TIME	AVAIL PCT	PRIME AVAIL	# OF HITS
CICS - VEC	9:45:00	9:45:00	100.00	100.00	0
CICS PRODUCTION	9:45:00	9:45:00	100.00	100.00	0
DMV DRIV INQ (DAY)	12:53:50	15:10:00	85.04	100.00	3
DMV DRIV INQ (NITE)	8:33:17	8:35:00	99.67	.	1
DMV VEHICLE UPDATE	12:54:26	15:10:00	85.10	100.00	3
IMS CONTROL REGION	12:45:00	12:45:00	100.00	100.00	0
IMS MSG PROC REG 1	12:30:56	12:40:00	98.81	100.00	1
JES2	23:39:15	24:00:00	98.56	100.00	1
LEGISLAT QUICKDRAFT	13:59:07	16:25:00	85.19	98.38	3
VTAM	23:25:25	24:00:00	97.60	100.00	1

The month-to-date and weekly reports are similar.

"Execution Time" is the total step execution time within the schedule, for the whole day (or month to date, or week). "Schedule Time" is the total time the application was scheduled. "Avail PCT" is the (24-hour) availability, as a percentage ratio of execution time to scheduled time. "Prime Avail" is the prime time availability percentage; prime time execution time and scheduled time are not included in the report. "# of Hits" is the number of hits, or interrupts, as defined earlier.

The reports are stored as ready-to-browse partitioned data set members, and are accessed through a TSO ISPF CLIST. The Library Access and Dialog Management services of ISPF are used to display a list of members from which the viewer can choose a report to browse. The member list includes all daily reports for the current and previous months, all month-to-date reports for the current month, all weekly reports for the current and previous months, and all previous monthly reports (last month-to-date report for each month).

HANDLING BAD DATA

All sorts of bad data can get into the availability report, either through bad input data or a program bug. These can generally be found in one of two ways: either the program detects a problem and issues a warning or error message, or the operations analyst who reviews the daily report notices that the report looks wrong. Such problems can be corrected by doing a rerun.

KINDS OF BAD INPUT DATA

Here are some examples of bad input data:

BAD ENTRY IN SCHEDULE TABLE. Either a data entry error or a miscommunication concerning the day's schedule could result in the schedule table having one or more bad entries. The resulting report would, of course, also be wrong.

WRONG SCHEDULE TABLE. The operations analyst could have the wrong member names on the schedule tables, in such a way that the program runs with the wrong table.

MISSING ENTRY IN SCHEDULE TABLE. A missing entry in the schedule table would make it look as if an application was not scheduled.

OUT-OF-DATE HOLIDAY TABLE. Errors in the holiday table could cause the program to select the wrong schedule table.

BAD ENTRY IN WINDOW TABLE. A bad entry in the window table could misstate whether a maintenance window and/or prime time was in effect.

AVAILABILITY REPORT JOB SUBMITTED BEFORE SMF OR MICS DATA UPDATED. If the report were generated before the input data were updated, it would use old data, resulting in a report showing zero or very low availability.

DAMAGED MONTH-TO-DATE OR WEEKLY DATA FROM PREVIOUS DAYS. If month-to-date or weekly data from previous days were not correct, the latest month-to-date or weekly report would also be incorrect, even though the latest daily report might be all right.

MISSING STEP TERMINATION RECORD. The SMF or MICS records representing a job step execution may show either of the following two conditions:

Completed step The last record for the step is an end-of-step record:

Incomplete step The last record for the step is an interval record.

The latter case is often okay; it may just mean that the step was still running when SMF was dumped. But if the last timestamp for the step was before midnight and before the end of the schedule period for the application, then it isn't known whether the step actually ended before or after it was scheduled to end. This problem can be caused when an initiator terminates abnormally.

MISSING INTERVAL RECORDS. It's possible for a step not to issue interval records even though SMF interval accounting is turned on. This has been a continuing problem for JES2; at IPL time, it is a matter of luck

whether JES2 or SMF gets completely started first. If JES2 is first, it doesn't get the signal from SMF to produce interval records. When a job step that does not produce interval records runs past the SMF dump time (as JES2 often does), MICS has no record that the step has been running.

CORRECTING BAD DATA BY DOING A RERUN

The effect of any of these kinds of bad input data, or of a program bug, can be corrected, assuming that the correct input data can be determined or that the bug has been fixed. A "full" rerun can be done for any past date for which the original execution data still exist. DIT keeps 10 cycles of MICS detail data; since two consecutive cycles are required as input, we can rerun any date from yesterday back to nine days ago.

We also allow a "partial" rerun, in conjunction with **manual** correction of the execution data. Manual correction is required when a missing step termination record and/or missing interval records obscure whether (or when) a step ran and ended. We allow two kinds of manual correction of execution data:

- Changing a job step's execution end time
- Adding a new job step execution

Of course, manual correction depends on the conscientiousness of the operations analyst, who must determine from the system log or other sources of information what the execution data should be. The partial rerun checks the manual corrections for consistency with other data, but this check doesn't eliminate the need for human carefulness.

In practice, DIT uses manual correction for JES2 almost every day. Manual correction for other applications, and full reruns to correct other kinds of bad input data or program bugs, are considerably less frequent.

USE OF THE EFFORT

The availability report is used by DIT managers, other DIT employees, and some customers. They use it in the following ways:

- As one measure of how well DIT is doing its job, while recognizing that availability is also affected by factors outside DIT;
- As an indicator of problems that may need further investigation, using other tools (such as the Incident Report or the system log);
- As a factor in evaluating the performance of DIT managers.

SUMMARY

Job step availability is based on the idea that an application is up when its main job step is executing. Availability is then the percentage of the scheduled time that the step was executing. Although this measure of availability doesn't always reflect whether the customer has access to the scheduled service, it's still a reasonable measure of data center performance. Calculation of job step availability is more complicated than one might think, but it is quite practical.

WHAT MODELS DO AND WHAT MODELS DON'T

Allan I. Levy
International Systems Services Company
New York, NY

This tutorial is intended for both intermediate and advanced level performance and capacity analysts. The tutorial presents details of the practical application of queueing network modeling technology to computer capacity planning. The tutorial explores realistically what can be expected of these models. It also explores the limitations of these models. Major emphasis is placed on identifying the modeling primitives required to address specific capacity planning and computer performance issues. Emphasis is also placed on the formulation and architecture of a model, modeling types, model input requirements, model modification analysis, and model validation requirements. Extensive use will be made of practical case studies drawn from the industry.

TUTORIAL OUTLINE

1. Models of Computer Performance

1.1 Rule-based models
1.2 Utilization models
1.3 Analytic models
1.4 Simulation models
1.5 Hybrid models
1.6 Hierarchical models
1.7 Benchmark models

2. Queueing Network Models of Computer Performance

2.1 Transaction processing models
2.2 Timesharing models
2.3 Batch processing models

3. Using the Model

3.1 Choosing the model to fit the problem
3.2 Model architecture
3.3 Model structure
3.4 Obtaining the model input
3.5 What to do when required input is not available
3.6 Using the model output
3.7 Mis-using the model output
3.8 How to validate a model
3.9 How not to validate a model
3.10 When is a model considered validated

4. Model Modification Analysis

4.1 How to modify model parameters
4.2 Tricks of the modeling trade
4.3 Modeling problem areas and their resolution
4.4 Models of batch precedence
4.5 Models of DASD
4.6 Models of CPU serialization
4.7 Models of shared DASD
4.8 Models of the I/O subsystem
4.9 Models of CPU-I/O overlap
4.10 Models of fork and join processing

5. Pragmatic Case Studies

5.1 Modeling economics in a credit card retail application
5.2 Modeling remote data base updates in a large bank
5.3 Modeling on-line transaction processing in a distributed environment
5.4 Other cases, including those requested by tutorial participants

ACCOUNTING FOR WORKLOAD VARIATION IN INTERVAL SELECTION AND ANALYSIS

Brian Williams
American Express
Travelers Cheque Operations Center

ABSTRACT

Selecting evaluation intervals which are representative of critical performance periods is important. This is particularly true if a period is to be used as the basis for an analytic model from which future performance projections will be made. Using a "peak" period based on CPU utilization alone may not be adequate in selecting a "representative" period of critical performance. This paper outlines a method of identifying periods of critical performance taking into consideration important factors such as workload mix, service levels, CPU utilization, and workload volumes. First, critical processing periods are defined. Then a process is described that combines all important factors into a single **indicator** that can be used to determine how well a particular interval represents a critical performance period. Uses and possible implementation strategies of this single indicator value are discussed along with the potential benefits of this methodology.

INTRODUCTION

Critical performance periods have traditionally been defined as "peak" intervals (usually hours). Peak intervals are determined by analyzing daily, monthly, and seasonal patterns to identify cycles and periods of workload variation. Peak periods are then defined as intervals in the cycles that have the highest workloads. Performance tuning and capacity planning are usually oriented towards the peak periods or "critical" performance periods because these periods have the highest demand on resources.

When selecting a peak period for analysis, it is important to know whether this peak period is representative of processing done by the configuration when workload variation is taken into consideration. Determining if a critical performance period is representative of processing done on the system will require a definition of "representative". A number of important factors that relate to workload variations must be considered in the definition.

A DEFINITION OF CRITICAL PERFORMANCE PERIODS SHOULD CONSIDER SERVICE LEVELS

Satisfying service objectives under every condition is not economically practical and may not be feasible. Therefore, a company must determine in what situations service levels may not be satisfied. One approach is to set a percent of the time that service levels may not be satisfied. For example, ninety percent or more of the time all service levels will be satisfied. Then only ten percent of the time (or less) service levels may not be satisfied.

The time period must also be defined. That is, ten percent or less of *what* periods will service levels not be satisfied. A company must determine what continuous periods of time can the users function while service levels are not satisfied. This will depend on the nature of the business, the type of processing provided, and the service objectives. For example, a system providing batch processing for randomly submitted jobs may be able to sustain unsatisfactory service levels for hours and still not significantly impact the user community. Selecting longer intervals for predominantly batch work will allow a better description due to the nature of longer running batch jobs. However, a system providing online services to support sales and customer service during a peak season of the year may lose substantial revenue if unsatisfactory service levels are sustained for more than one hour. Therefore, with critical online workloads short periods would be more appropriate.

For example, a company may determine that ninety percent or more of all one hour periods must satisfy service objectives. The company may also determine that the time period may need to be confined to a particular part of the year or a particular season (i.e. peak season). The critical performance periods must be part of the periods for which service levels must be satisfied. For example, ninety percent of the one hour periods during peak season are candidates from which representative critical performance periods can be selected.

The most critical performance periods are those periods which border the intervals for which service levels are not expected to be satisfied. For the purposes of this paper, critical performance periods will be referred to as ninetieth percentile performance periods. Ninetieth percentile periods are those borderline periods which separate the ninety percent or more periods in which service levels are expected to be satisfied from those ten percent or fewer periods in which service is not expected

to be satisfied. Based on the discretion of a company the ninetieth percentile or any other percentile could be selected.

The remainder of this paper assume the following critical performance period definition:

> Critical performance periods will be any continuous four hour ninetieth percentile periods during any quarter of a standard calendar year.

This definition uses a less traditional four hour period and allows selection criteria to be established quarterly. Using this criteria over a specified period such as a calendar year quarter will account for all daily, weekly, and monthly cyclical patterns and/or peaks. If applied over a one year period, seasonal patterns and/or peaks are also accounted for. If one month is analyzed, daily and weekly cyclical patterns are accounted for but monthly and seasonal patterns may not be considered. The interval of data to be analyzed should depend on the types of cycles expected in the processing schedules. Analyzing longer periods will consume more resources.

Where there is a large seasonal variation in workloads, it is likely that all periods in a seasonally slow quarter would meet service objectives. However, by definition the periods representing ninetieth percentile workload volumes are the critical periods. If quarterly data is analyzed and seasonal variations in workload exist, seasonal adjustment would be necessary for predicting peak season performance.

THERE IS NOT ONE UNIQUE FACTOR THAT CAN IDENTIFY CRITICAL PERIODS

Once critical performance periods have been defined, criteria must be established for identifying these periods. A technique must be developed to identifying those periods for which service levels are not expected be satisfied. One alternative is to use CPU utilization. Critical performance periods could be selected from periods where CPU utilization was the same or lower ninety percent of the time. However, consider the data collected from an IMS system in **TABLE I.**

Each interval in the table is bordering on the ninetieth percentile period for CPU utilization. The range of CPU utilization is only 3%, but the range in workload volumes is significant. Which is the the most representative interval? The interval selected will have a large impact on future IMS response time projections. The use of CPU utilization exclusively to select a representative period is clearly insufficient.

If CPU utilization is not sufficient to determine if an interval is representative of a ninetieth percentile period, perhaps workload volumes should be considered. The intervals in **TABLE II** are borderline ninetieth percentile intervals based on IMS transaction volumes.

The difference in IMS transactions for each interval is insignificant. However, the range in CPU utilization and the range in BMP data base DL/1 calls is very significant. The IMS transaction response time is more consistent but the highest response time is twice as large as the lowest response time which also would significantly impact future performance projections. Using only workload volumes from one workload is also not sufficient to indicate that a period is representative of

TABLE I

INTERVAL	AVERAGE CPU UTILIZATION	NUMBER OF IMS TRANSACTIONS	IMS TRANSACTION RESPONSE TIME	BMP DATA BASE DL/1 CALLS
1	77.66%	16,826	3.66 SEC	2,167,797
2	77.36%	17,453	0.28 SEC	709,770
3	76.40%	22,278	0.97 SEC	1,737,203
4	76.35%	19,964	0.41 SEC	1,098,527
5	75.68%	21,804	0.53 SEC	1,916,961
6	74.84%	17,488	1.59 SEC	2,221,426

Figure 1. Periods with similar CPU utilization: Although CPU utilization is similar, IMS online transactions, online response times, and BMP data base calls are significantly different. This indicates that using only CPU utilization as an indicator of performance levels for selected period is inadequate.

TABLE II

INTERVAL	NUMBER OF IMS TRANSACTIONS	AVERAGE CPU UTILIZATION	IMS TRANSACTION RESPONSE TIME	BMP DATA BASE DL/1 CALLS
1	23,707	64.6%	0.35 SEC	1,445,604
2	23,640	56.4%	0.29 SEC	1,672,766
3	23,551	47.7%	0.49 SEC	170,773
4	23,525	49.7%	0.31 SEC	147,937
5	23,516	29.3%	0.24 SEC	44,280
6	23,355	52.9%	0.28 SEC	2,513,754

Figure 2. Periods with similar IMS online transaction volumes: These periods have similar IMS online transaction volumes. However, it can be seen by the CPU utilization, IMS online response time and BMP data base calls that these periods are also very different. Many factors must be used to determine the similarity of different periods when there is variation in workloads.

ninetieth percentile periods. Furthermore, service levels (IMS response times) vary due to the change in mix within the workloads (IMS online transaction workload). Therefore, service levels must also be considered.

It becomes apparent that the levels of several measurement factors must be considered to determining if an interval is representative of critical performance periods.

FACTORS USED TO IDENTIFY INTERVALS WILL BE DIFFERENT FOR EACH COMPANY

The factors that should be considered in identifying intervals representative of ninetieth percentile periods will depend on the nature of the business, the workloads, and service levels. Workload volumes and service levels of the major workloads in the configuration should be used in identifying ninetieth percentile periods. For capacity planning purposes, since a major objective is to plan for adequate processor resource, CPU utilization should also be considered.

For example, consider the following system. The primary production work involves IMS online and BMP processing with some O/S batch processing. Based on these workloads, the following factors might be used to determine ninetieth percentile periods:

IMS online transactions (for each different class of transactions)

IMS online transaction response time

BMP data base DL/1 calls (for each different class of BMP's)

BMP multiprogramming level

Production O/S batch job-steps per hour

CPU utilization

Let IMS transactions be classified by resource consumption with class 1 consuming the least resources and each class after that requiring more resources per transaction. Let BMP's be classified in a similar manner with class 1 requiring the least amount of resources per data base call.

Using the definition previously established for critical performance periods (four hour periods over a quarter) and the factors above, the critical performance periods must be identified by analyzing fifteen measurements for every four hour period in the quarter. That is, using the fifteen measurements from each four hour period, ten percent of the four hour periods must be identified as periods where service levels would not be *expected* to be satisfied (although service objectives may have been satisfied during those periods). Furthermore, periods which border the ninetieth percentile based on these fifteen measurements must be identified as the critical performance periods. To accomplish this, a definition of the *ninetieth percentile borderline* must be made in terms of these fifteen measurements.

A Ninetieth Percentile Borderline is Defined by the Identification Factors

A ninetieth percentile borderline period should be a period which represents ninetieth percentile CPU utilization. By considering the workload volumes, an appropriate workload "mix" will be determined as criteria for a ninetieth percentile borderline. In considering workload mix, is the "normal" workload mix the

desirable mix for a ninetieth percentile period? This is a decision made at the discretion of each company. Past experience would indicate that for a ninetieth percentile borderline period, each workload volume should be at a ninetieth percentile level. Furthermore, *each* factor used in the evaluation should be at a ninetieth percentile level.

Therefore, the ninetieth percentile borderline is defined as a period where all factors are at ninetieth percentile levels. It is reasonable to believe that if the CPU utilization is at the ninetieth percentile level, that workload volumes should also be at ninetieth percentile levels.

Ninetieth Percentile Periods Will Probably Not Have "Typical" Workload Mixes

It may be of some concern that the workload mix is *typical* if all workload volumes are at ninetieth percentile levels. However, the following should be kept in mind:

1. An interval will be selected which is an actual interval that was processed by the system. **This interval will be similar but may not match the borderline period exactly.**

2. If the objective is to process ninety percent of all periods incurred with satisfactory service levels, the periods near this ninetieth percentile borderline must be processed and service levels must be satisfied.

3. In the future, ninetieth percentile intervals will be processed and it will be required that the service objectives be satisfied. It is not likely that these intervals will have a "typical" workload mix, since "typical" is more like "average" mixes and the objective is to identify ninetieth percentile periods. However, it is likely that the workload mix will be similar to the critical performance periods identified using this criteria.

Workload Mix Impacts Occur in Two Different Ways

There are two types of workload mix to be concerned with:

- Inter-workload
- Intra-workload

Inter-workload mix is the mix of workload volumes between major workloads. For example, inter-workload mix would involve the number of IMS online transactions, the number of BMP data base DL/1 calls processed, and the number of production O/S batch jobs. These volumes are all at ninetieth percentiles for the the borderline interval.

Intra-workload mix is the mix of workload volumes within a major workload. For example, the mix of inquiry and update transactions in an IMS online transaction workload will vary. Resource requirements and response times for inquiry transactions will be much different than for update transactions. One approach is to classify transactions by resource requirements as described above. This reduces the impacts of intra-workload mix because all transactions in a class require the same resources. However, this may not be possible in every company. Therefore, two methods of accounting for proper intra-workload mix can be used:

- If classification of work cannot be done by resource use, intra-workload mix is indicated by three factors: service level, resource utilization, and workload volumes.

  Consider two different intervals. If the CPU utilization is similar, the workload volumes are similar, and the service levels are similar then it is likely that the workload mix is the same. For example, if two intervals have a CPU utilization of 80% and the workload volumes are similar, then IMS response times should be similar unless the mix of IMS transactions (intra-workload mix) is different. If IMS response times are similar and workload volumes are similar but CPU utilization is significantly different, there is probably a difference in intra-workload mix.

  Then if all three factors (resource utilization, workload volumes, and service levels) for an interval are similar to the ninetieth percentile borderline period, then the intra-workload mix should be similar.

- If classification of work can be done by resource use, intra-workload mix can be determined by each class.

  Two methods of using classes to determine intra-workload mix have been used. Both appear to give similar results.

  - Method 1.

    The *class* volume levels for the ninetieth percentile borderline interval are set at ninetieth percentiles. This will usually result in higher total workload volumes.

  - Method 2.

    The *total* workload volume for the ninetieth percentile borderline intervals are set at ninetieth percentile levels. The class levels are based on the average percent of the total workload volume that each class normally represents. The calculation in **TABLE III** shows how the class volumes are determined

  Method 1 sets workload *class* volumes at ninetieth percentiles while Method 2 sets *total* workload volumes at ninetieth percentiles and class volumes are calculated based on an *average* mix. Both appear to give similar results. However, Method 1 appears to be more restrictive and may not provide enough tolerance in identifying critical performance periods.

TABLE III

Class(i) volume = (ninetieth percentile workload volume) x weight(i)

where:

$$\text{weight}(i) = \frac{\sum_{\text{over all intervals}} \text{CLASS(I) VOLUME}}{\sum_{\text{over all intervals}} \text{TOTAL WORKLOAD VOLUME}}$$

i = the number of class within the workload

Figure 3. **Calculations to determine Class volumes within a workload:** The workload volumes for a ninetieth percentile borderline period are used to determine the workload volumes of each class within the workload. It is assumed that the proportion of class i volumes to total volumes for the workload will remain the same during the "critical" performance periods.

A SINGLE INDICATOR FOR EACH PERIOD SIMPLIFIES INTERVAL SELECTION

With many factors to consider in determining critical performance periods (15 for the example used in this paper), identifying representative intervals of critical performance can be complex. Developing a single indicator for each interval that reflects the similarity to the ninetieth percentile borderline interval simplifies the interval selection process.

This single indicator must be a combination (or function) of all the factors. However, combining the factors must be done carefully. Simply adding the factors together would result in the domination of the workloads by measurements of larger magnitude. For example, BMP data base DL/I volumes may exceed millions while IMS response time will likely be less than 10 seconds. This problem is similar to the problem that occurs in clustering. The problem is resolved in clustering by scaling the factors. A scaling solution will also work in this application.

All Factors Must be Scaled Before Combining into a Single Indicator Value

There are many methods of scaling. One common method is known as the zscale which scales each value by subtracting the mean and dividing by the standard deviation. The ZSCALE equation is shown as equation 1 in **TABLE IV.**

The scaled factor can be interpreted as the number of standard deviations from the mean of each factor. This scaling is successful in providing a uniform scale for all factors. However, in addition to obtaining a uniform scale for all factors, it is also important to know how close each factor is to the ninetieth percentile borderline interval.

Equation 2 in **TABLE IV** is modification of the common zscale which also indicates how close an interval is to the ninetieth percentile borderline period. This scaled factor can be interpreted as the number of standard deviations each factor is from the ninetieth percentile. The scaled factor then accomplishes two things:

- Puts all factors on a uniform scale.
- Relates how close the factor is to the desired level.

A Single Indicator Can be Found Through a Weighted Sum of Scaled Factors

By simply adding all scaled factors together for an interval, some indication of the similarity to the ninetieth percentile borderline period can be determined. If all of the factors are exactly equivalent to the ninetieth percentile values, then the sum of the scaled factors will be zero (i.e. each scaled factor would be zero). If the sum of the scaled factors is less than zero, then the interval generally is lower than the borderline interval. If the sum of the scaled factor is greater than zero then the factors are generally higher than ninetieth percentile borderline periods.

However, some factors used to calculate the interval indicator may be more important than others. For example, because much of a capacity planning process is done to ensure adequate CPU resources, it may be more important for CPU utilization to be close to the ninetieth percentile. It may be more important that the workload volumes of a workload that uses 40% to 50% of the resources be nearer the ninetieth percentile than the workload volumes of a a workload that uses only 10% of the resources.

Because there are factors which are more important in determining the similarity of an interval to the ninetieth percentile borderline period, they should be weighted

TABLE IV

1. The ZSCALE commonly used in clustering to give each factor a uniform scale

$$\text{scaled factor} = \frac{\text{factor} - \text{mean of factor}}{\text{standard deviation of factor}}$$

2. The modified ZSCALE using ninetieth percentiles instead of the mean

$$\text{scaled factor} = \frac{\text{factor} - \text{ninetieth percentile of factor}}{\text{standard deviation of factor}}$$

Figure 4. Scaling of factors: The first equation is a typical calculation to scale a variable to a common distribution with mean = 0 and variance = 1. The second equation is used in this paper to scale the factors to uniform variance. However, equation 2 is a modification of equation 1 which centers the scaled factors around the ninetieth percentile.

appropriately. Therefore, the single indicator factor can be calculated as shown in **TABLE V.**

THE INDICATOR CAN QUICKLY IDENTIFY REPRESENTATIVE PERIODS

The following criteria can be applied to the indicator value to determine the similarity of an interval to the ninetieth percentile borderline period:

1. Indicator > 0 : higher than ninetieth
2. Indicator = 0 : exact match to ninetieth
3. Indicator < 0 : lower than ninetieth

The "ideal" periods for modeling are periods where the indicator is 0. It is unlikely that any period will have an indicator of 0. Therefore, periods with indicators "close" to 0 will be good modeling periods. Experience has shown that the following guidelines should help select representative periods:

$$-.26 < \text{indicator} < .26$$

TABLE V

$$\text{indicator} = \sum_{\text{over all i}} (\text{scaled factor(i)} \times \text{weight(i)})$$

Where:

scaled factor(i) = the scaled value of factor i (as defined above)

weight(i) = the weight of factor i (based on importance)

and $\sum_{\text{over all i}} \text{weight(i)} = 1$

Figure 5. Calculation of the indicator factor for an interval: The table shows the calculation of a single indicator factor for each interval. This factor can be used to determine the similarity between a specific interval and a ninetieth percentile period. However, this equation contains offsetting factors that can effect the indicator value.

THE WEIGHTS USED IN CALCULATING THE INDICATOR FACTOR CAN BE OFFSETTING

CPU utilization and workload volume factors have a compound effect on the indicator. Consider the following:

First - Workload volumes and CPU utilization are both low.

When this occurs, the scaled factor for CPU utilization will be negative. The scaled factor for the workload volumes will also be negative. An interval that is slightly below the ninetieth percentile borderline period should have slightly lower workload volumes and slightly lower CPU utilization. When the factors are combined through the weighted sum calculation, the results are a lower negative indicator.

Second - Workload volumes are low and CPU utilization is high.

When this occurs, the scaled factor for CPU utilization will be positive and the scaled factors for the workload volumes will be negative. It is possible that when the indicator is calculated using the weighted sum, that the positive CPU factor and the negative workload volume factors will offset each other and an indicator value near 0 may result.

Similar analogies can be made for the other two possible conditions where CPU utilization is low and workload volumes are high, or CPU utilization is high and workload volumes are high. The weighted sum calculation then favors periods where CPU utilization is high and workload volumes are low, or CPU utilization is low and workload volumes are high. However, these periods are the less "representative" periods. The periods where CPU utilization is low and workload volumes are low, or the periods where CPU utilization is high and workload volumes are high are more representative (if they are close to the borderline).

The offsetting factors of CPU utilization and workload volumes can be corrected in the indicator calculations. The indicator calculation is made by subtracting the weighted scaled factor from the sum of all of the other weighted scaled factors. The final indicator equation is shown in **TABLE VI.**

ADDITIONAL CRITERIA WILL BE NECESSARY FOR THE FINAL INTERVAL SELECTION

Using the indicator value, a small number of intervals should be identified as candidates for modeling periods. The final modeling period selection can be done using the following additional criteria.

- The interval should represent the current configuration.

  The more current an interval is, the more likely that the interval will represent the current configuration. The last change to the configuration and the possible performance impacts of that change should be considered.

- Does the interval represent normal processing

  Specifically, will the processing done during an interval continue to be done in the future or was the

TABLE VI

$$\text{indicator} = \left(\sum_{\substack{\text{all factors but} \\ \text{CPU utilization}}} (\text{scaled factor(i)} \times \text{weight(i)}) \right) - (\text{scaled CPU utilization factor}) \times (\text{weight of CPU utilization})$$

Where:

scaled factor(i) = the scaled value of factor i (as defined above)

weight(i) = the weight of factor i (based on importance)

$$\text{and} \quad \sum_{\substack{\text{over} \\ \text{all i}}} \text{weight(i)} = 1$$

Figure 6. Modified indicator factor calculation: The table shows the modified calculation of a single indicator factor for each interval. The modification adds all factors except CPU utilization which is subtracted. This moves the value of the indicator farther from 0 (the ninetieth percentile borderline value) when workload volumes are high but CPU utilization is low or when workload volumes are low but CPU utilization is high.

processing a one-time function such as the initial population of a new data base etc.

- Restricting the acceptable CPU utilization range.

  The indicator value may allow a wider range of CPU utilization than may be desired. Adjusting the CPU utilization weight factor will help. However, if the CPU utilization weight factor is too high, the selection process will tend to ignore the other factors and some recommended periods may not be representative. An alternative is to keep the CPU weighting factor in the indicator calculation lower and then eliminate some recommended periods by establishing an acceptable range of CPU utilization (which should be around ninetieth percentile CPU utilization).

THE INTERVAL INDICATOR CAN SAVE TIME AND IMPROVE PLANNING.

The indicator method of interval selection can save time and improve the planning process because:

1. Periods are not modeled and later determined to be unrepresentative.
2. The cyclical nature of the processing is automatically handled.

   It is still important to understand the processing cycles and efforts should be made to do this. However, the indicator method assures that critical periods in the cyclical patterns are modeled.
3. The number of representative intervals are objectively reduced to a reasonable number from which an analyst can quickly select one.
4. It is assured that the periods which are modeled are representative.

This technique will result in a faster decision on selecting an interval for modeling and a better interval selection.

THE INTERVAL INDICATOR CAN BE USED IN ALTERNATIVE WAYS.

For model interval selection, there are two methods of implementation depending on the planning and modeling frequency. One method is to select intervals on a quarterly basis. is then selected from the previous quarter. The ninetieth percentiles and standard deviations used in calculating the scaled factors (which are eventually used in developing the indicators for each interval) are calculated quarterly at the time the model interval is selected.

Another method of developing indicators is to update the ninetieth percentile and standard deviation values used in the scaled factors on a regular basis. Then an indicator value for any recent period can be developed based on the most recent ninetieth percentiles and standard deviations. This approach has two advantages:

1. Identification of representative periods can be readily done for any current period.

   Specifically, when selecting a period from the previous day to be analyzed, the indicator can quickly determine what periods might be most representative.
2. If a performance problem occurs in a current period, it can be determined if this is a period above the ninetieth percentile borderline interval.

   If the period where the performance problem occurred is a period for which service levels are not expected to be satisfied, it may not be the necessary to analyze the performance problem. Some discretion is necessary in a decision such as this, but the indicator value can help the decision process.

THERE ARE SIX ADVANTAGES OF THIS INTERVAL SELECTION METHODOLOGY.

The interval selection methodology presented in this paper has many benefits. Six advantages of using this methodology are:

1. Intervals selected for modeling are representative.
2. The interval selection process becomes more objective.
3. The planning process will be improved by more clearly defining current performance/capacity levels.
4. The interval selection process is based on service objectives.
5. The process can eliminate wasted time modeling unrepresentative periods.
6. The indicator values can be used to reduce performance analysis of periods for which service levels would not be expected to be satisfied.

TOOLS AND METHODS AVAILABLE FOR IN-DEPTH VM PERFORMANCE ANALYSIS

Deborah C. Christopher
Duke Power Company

ABSTRACT

VM performance analysis and tuning can be a very complicated process. The normal performance analysis tools (VMMAP, SMART) lack key data that is required to adequately characterize a VM system. However, additional information can be gathered using simple user-written programs and methods, and using other software packages. Topics to be discussed include 3880-23, 3880-21, PROFS, 3090-200 migration, the latest releases of VM/HPO, the VM real storage constraint, and some ways to analyze their effects on VM performance.

1. INTRODUCTION

The key to successful VM performance analysis is having multiple sources of performance data. No one source should be depended on to thoroughly represent a VM system. This statement is especially true for a large HPO system. At Duke Power, we currently execute on a 3090-200E with 64 Mb of real storage, 128 Mb of expanded storage, two 3880-E23 cache controllers with one 3380-AA4 each (four single density 3380's), six full strings of single density 3380's (sixteen volumes each), and one full string of dual density 3380's (sixteen volumes each). At this writing, there are 1025 logged on users; this number is expected to grow 45 per month through 1987, and approximately 30 per month in 1988.

Instead of giving an overall description of each source of performance data, a specific use of the data will be presented as it relates to solving a particular problem or gaining insight into a situation or trend.

2. REAL STORAGE CONSTRAINT

2.1. BACKGROUND AND DESCRIPTION

The real storage constraint condition that exists for installations with large numbers of users logged on (1000+) may hinder the efficient use of IBM 3090 processors in the current VM environment. Since VM/SP HPO Release 1 was available in early 1982, there have been advances in processing power, DASD, and operating system software. Concurrent with these technological advances is the emergence of large VM communities on a single machine such as Duke Power's PROFS workload on a 3090-200E. However, since VM/SP HPO was designed with 24-bit addressing (16 Mb of storage is addressable), CP is limited to executing below the 16 Mb line. CP must reference (< 16 Mb) a V=R region, dynamic paging area (DPA), free storage (and prime free storage), and the trace table. Refer to Figure 1 for a map of real storage as it currently exists on Duke Power's 64 Mb 3090-200E.

Figure 1.

As early as Summer 1985, it became apparent that Duke Power would have to slow down expansion of PROFS because of the real storage constraint below the 16 Mb line (we did not call it that at the time). Free storage allocation was increasing with the rising number of users logged on. Ten megabytes seemed to be about the most free storage that could be allocated and still have a useful Dynamic Paging Area. Table 1 shows the relationship between free storage allocation and the number of logged on users, as was experienced at Duke Power Company.

Table 1

APRIL 1985 - NOVEMBER 1986

Free Storage Alloc.	Users Logged On
4 Mb	320
5 Mb	400
6 Mb	500
6.5 Mb	600
7 Mb	700
8 Mb	750
8.5 Mb	800
9 Mb	850

Free storage is used for CP control blocks - page and swap tables, and control blocks for spool files, virtual channels, virtual control units, and virtual devices. The amount of storage set aside as free storage is determined by the number of pages coded in the FREE operand of the SYSCOR macro in DMKSYS. The default is three pages for the first 256 Kb of storage, one page for each 64 Kb after that, additional pages are allocated if the system used extended storage, one page is allocated for every 256 Kb of > 16 Mb storage, and the default is 25% higher in AP and MP modes.

Prime free storage is an area within free storage dedicated to cache-aligned (16 doubleword) control blocks. The default allocation for prime free is 10% of the free storage allocation. For example, if free storage is set at 6 Mb (1536 pages), then the default allocation for prime free would be 154 pages. Sixty (60) pages have been enough for us; prime free storage utilization averages 55% for 15-minute summarizations. The prime free setting is coded in the PRIME operand of the SYSCOR macro in DMKSYS. Planning guides usually give a recommendation on the size of FREE and PRIME. However, we have needed more free storage and less prime free than IBM has estimated (approximately 2.5 pages per user HPO 3.4 and 1.4 pages per user under HPO 4.2). Once the system is running, the settings should be reevaluated using information from the Virtual Machine Monitor Analysis Program (VMMAP) OUTFREE1 report (for free storage), and OUTFREE2 report (for prime free storage).

OMEGAMON/VM (Candle Corporation) can provide detailed real-time information about free storage utilization:

1. TTFR - summary of free storage utilization by userid

2. FREA - number of CP free storage frames available

3. FREE - number of CP free storage frames defined in DMKSYS

4. FREL - number of CP free storage frames in use

5. FREX - number of CP extended free storage frames

VM Real Time Monitor (SMART) provides a summary of free storage calls in the FREE display. SMART's LOGMSG 6 will indicate when CP FREE STORAGE is extended beyond the number of pages specified in the LIMIT.

2.2. MINIMIZING THE REAL STORAGE CONSTRAINT

IBM has made several recommendations on reducing low storage requirements in general, and on reducing free storage requirements in particular [3]. These recommendations include the following:

1. Migrate to HPO 4.2.

2. Reduce the size of the CP nucleus by tailoring the standard load lists.

3. Reduce the size of the CP internal trace table, if feasible. Settings other than the default are specified in the SYSCOR macro of DMKSYS, TRACE option.

4. Reduce the number of monitor buffers. Watch for VM monitor suspension records. This parameter, BUFFS, is also set in the SYSCOR macro of DMKSYS.

5. Reduce SET RESERVE (if any) as much as possible.

6. Check free storage and prime free for overallocation and adjust.

7. Encourage inactive users to LOGOFF, thereby freeing up their free storage pages.

8. Eliminate unnecessary devices from directory entries; each virtual device control block requires free storage.

9. Number virtual device addresses consecutively to minimize the number of virtual channel and control unit blocks.

2.3. FREE STORAGE GAINS WITH HPO 4.2

With approximately 850 users logged on when Duke Power implemented HPO 4.2, free storage requirements dropped dramatically - from 9 Mb down to 6 or 7 Mb. This drop can probably be attributed to the automatic migration of the page and swap tables of inactive users. HPO 5.0 should reduce free storage requirements even more.

3. 3880-23 CACHE CONTROLLERS

3.1. EVALUATING CACHE CANDIDATES

Planning is the key to making effective use of IBM 3880-23 cache controllers; the Model 23 is used to cache non-paging data. When cache is properly used, significant reductions in response time can be realized, especially in a PROFS environment. Good candidates for caching include data with relatively high activity and high read to write ratio. Other questions to consider are:

- Will better response times on this I/O measurably reduce end-user response time?

- How much cache is available?

- How many minidisks on the volume should be cached?

To determine minidisk access rates and read/write ratios, the SEEKS class of VM Monitor data should be enabled. However, enabling SEEKS for an entire eight or nine hour period would produce an unmanageable amount of data. A better alternative is to randomly enable the SEEKS monitor class, divide the prime time period into five-minute intervals and randomly choose a percentage of those intervals (10% works well). This random sampling method should provide the kind of information necessary to characterize minidisks for caching purposes. VMMAP can produce four reports from SEEKS data:

1. Detail by VOLSER, starting cylinder, inactivity included.

2. Summary by VOLSER.

3. Summary by VOLSER, sorted by descending usage.

4. Detail by extent, sorted by descending usage, inactivity excluded.

Each SEEKS detail report lists volser, start and end cylinder, owner id, virtual address, total seeks, percentages of the device and system that the seeks constitute, and a read percentage. The read percentage is only available on systems running VM/SP HPO 4.0 and up. This value is used to determine the read/write ratio for the data. That data, combined with the size the minidisk and percentage used should be enough information to select preliminary caching possibilities. The percentage of the minidisk that is currently being used can be extracted (using disk queries) and multiplied by the size of the minidisk to determine the actual number of blocks/cylinders of data. All of the information can be combined (using SAS, for example) to produce a list of frequently used minidisks and their access rates, read percentage, and DASD occupied. Certain data areas should be excluded from the list: PAGE and SWAP areas, SPOOL, and TDISK areas. The effect of caching data on end-user response time can be estimated by modeling or tested through trial and error.

Data can be cached by volume or by minidisk. Duke Power had E23 cache controllers prior to running HPO 4.2; at that time, we used VM/SP CMS Support for 3880 Model 13 and 3880 Model 23. The Program Offering allowed us to designate which CMS minidisks should use the cache, and also provided a new VM Monitor record (MN606 - VM Monitor Cache Performance Data). This monitor record included basic information about I/O requests, and read and write hits; we created our own Cache Activity reports using these records. With HPO 4.2, VM Monitor now records cache performance data and VMMAP provides a basic analysis of the data.

3.2. ANALYZING CACHE PERFORMANCE

Using this process at Duke Power, for two 3880-E23's (16M each = 23.56 cylinders (3380 DASD)) the following minidisks were placed at the top of the list:

SYSADMIN 399 - 17 cyl (3380 DASD) * 61% used = 10.37 cyl = 7.04 Mb

SYSADMIN 498 - 5 cyl (3380 DASD) * 96% used = 4.80 cyl = 3.26 Mb

MAINT 190 - 31 cyl (3380 DASD) * 84% used = 26.04 cyl = 17.69 Mb

Caching this data reduced the response time from 22 to 3 MSEC/IO in each case, with a read/hit ratio of approximately 100%. This reduction brought about a noticeable improvement in the elapsed time for logons to our PROFS system, and is a significant factor in our ability to support more than one thousand logged on users today.

The VM Real Time Monitor (SMART) provides some information on read/hit ratios in the CACHDBSE display. Figure 2 is an example of the 3880-23 display. Devices 0300 and 0800 contain cached data. Notice that there is one line on the display for each storage director. VMMAP's 3880-23 Subsystem Activity Log also summarizes cache usage including cache hit ratios, I/O rates, and read percentages.

Figure 2.

4. 3880-21 CACHE CONTROLLERS

The IBM 3880-21 cache controller was designed for use by the paging subsystem. At Duke Power, before our HPO 4.2 system was moved from a 3081-K to a 3090-200E, two 3880-J21 paging cache controllers were used. The utilization of the J21's, along with the associated tuning that was performed resulted in a dramatic improvement in host response times:

Trivial Response - 45% improvement

Average Response - 21% improvement

The J21's were configured symmetrically, with the ALTCU at the same address as the primary storage director. Using this method, the second storage director is also a second channel path. If ALTCHAN had been used, the second control unit would not have been recognized, causing unnecessary control unit busy conditions.

For each real paging address defined to the 3880-21, three other paging addresses are generated. For a real address 200, for example, the generated paging addresses would be 204, 208, and 20C. For a real paging address 201, the generated paging addresses would be 205, 209, and 20D. After a 3880-21 actuator has been selected to service a paging I/O, the first paging address is looked at. An I/O is issued to that address if it is free. If it has an active I/O or if it is already scheduled, the second paging address is looked at, then the third, etc. If all addresses are scheduled or active, the I/O will be queued to the address with the smallest queue. The I/O is distributed over the paging addresses as described in Table 2.

Table 2

Distribution of I/O

Paging Address	Percent of I/O	MSEC/IO
1st	68	4.1
2nd	18	9.2
3rd	14	12.1
4th	< 1	3.6
	Average Page Service Time	6.138

5. EXPANDED STORAGE

At present, there seems to be no accurate way to calculate response time per page or swap from expanded storage. Fortunately, this lack of information should not significantly impact the duties of a performance analyst. The response time for expanded storage operations should be positively reflected in lower system response times. Data is available on the allocation and usage rates of expanded storage.

The SMART PAGEAREA display includes allocation and deallocation rates, reads and writes, start I/Os per second, and percent full of each SW, PP, PG, PM, and PS area. Refer to Figure 3 for an example. VMMAP includes similar information on allocation rates, reads, and writes.

6. ANALYZING PROFS WORKLOADS

6.1. VM COMMAND MONITORING

In the current VM environment, the choices for performance monitors are limited, especially in the area of command monitoring. Various mechanisms are available for MVS with which to capture detailed information by userid, job, TSO command, CICS transaction, etc. The lack of information of this type for VM does not suppress the need for it. Command level information can be a valuable tool in VM performance analysis, tuning, and capacity planning.

VM Monitor can provide some data, but it is not very comprehensive. The USER (Class 4) records from VM Monitor show resource usage statistics for the interval (usually 60 seconds) for each user in the system. RESPONSE (Class 1) records show some terminal activity information, but the input and output terminal data collected is limited to first 128 bytes [6].

The VM Accounting data also includes user-specific information, but in less detail than the VM Monitor data. The virtual machine user records are stored when a user ends his terminal session or when the ACNT command is issued. The resources used (connect time, CPU time, page reads and writes, sios, spool information, etc.) are summarized for the session. Obviously, accounting data is not retained at the command level either.

6.2. PROFS COMMAND MONITORING

There are few command monitoring facilities available. IBM provides exits with PROFS that allow data collection with customized exit routines [4]. These exits, called by PROFS, are sent information on the size and frequency of messages, notes, and documents sent and received.

The exits are listed below along with a brief description of when each is called.

- EPRACCTG - called at the start and end of PROFS sessions, PROFS commands, non-PROFS commands from the PROFS command line, when a message or note is sent, when a message is received, and when a document is stored.
- EPRRACCT - called whenever a user opens the mail.
- EPRMACCT - called whenever mail is sent or received.
- EPRLACCT - called whenever an item is stored in or retrieved from the document or calendar data bases.

Each exit can collect several different observations, and there are some restrictions and guidelines that must be considered when coding each exit. Additionally, since all PROFS users would be executing these exits for potentially each task performed, the amount of data collected could be prohibitive. The *PROFS Programmer's Guide* cautions that "If you enable the accounting user exits, you risk degrading performance." Such notes regarding system performance are rarely present, but when they are they should be adhered to and certainly not taken lightly. All of these cautions should be magnified for large PROFS communities on a single machine. The documentation also suggests avoiding spooling by using SMSGs to a PROP (Programmed Operator) machine.

6.3. OTHER OPTIONS

There are a handful of performance monitors that collect information in varying degrees of detail at the command level. Duke Power has successfully used CMAP (Command Monitor/Analysis Package from VM/CMS Unlimited, Inc.) for studies requiring command information. One study involved determining the number of PROFS ids that use the REMINDER function of PROFS. Using SET CLOCK OFF as the default for all PROFS users was under consideration. Eliminating activity caused by timer "pops" would reduce the resource consumption by truly inactive users. Setting the clock off would also reduce the effectiveness of reminders since the reminder would not be displayed during periods of inactivity without a timer pop. However, if the REMINDER function is used by a small percentage of users, it may not be an issue.

Certain minor changes in the PROFS environment are necessary to take advantage of CMAP monitoring. Once the changes were made and after gaining more experience in using the product, we collected data that showed that 7% of our PROFS users had used the reminder functions.

7. HOME-GROWN PERFORMANCE DATA BASE

Instead of running the VM Monitor data through an expensive data base system (expensive to buy, maintain, support, use, and store), in-house software was developed to retain key parts of VMMAP and SMART in a SAS data base for use in daily performance analysis and short-term capacity planning and trend analysis. The data base provides added flexibility in data manipulation and trend analysis beyond VMMAP ACUM files. Variables in the data base come from the following VMMAP reports:

1. Monitor Statistical Summary (OUTSTAT)
2. User Response Time Analysis (OUTRESP)
3. User Resource Utilization Summary (OUTUSER)
4. Disk and Tape I/O Activity Summary (OUTDASD)
5. Channel Activity Summary (OUTCHAN)

In many cases, data from this performance data base is enough for analysis. However, if more detailed information is needed, there are several ways to derive it:

1. Produce a more detailed VMMAP report. For example, if you need to know system resource utilization (CPU busy, paging, swapping, storage) by minute, then run VMMAP with an interval of one (1). This interval is specified in the MON PARM file; this file is used to select VMMAP reports to be produced.
2. Process the VM Monitor data.
   a. The format of the VM Monitor tape is described in the *Systems Programmer's Guide*. For more information on individual fields, consult *VM/SP HPO Data Areas and Control Block Logic - CP*.
   b. The time-of-day field must be decoded.
      1) Each record has a header portion. BYTE 1 is the Monitor Class, BYTE 2 is the Monitor Code, and BYTES 3-7 are the time-of-day. The Systems Programmer's Guide notes, "Time of day occupies 2 fullwords in storage, with the rightmost 12 bits zeros. The rightmost 2 bytes and the leftmost byte are ignored, giving 16-microsecond accuracy instead of 1-microsecond." More simply stated, use the SAS informat PIB5.6 (or the equivalent), positive integer binary 5 bytes long, 6 decimal places.
      2) The time-of-day contained on each data record is relative to the Date and Time of data collection on the CLASS 0 Code 97 record.
3. Process the VM Accounting data.
   a. The VM Accounting dataset is much smaller than the VM Monitor dataset. The timestamp needs no conversion, and the records are fixed length, 80 bytes.
   b. This data can provide quick information on the number of logons and logoffs per day. Using user accounting fields, the amount of resources consumed by groups, divisions, and departments (for example) can be reported. In general, the basics about each terminal session can be extracted.
4. Process the operator's console log.
   a. The operator's console log is the only place that terminal id can easily be determined. The terminal id can be used to analyze the distribution of ids across lines.
   b. Exception messages from SMART can be seen in relation to other activities in the system: logons, logoffs, disconnects, reconnects, VTAM activity, and any user-generated messages. Information such as system time, spool utilization, and query users (if issued by the operator) will also be included.

Figures 4, 5, and 6 were created using data from the performance data base and SAS/Graph. Please note that a 3090-200E replaced a 3081-K in WEEK 24 of 1987.

8. SUMMARY

Understanding the performance characteristics of large VM systems can be a complex process. However, the task will be made easier and more reliable by using multiple data sources and tools. Conventional methods will not always point out potential problems, especially in the following areas:

- Real storage
- Cache controllers
- PROFS workloads

- Large VM systems

The sources of VM performance data mentioned include the following:

- VM Monitor data
- VM Accounting data
- Operator's console log
- Command information
- Real-time monitors (SMART, OMEGAMON/VM, for example)
- VMMAP

With VM/XA on the horizon, the sources of data and tools available to deal with that data will probably change. However, the basic idea behind VM performance analysis should always remain the same: the more you know, from as many sources as you can find, the better.

CICS AND DB2: A MARRIAGE MADE IN HEAVEN?

Jason Shane
Coldwell Banker Residential Group

James Cook
Data Strategies, Inc.

ABSTRACT

The use of IBM's CICS and their DB2 data base systems continues to grow in popularity, yet most are unaware that a basic inconsistency between CICS and DB2 architectures exists which can cause response time degradation, user dissatisfaction with the application and additional network traffic.

This paper documents in detail each of the known problems and discusses their impact on user productivity and system resources. In addition, the CICS architectural features, DB2 restrictions, and SNA protocols involved are reviewed and their effects on the application design are discussed.

Because architectural incompatibilities are difficult to detect and impossible for the user community to resolve, the authors will also discuss how these problems were detected and the mechanism through which a resolution was pursued with IBM.

INTRODUCTION

Early in 1986 IBM began to stress its commitment to its relational database DB2. Significant performance enhancements were made and more were rumored. Additional incentives were generated for seriously considering the development of DB2 applications when IBM announced that its coming data repository would make DB2 an MVS prerequisite. In the midst of this confusion and uncertainty, IBM attempted to pacify a customer base concerned over the viability of its investment in existing products and strategies. To this end, Merry Quakenbush, Director of Industrial Sector Marketing for IBM in Atlanta said:

> "IBM will continue to pursue a dual database strategy for the balance of this decade. We are going to protect the investment of our customers. By 1990 however, things could change. Over time you will see IBM developing into a relational database provider."[1]

Statements of this type encouraged progressive installations to "jump on the DB2 bandwagon". Those developing online applications utilized CICS for communications by default, since no other vehicle was available. Given the lack of choices, they felt confident that IBM had clearly "marked" this approach as a migration path.

Now, with IBM's promise two-and-one-half years old, some of these "pioneers" have fully-functional, production DB2 systems. Only recently have they discovered that there were a few "unpaved stretches" on the migration path. CICS' support of DB2 is substantially different than its other support. As a result, IBM has exacted a high toll in performance. This paper endeavors to document the nature and consequences of one known problem.

THE PROBLEM AND ITS IMPLICATIONS

A large number of CICS applications have been designed to execute as pseudo-conversational transactions. To pass control from one application program to another the CICS transfer control function (XCTL) or LINK are most often used. Doing so, causes the original CICS transaction to remain in control. Several different application programs may have been executed, but only one CICS transaction was involved.

However, when using DB2 with CICS, neither the XCTL or LINK have any effect on the DB2 thread! Therefore, the XCTL and LINK will not work the same in a CICS/DB2 environment as they did in a CICS/VSAM environment. This is because each CICS application program is associated with a single DB2 plan in the CICS Resource Control Table or RCT--one application program to one plan. In other words, as a result of an architectural incompatibility between CICS and DB2, two of the most widely used of CICS functions, the XCTL and LINK will not work as before.

As a result, to execute an application program other than the one that was originally started, the first CICS transaction must terminate and then start a new CICS transaction whose definition in the RCT points to a different DB2 plan.

When the first CICS transaction ends, CICS architecture dictates that an SNA End Bracket (EB) be sent to the user's 3270 terminal. Then, before the second CICS transaction can begin, the terminal must be reacquired using the SNA BID request. Only after an SNA positive response is received, can the second CICS transaction execute.

Consider the following scenario (Follow along with the illustration in Figure 3). The user starts the menu transaction by entering "MENU." An SNA Change Direction (CD) and Begin Bracket (BB) are sent locking the user's keyboard. The MENU CICS transaction is started, obtains service from DB2 and transmits the menu screen to the user, ending the transmission with an SNA End Bracket (EB) which unlocks the user's terminal. Options 1 thru 6 are now displayed on the user's terminal.

The user now selects Option #1 and hits Enter. Another SNA Change Direction and Begin Bracket are sent locking the user's keyboard. The MENU transaction starts a second time to interpret which option the user selected. Having deter-

mined that Option #1 was selected, the MENU program now needs to pass control to the program that will execute Option #1. The CICS XCTL function cannot be used because the Option #1 program will execute a different DB2 plan than the MENU program. Therefore, the MENU transaction issues a start transaction for the Option #1 transaction (Transaction #3 in Figure 3). The MENU transaction ends by transmitting an SNA End Bracket which unlocks the user's terminal.

Before the Option #1 transaction can start, CICS must re-establish communications with the user's terminal. Since, according to convention, CICS does not know if the terminal is still available (even though CICS released the terminal only a fraction of a second ago), CICS must transmit an SNA BID to request the terminals attention. The Option #1 transaction must now wait until an SNA positive response is received, indicating the terminal is available for communications.

When the positive response is received, the Option #1 transaction starts executing, obtains DB2 services, and transmits the data starting with an SNA Begin Bracket that locks the user's terminal again. When all data has been sent, CICS sends an SNA End Bracket to again unlock the user's keyboard. The user's transaction is now complete.

Thus, to complete a single user transaction, two or more CICS transactions must be executed. This one-to-many mapping of transactions has significant impact on service levels, user satisfaction, network capacity and network management.

USER SATISFACTION OF ONLINE SERVICE

In the example, it was noted that when the MENU transaction ended, an SNA End-Bracket was transmitted to the user's terminal causing the user's keyboard to be unlocked. The user's keyboard remains unlocked for the duration of the following transaction (point 4 to point 8 in Figure 3) which could be several seconds.

When a user sees the "clock" symbol go away and no data appear on the screen, it seems to be human nature to try the last transaction again. Who knows maybe it will work better this time. However, an annoying situation occurs when the user enters a second transaction from the same terminal from which one is already in progress. The CICS node error program (NEP) generates an ATNI abend and the user's SNA session with CICS is immediately terminated. The only way to recover is for the user to call the company's help desk staff and for them to provide the necessary support to restore the user's CICS session.

To summarize, a user enters a transaction and waits. The system responds by unlocking the keyboard in the manner the user has observed many times before; only this time, no response to the user's request is received. The frustration begins. Thinking things have failed, the user tries the transaction again only to be knocked completely off the air. The user's temperature soars as he calls the company's help desk. Any help desk problems encountered about now, make the situation intolerable in the user's eyes. Information Services has failed again!

These problems occurred as a result of the first, unnecessary End Bracket that unlocked the user's keyboard. The EB was sent because the CICS XCTL was not available in a CICS/DB2 environment. As a result, multiple CICS transactions were needed; but whenever a CICS transaction ends, by convention, the End Bracket is sent.

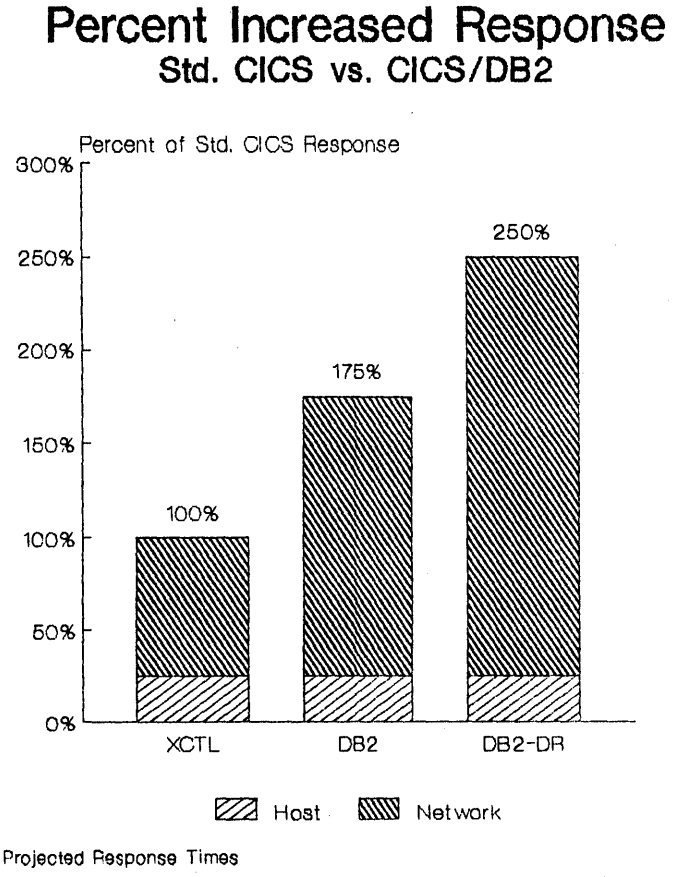
RESPONSE TIME IMPACT

In a CICS/VSAM environment, the transfer of control from one program to another (XCTL) within a CICS transaction usually occurs somewhere in the millisecond time frame--a small effect on user response time. However, the multiple transactions required in the CICS/DB2 environment have considerably more impact.

In the example, when the first CICS transaction ended, it released the terminal (point 4 in Figure 3). Before the second CICS transaction could process a complete round trip of the network was required to reacquire the terminal (refer to points 5 to 7 in Figure 3).

For locally attached users, the extra round trip of the network to BID for the terminal is typically quite fast and is generally unnoticeable to the end user. Remote users in single-domain networks, generally see a definite, perceptible, but not intolerable addition to their response time. However, when the "extra" BID must traverse the backbone of a complex, nationwide, multi-domain SNA network the overhead is intolerable!

Figure 1



Such a network, with a host response time of one second and a network response time of three seconds, would add 75 percent to the user's response time for each additional CICS transaction that must be "started" by a previous transaction rather than using XCTL. What could have been a four second response time became a seven or ten second response time as shown in Figure 1. This quickly results in user dissatisfaction. This increase in response time could be termed the "service cost" of electing a CICS/DB2 implementation.

NETWORK OVERHEAD AND PERFORMANCE

Along with the response time impact of the BID described above, additional network traffic is added. Even though the SNA BID generates a relatively small amount of network traffic in relation to an inquiry, some capacity is still being consumed for no productive purpose. Also, some line band-width is being consumed which could otherwise be used for polling, thus increasing the wait-for-poll component of response time. What is worse, if a company is being charged for network traffic, these extra BIDs are now costing you money and buying you nothing.

Of greater impact are any performance problems that may exist in a given network configuration. Every problem will likely generate twice the impact it might otherwise cause. Every time the BID is transmitted, it will encounter the same network delays (poll delay, queuing, line errors) that normal data traffic encounter. So, if a network configuration bottleneck was degrading response time by one second, the extra BID would now cause the degradation to total two seconds. Network problems have been magnified.

USER RESPONSE TIME MEASUREMENT

User response time measurements are a fundamental part of IBM's network management methodology. Computer Center management and User management are no longer satisfied with only internal host response time reports. User response time reporting has come of age.

However, some interesting complications arise when one attempts to collect and report user response time measurements of pseudo-conversational CICS/DB2 transactions. Lets consider why this is so.

To obtain user response time measurements, software monitors have traditionally used the SNA definite response (DR1) feature. This facility, started by making table changes in CICS, requests that the user's terminal positively acknowledge the receipt of every transmission sent to it. Doing so allows software monitors to measure quite accurately, the user's total response time. The definite response has little impact on CICS performance since nothing critical is waiting for the definite response to return.

Starting definite response in a pseudo-conversational CICS/DB2 environment will add another round trip of the network to the round trip already being made by the BID.

Recall earlier how the second CICS transaction had to wait for the positive response from the BID request before execution began. Now, with CICS definite response started, the first End Bracket transmitted will request a definite response too! This positive response must be received before the BID can be transmitted. The BID will then be sent and must still wait as before. The net result is now two full round trips of the network must be made between transactions one and two. All of the waiting described here is part of the user's response time. Therefore, the use of definite response becomes intolerable. We are degrading response time just to be able to measure it.

What is needed is a means of using the definite response function from outside of CICS, in VTAM itself. This approach immediately rules out IBM's Network Performance Monitor (NPM). The only software monitor that supports this type of operation at present is Netspy from Duquesne Systems. The VTAM activated definite response capability has been developed for Mazdamon and has been successfully tested by the author. But, Mazdamon's new owners, Computer Associates, have chosen not to release this critical feature at this time. Therefore, Mazdamon, as it exists today, is not a realistic alternative for a response time monitor in a CICS/DB2 environment.

By dynamically switching on definite response in VTAM, the second CICS transaction does not have to wait for the End Bracket's positive response to return because CICS knows nothing about the definite response request. So, we once again have measurement at an acceptable overhead cost.

Another problem created by this CICS/DB2 incompatibility arises in how some monitors determine when a "user" transaction has ended. Traditionally, many monitors have used the End Bracket to signal the end of user transaction in a 3270 environment. However, as we have noted earlier, pseudo-conversational CICS/DB2 transactions send at least two End Brackets in each user transaction. Therefore, such monitors will erroneously report two transactions, one short and one medium, rather than one long transaction.

NPM interprets the end of a user transaction as occurring when the Last in Chain, Last in Segment, Change Direction, or End Bracket bit in the last PIU is received. However, these SNA indicator bits, except for the Change Direction indicator, have been observed in the PIU that sends the End Bracket for the first CICS transaction. Therefore, the NPM monitor is effectively useless in the CICS/DB2 environment.

IBM's Response Time Monitor (RTM) functions somewhat differently than NPM. The NLDM/RTM parameter RTDEF allows the user to define what event should signal the end of a user transaction. The CDEB and KEYBD options will not work for reasons described above. These parameters tell RTM to end the response event when Change Direction or End Bracket bits are sensed or when the user's keyboard is unlocked (remember End Bracket unlocks 3270 terminals).

The default for the RTDEF keyword is FIRST. This parameter tells RTM to end the response event when the first character of the reply from the host, that will modify the presentation space, arrives at the user's terminal. This option should work, but has not been tested by the author. The assumption here is

that between transactions one and two, the application program does not send out any intermediate messages to the user's terminal such "Your request is in progress. Please wait." Such an intermediate message would fool this RTM option and provide erroneous response times. Also note that "first character" does not fit the usual definition of response time any may vary significantly depending on the length of time required to display the entire response.

Though not tested by the author, the developers of Netspy claim their product is also able to determine the proper end of a user transaction. The bottom line is that selection of the correct software monitor is a prerequisite to user response time reporting in a CICS/DB2 environment.

PROBLEM DETECTION

To help readers to discover if they have the same problem, we will describe our measurement approach. When response time was not meeting expectations, an analysis was performed on performance of CICS and DB2. After running out of ideas for tuning the host environment, we decided to review the network activity.

To analyze the network traffic in detail, we needed a path information unit (PIU) listing. We used Mazdamon to capture and produce these listings. However, a VTAM buffer trace will produce the same results. The goal was to list the request/response header (RH) and request/response unit (RU) information.

To make the test results as easy to interpret as possible, a series of poor performing test transactions were selected. The same type of terminal being used by our users was used for the test just in case the terminal was having some kind of effect on performance.

After executing each of the test transactions is a specific documented sequence, a list of all of the PIUs was produced. The basic PIU flow observed is shown in Figure 2. As can be seen, an End Bracket was sent in PIU number 0097. Because of the EB, CICS reacquired the terminal with a BID in PIU number 0098. From the time stamps, it was observed that CICS waited for the positive response to the BID PIU, 0098, before continuing processing. The first clue to a serious problem was found!

Figure 2

SNA PIU Flow for CICS/DB2 Transactions

PIU Direction	Seq. Numb	Req/Resp. Header	Req/Resp. Unit	PIU Function Description
Inbound	001F	03 90 A0	7D-ENTER	User hit ENTER BB and CD received
Outbound	0097	03 91 40		End Trans #1-EB sent
Outbound	0098	40 80 00	C8	BID Request sent
Inbound	0098	CB 80 00	C8	Positive Response to BID received
Outbound	0099	02 90 80		BC/BB and data sent
Outbound	009A	01 90 00		EC & last data sent
Outbound	009B	03 90 40		EB sent a 2nd time

When checking the PIU flow in your installation, the key PIU to look for is the BID PIU, number 0098 in Figure 2. The presence of the BID in a 3270 environment, indicates you have this CICS/DB2 problem. If you find that this problem does exist in your installation, the next section discusses IBM's recommended solution, the impact of IBM's recommendation and additional follow-up information.

IBM's RECOMMENDATION - A SOLUTION?

When this problem was first detected in 1985, local IBM SEs were contacted and questions were submitted to IBM via their Equal System. In response, IBM said that if two programs are separate load modules operating under a single CICS transaction, you would need to bind the DBRMs for each program into a single DB2 plan, and this is the plan that would be specified in the CICS RCT. Since the severe performance impact of using large Plans was fixed in DB2 Release 2, IBM suggested this was a reasonable solution to the problem.

While this solution can help to reduce the problem, it by no means eliminates the problems described above and creates several more. In an installation where user productivity and flexibility was one of the primary application design goals, users were given the ability to "jump" from almost any system to any other system. From a personnel system screen, a user can switch to the accounts receivable system or to any other system available. This means to apply IBM's recommendation, the DBRMs for every load module from almost every system would need to be bound together into a few immense DB2 plans. Consider the colossal change control problem this would create.

Also consider, should a small change to any load module or SQL code in any part of a system be in error, DB2 will invalidate the entire plan. Now, instead of losing a single function of a system, one could potentially lose an entire system. In addition, a simple change that required a rebind of a plan, could be very complex to implement. Remember that every time RUNSTATS is executed, it stores data in the DB2 catalog. This data is used at bind time by DB2 in the extremely critical data access path selection process. If the last time RUNSTATS was run, the data base was in a less than optimal condition, the entire data base accessed by the system being changed may need to be reorganized before the rebind is accomplished. If this is not done, the data access path selection process may not pick up data base indexes or decide to perform tablespace scans--both of which can severely impact response time. Thus significant exposure and effort are required for each application code change or any other change requiring a rebind.

The complexities involved in tracking which DBRMs to combine with which load modules, modifying compilers to combine the correct load modules, and testing these combinations all serve to increase the complexity of application software maintenance and the chances for error. This is an absolutely intolerable condition with today's ultra high availability online systems.

In short, the massive binding together of DB2 plans is a "band-aid" solution to a serious problem. In a system of strategic importance

to both IBM and their customers, a more robust approach is required.

As noted above, this problem was first reported to local IBM SEs in 1985. However, little progress toward a resolution was made until March, 1987 when a PASR was finally created on this problem. The PASR was assigned number RKBU110. The title of the PASR is "ALLOW XCTL BETWEEN CICS TRANSACTIONS WHEN USING DB2 PLANS." The description reads as follows: "Need to be able to go from one DB2 plan to another within a single executing CICS task, just as one is able to go from one application program to another program within a single task."

In July, 1987, a request was made for the status on the PASR. The following is the response received from an IBM Senior Product Administrator on the DB2 DB/DC Product Management team: "Regarding PASR RKBU110, your understanding is correct in that development is fully aware of the situation and is working on resolving it. We do not, at this time, have a solution but have taken this PASR as INPUT TO PLANNING" (emphasis theirs).

As of September 1987, no additional information has been received from IBM. If this problem has application in your installation, the author recommends you ask your local IBM SE for a status of PASR #RKBU110.

CONCLUSION

In all fairness to IBM and all others involved in this problem, it is one of those that would have been most difficult to prevent or detect. The complexity of this problem spans the internal architecture of DB2, the internal architecture of CICS and SNA communications protocols. Each of these areas represents a lifelong career to really gain an in-depth understanding. As a result, few people have an in-depth working knowledge of all three. This fact slowed down our ability to communicate the problem to others. In the words of one CICS expert the author spoke to, "I never would have thought of that problem. But now that you describe it in detail, it all makes sense."

In any event, the author is sure that the problem is now being energetically worked on by IBM. Considering the strategic importance of DB2 and CICS to both IBM and their customers (especially those installations that made early commitments to use DB2 in full-scale production), it would seem reasonable that a resolution will not be too long in coming. DB2 Release 4 maybe?

MODELLING CICS SYSTEMS: THE PERFORMANCE IMPACT OF MRO IMPLEMENTATIONS AND DATA BASE CONSIDERATIONS

Ellen M. Friedman
E.M. Friedman, Inc.

ABSTRACT

Today, CICS systems are more complex and require more resources than ever before. The process of measuring and modelling CICS systems has also become more elaborate, a result of recent architectural enchancements in Inter-system Communication (ISC), inter-region communication and particularly with Multiregion Operation (MRO).

As performance analysts, we are concerned with measuring CICS performance and determining its resource usage, regardless of the particular CICS design architecture. As capacity planners, we are concerned with anticipating the impact of alternate implementation strategies on future on-line system performance.

This paper reviews the various CICS architectural options including: MRO, ISC and database interfaces, and presents the relevant performance measurements available to quantify CICS resource utilization under each of these implementations. A general methodology for representing CICS workloads in analytic models is presented, as well as a specific workload characterization and modelling methodology for an MRO system with several data base interfaces (DL/1, Adabas). Several examples illustrating the applicability of these techniques are included. A case study comparing projected MRO usage with actual measured data will also be discussed during the presentation.

Introduction

CICS provides an environment that allows for considerable architectural flexibility in the design of DB/DC applications. As a result, the number of installations utilizing CICS has grown significantly in recent years. CICS systems can support a wide variety of customized on-line applications encompassing multiple subsystems which are capable of communicating across a large SNA network. The variety of design and architectural features are numerous. CICS provides file control capabilities to support various IBM data access methods and data base products and can interface with other non-IBM data bases including IDMS, Adabas and DATACOM/DB. Furthermore, CICS systems can communicate with other CICS systems and data base regions, within the same processor complex, as well as across TP links to other CPU's.

The modes of intercommunication available with CICS include Intersystem Commmunication (ISC) Multiregion Operation (MRO) [ref.1] . With Intersystem Communication, one CICS system can access files and data bases from another region (CICS or IMS) in a connected system via SNA links. The Multiregion Operation (MRO) feature allows for communication between multiple CICS regions executing within the same processor complex. The use of data base handlers such as DB2, Adabas, or IDMS is an example of Interregion Communication between CICS and a particular data base region.

The use of MRO and ISC has increased significantly in recent years. There are numerous reasons why a CICS installation might consider an MRO or ISC implementation. For example, using multiple CICS regions, applications can be designed to control resource accessibility, to maximize on-line availability and to ensure proper security measures for sensitive applications. In addition, transactions can be grouped based upon response time criteria, permitting consistent performance to time-sensitive requests (e.g., ATM banking transactions). In a multiple CPU processor complex, several subtasks can execute concurrently. As a single address space, CICS cannot take full advantage of the processor complex. If the application were partitioned into several regions, overall throughput could be improved. Other advantages offered for multiple regions include virtual storage constraint relief and the ability to share resources, such as terminals and files, among several CICS regions.

Following Release 1.5 of CICS, there have been significant enhancements and improvements in the ability of CICS to communicate with other subsystems. Release 1.6 offered many performance improvements in MRO, and the most recent Release 1.7 is expected to provide even better performance and improved monitoring capabilities. As a result of these improvements, many CICS users have considered redesigning their applications to process in multiple CICS regions. Since there has been an increasing number of installations contemplating the use of the MRO and ISC features, the concern for modelling this environment has increased as well.

The remainder of this paper will address the data analysis and modelling issues relevant to the prediction of future system performance for CICS systems utilizing MRO or ISC architectures. In the first section, we will present a brief overview of the interregion communication facilities and discuss the data sources and analysis issues relevant to measuring and modelling CICS MRO systems. Secondly, we will discuss the general techniques for evaluating the performance of CICS systems utilizing MRO with analytic modelling tools. As part of this discussion, we will present a methodology for determining the performance impact of converting an application that is currently executing in a single CICS region to one processing in multiple regions. We will give specific examples of modelling existing CICS systems which utilize MRO. During the presentation, we plan to review a case study to illustrate the techniques and highlight some of the performance considerations in implementing the MRO feature.

Background

Overview MRO and ISC

The CICS intercommunication facility includes CICS function request shipping, transaction routing, distributed transaction processing and interregion communication. Intersystem Communication (ISC) provides CICS function shipping and distributed transaction processing, enabling an application runnning in one CICS system to access files and data bases and to start processing on connected processors. With the Multiregion Operation (MRO) facility, transaction routing, function shipping and distributed transaction processing functions are all provided [ref.4,5].

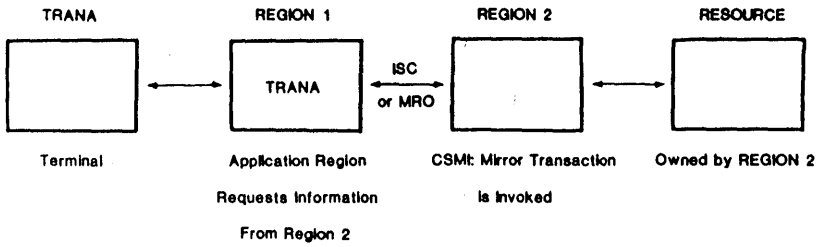

Figure 1. Function Shipping

Function shipping allows an application program to make a request for a resource in a different CICS system, have that request shipped to the system controlling the resource and receive the information back without knowing where that resource is. The CICS system can be in a different processor or a different region [Ref. 4,5].

With transaction routing, a terminal in one CICS system can initiate a transaction in another CICS region. Distributed transaction processing allows communication between transactions executing in either an MRO connected region or an SNA-connected system. [Ref 1].

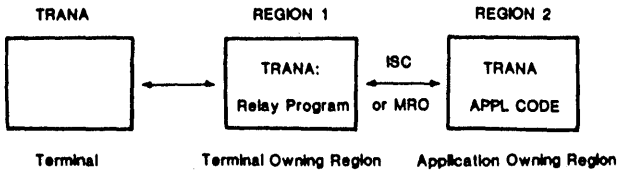

Figure 2. Transaction Routing

In order for a region to utilize MRO for function shipping or transaction routing, it must identify itself to the other regions and define the connection to those regions with which it wishes to communicate. The connection between systems is accomplished by coding system entries in the terminal control table (TCT) identifying all remote systems with which that system is able to communicate. The implementation of function shipping requires that all remote files, remote transient data destinations and remote temporary storage queues be defined in the appropriate tables. Transaction routing permits an operator to enter a transaction at a terminal and have that transaction routed to another CICS region for execution. This is accomplished by defining the transaction as remote in the program control table (PCT) and identifying the region in which the application code corresponding to that transaction resides.

Data Bases

CICS allows access to data held within standard OS data sets, areas within CICS and in data bases. Information can be accessed from standard data sets using the CICS file control facility with VSAM, ISAM or DAM files. The information can also be accessed from both hierarchical and relational data base systems, such as IMS/DLI and DB2.

Data Analysis

Performance Monitoring and Analysis

In terms of measuring CICS performance, various statistics are available with both IBM and non-IBM monitoring products. The performance data is typically summarized for each transaction, or transaction/terminal combination and includes some information concerning the usage of memory, I/O and CPU resources. For the most part, CICS monitors and report writers simply collect the data without performing any analysis. Performance analysts, however, must concern themselves with resource usage by region and by transaction, regardless of the particular CICS design architecture or data base product used.

Performance data is recorded separately for each region. Depending upon the architecture, transaction response time recorded in the local region may include the time it spent processing in a remote region. This typically occurs with remote data base usage, transaction routing and function shipping. The resources consumed by the transaction in the remote region will normally not appear as part of the CICS performance records (The exception is if event monitoring points are used for data base requests.). As a result, it is up to the analyst to determine the component parts of transactions and reconcile the amount of resources utilized in remote regions. This analysis is particularly important for job accounting, service level management and in the development of analytic models to predict future system performance.

Function Shipping

The manner in which performance data is collected and reported by various monitor facilities depends upon the particular architecural implementation that is used. Within the CICS monitor facility data, mirror transactions initiated by function shipping requests appear as CICS CSMI transactions. The types of function shipping requests include temporary storage, transient data, interval control, file control and DI/I. The specific CSMI transaction name coded depends upon the type of request. However, in Releases prior 1.7, no information that indicates the relationship between the two communicating regions is recorded. As such, there is no direct method of determining the resources consumed by a transaction in a remote region when the mode of inter-region communication is function-shipping. In this case, since no terminal identifier is recorded in the receiving region, transaction resource usage can only be reconciled based upon the date/time stamp. In a busy system with several regions, the accuracy with which one can pinpoint the resource usage is questionable.

With Release 1.7, the VTAM Applid (a 20-byte field) and a UOW field (8 bytes), the name by which this unit of work is known within the originating system (assigned at attach using an STCK-derived token), will be passed. The STCK time stamping ensures the uniqueness of each entry and facilitates mapping the originating systems request for service with the actual usage in the processing region [ref.2].

Transaction Routing

In a typical scenario, transaction routing takes place between a single terminal- owning region (TOR) and many

different application-owning regions (AORs). The terminal region is responsible for servicing and routing transactions to the appropriate application region. There are two different types of transaction routing which exist: explicit routing through use of the "routing transaction" CRTE and routing through the use of a "relay transaction". In the first case, the operator signs onto a terminal-owning region and explicitly enters "CRTE" followed by the SYSTEM ID of the CICS region with which he wishes to establish a routing session. In the second case, a terminal operator enters a transaction code which is associated with a remote region. The transaction which is attached executes the CICS "relay program" and therefore is referred to as the "relay transaction". The major difference between the two types of transaction routing is their implementation and the resulting manner in which performance data is recorded within the CICS monitor facility (CMP).

Regardless of the implementation, the analyst needs to be able to attribute the time spent and the resources used within the terminal-owning region to total transaction resource consumption and response time. Where the routing information is explicitly coded in the program control table, the task of correlating transaction resource usage across regions is that much easier. In this case, the same transaction ID will be reported in both the receiving and sending regions. As a result, the transactions usage of resources in both the terminal and application owning regions can be identified. When the CRTE transaction is executed within the terminal-owning region, no data will be recorded that identifies the transaction to be routed to an application region. In this case, the analysis effort is slightly more complex. To correlate resource usage in the terminal-owning region with transaction response time in the application-owning regions, the analyst must compare terminal and operator identifiers, and date/time stamps between the two regions. Table 1 illustrates the analysis.

Data Base Usage

With the CICS monitoring facility (CMP data), transaction usage of CICS VSAM data bases and DL/1 data bases are automatically recorded in the performance records. Transaction usage of DB2 data bases can be obtained from the DB2 accounting data which is written to SMF as a type 101 record [ref. 7,8]. By defining event-monitoring points in user application programs, the number of file calls and their associated timings can be obtained for all other data base products [ref. 3].

Specifically, there are 255 user-defined counter and clock fields available with CMP. To make use of these counters and clocks, event monitoring points (EMP's) are coded at the desired location within the application program. In addition, the EMP's must each be uniquely identified by a number and an entry corresponding to that number must be coded in the monitor control table (MCT) [ref. 3].

By coding EMP's, the number of file control calls and their associated timings can be recorded in the performance record for each transaction that utilizes interregion communication to access data from another data base region, such as Adabas. Table 2 illustrates the usage of user fields.

Table 1: Example of Transaction Routing
Performance Data including CRTE

(In descending order of START TIME)

SYSTEM	START TIME	END TIME	TRANID	TERMID
CICS1	10:32:17.22	10:32:18.76	X100	ABCD
TOR	10:32:17.21	10:32:18.77	CRTE	ABCD
CICS1	10:31:59.52	10:31:59.57	Y100	ABCD
TOR	10:31:59.51	10:31:59.57	CRTE	ABCD
CICS1	10:31:38.13	10:31:40.44	X100	ABCD
TOR	10:31:38.13	10:31:40.45	CRTE	ABCD
CICS1	10:31:30.02	10:31:30.09	Y100	ABCD
TOR	10:31:30.01	10:31:30.09	CRTE	ABCD

Table 2: Example of User Clock and Count Field
Adabas file usage with Event Monitoring Points

(Average values are recorded and
timings are reported in seconds)

TRANID	N	RESPONSE	CPU	AMCT	USERCLK	USERCNT
BAG	5	.53	.024	0	.304	4.8
CRTE	28	.63	.008	0	0	0
GAB	419	.91	.057	3.4	.182	2.8
MACK	6	2.18	.348	253.2	0	0

NOTE: This example illustrates that any transaction can issue file I/O to: CICSVSAMdatasetsand other data base systems or not issueanyI/O whatsoever, or some combination. USERCLK represents average data base service time; USERCNT represensts average number of data base requests.

Modelling Considerations

Overview

Analytic modelling tools can be successfully employed to predict future workload performance for MVS systems. The basic inputs to these tools are descriptions of the hardware, software and workloads operating in the environment. In describing the workload, one must include CPU and I/O resource usage information, define the amount of real memory available for the workload and specify the workloads CPU priority. Memory usage is represented to the model in terms of maximum multiprogramming levels (MAX-MPL), attained multiprogramming levels (ATT-MPL) and measured page/swap service times.

In a previous paper we outlined a methodology for modelling CICS systems. We indicated that there are some particular issues to be considered when modelling CICS systems [ref. 9,10]. Specifically, the issues include paging delays, enqueue delays, single address dispatchability in a multi-processor environment and the ramifications of modelling heterogeneous CICS workloads. In addition, we discussed the techniques for forming multiple CICS workloads in an analytic model. We will not repeat the general techniques for parametrizing a CICS system within the analytic model construct, but rather we will focus on the particular issues involved in modelling interregion communication between CICS systems. As a special case of interregion communication, we will also discuss modelling the interface between CICS and other data base regions.

To model a CICS application executing in multiple regions, the following steps must be performed:

1) Identify the relationship between the regions (e.g., Terminal-Owning Region, Application-Owning Regions or Sending and Receiving regions).

2) As an initial step, place each region in a separate workload. (In this case, we are assuming that each region appears as a distinct performance group in the IPS.)

3) Determine the CPU priority and MAX-MPL for each workload/region.

Given that you have identified the relationship and communication path between the regions, the next step is to obtain the data required to parametrize the specific resource requirements of each of these regions within the analytic model.

Iterative Modelling Technique

The method employed for modelling both MRO and ISC implementations will utilize "iterative modelling" techniques. This technique can be used to anticipate the performance impact of converting to MRO and to model an existing MRO implementation [ref. 11].

With both function shipping and transaction routing, a transaction in one region (sending) causes a transaction in another region (receiving) to be initiated. The transaction in the sending region must wait for the task to be completed in the remote region. As a result, the response time for the initial transaction, includes the time necessary for the receiving region to process the work requested. However, the resource profile developed for the sending region only accounts for resources that have been utilized by and charged to that region. Since RMF/SMF information is recorded at the performance group level, average resource profiles constructed for a particular CICS application (based upon an analysis of this data) would not reflect the resources that application consumed while executing in a remote system or region. Therefore, any model based upon this particular resource profile description, which only accounted for locally consumed resources, would be inaccurate.

Utilizing the technique of iterative modelling, one can include the processing time for the transaction in the receiving region as input to the calaculation of the response time for the sending region. This is accomplished by defining a delay server representing the processing time occuring in the receiving region. (A delay server is defined as a server at which no queueing occurs and as such, it is just a method of adding a constant value to the model). This delay server is then added as part of the resource profile for the sending region [ref. 11].

In summary, using iterative modelling techniques, two regions communicating via MRO or ISC implementations can be analyzed as follows:

1) Begin with a model containing at least two workloads, corresponding to the sending and receiving regions.

2) Execute the model and determine the response time for the receiving region.

3) Define a "delay server" in the sending region which is equal to the response time of the receiving region.

4) Evaluate the model. If response time for the receiving region has changed since the last iteration, change the value of the "delay server " in the sending region to equal the new calculated response time.

5) Repeat the process until the calculated response time for the receiving region approaches a consistent value.

The next few examples illustrate some of the specific considerations and parameters necessary to model the performance impact of converting to MRO. They also demonstrate the techniques for modelling an existing MRO system and highlight the methods necessary for modelling a CICS interface with another data base system.

Modelling an MRO conversion

This first example illustrates the modelling techniques for anticipating the impact of converting to MRO. In the original environment there are two application-owning regions, each of which is responsible for its own terminal control. The installation has considered adding a single terminal-owning region to handle all terminal interactions and route the transactions to the appropriate AOR, as necessary. By maintaining a single copy of the TCT, some virtual storage relief is expected. In addition, under an MRO implementation, CICS end users will only need to log on to a single region and still be able to access information from either of the two AOR's.

Converting to MRO or implementing ISC will result in an increase in CPU overhead to support interregion communication. If the implementation requires an additional region, an increase in the demand on real storage demand can also be expected. One can estimate the additional amount of real memory required from guidelines reported by IBM in "MVS/XA Processor Storage Estimates and Performance " [ref.6]. The guidelines presented suggest that the base storage requirements for a production CICS/VS region (under XA), is in the 1.5 to 2.5 megabyte range. The amount of real memory required depends upon the number and size of resident programs, the amount of concurrently executing transactions, and the average storage requirements for each transaction.

Of specific concern is the prediction of CPU utilization and response times for the new MRO environment, with a single TOR servicing each of the AOR's.

Modelling Assumptions

1) The majority of the terminal control activity occcurs in the TOR causing a significant reduction in the TC portion of CPU time utilized by each of the AOR's in the current environment.

2) The TOR will utilize TC and KC facilities. Determining the total CPU time that the TOR will consume requires knowledge of the average pathlengths for Task Control and Terminal Control for a Terminal Owning region (under MRO). This is expressed in Equation 1.

Model Inputs

1) Build a model with CPU time for the TOR workload defined as above.

2) Recalculate the CPU time for each AOR by subtracting out the portion of TCB attributable to terminal control.

3) Determine the MAX-MPL for the TOR and each of the AOR's.
(The value will depend upon the size of the Dynamic Storage Area, and the amount of real memory available for each transaction. Discussions of memory modelling as they pertain to CICS can be found in reference 10 and general memory modelling techniques are discussed in reference 12).

4) Run the model.

5) Use the iterative modelling technique as defined above, with delay servers defined for each AOR equal to the average response time for the TOR.

Modelling the performance impact of converting to MRO when the mode of interregion communication will be function shipping will follow the same principles.

Modelling an Existing CICS/MRO System

CASE I: MRO/Transaction Routing

This example illustrates transaction routing in an environment with two application owning regions (AOR) and a single terminal owning region (TOR). All CICS users sign onto the TOR and transactions are routed to the designated AOR. (See figure 2) Since the TOR can also execute application code and contain resources which are accessible to other regions, one must divide the corresponding TOR workload into two workloads. The first workload will contain the transactions which serve as the communication vehicle to the other two AOR's. The second workload will contain the remaining transactions. The same division of transactions (those communicating with the TOR and those not) needs to be applied to each of the AOR's.

The two methods of implementing transaction routing are:

A) Using the relay transaction
B) Using the routing transaction, CRTE

The advantage of using the relay transaction is that one can readily map the movement of transactions across the regions. The same transaction ID will usually be specified in both the terminal and application-owning regions.

A) With the relay transaction-

1) Divide the TOR into at least two workloads- one corresponding to each AOR
2) Divide the AOR 's into those transactions communicating with the TOR and those not.
3) Specify the MAX-MPL and CPU priority for each workload
4) Determine the resource profiles for each of the new workloads.

B) With the CRTE transaction-

1) You can separate the resource usage for the CRTE transaction, on behalf of each AOR, by the terminal/operator identifiers and date-time stamp generated for each CRTE transaction. (The terminal and operator ID for each AOR will correspond to that generated for specific CRTE transactions.)

Repeat steps 2 through 4 in A) above.
Alternatively, leave the TOR as a single workload and determine its average processing time (without waits).

2) Add this time as a delay server to each of the AOR's.

3) Adjust the MPL's for each of the AOR's to represent the maximum number of tasks that the TOR could execute concurrently on behalf of that AOR.

4) Refine the process and perform "what-if" analysis utilizing iterative modelling techniques.

Predicting the Impact of Workload Growth

To anticipate the effect of additional volume on system performance, one must first determine which transactions are expected to increase. If an increase in volume is expected for only one of the applications, then the model inputs need to reflect this. To facilitate this, two new workloads should be constructed based on a decomposition of the terminal-owning region. Each of the newly formed workloads would correspond to the activity performed on behalf of each of the individual application owning regions. As a result of forming these workloads, one can directly increase/decreasse the volume for the TOR workload corresponding to the portion of the terminal owning region which is expected to change on behalf of that application. Without separating the TOR in this fashion, we would not be able to determine the additional overhead that the application would cause in the terminal owning region.

Case II: Function Shipping

The facility with which one can model a function shipping implementation of MRO or ISC is dependent on the data available and the ability to correlate resource usage in a remote region with transaction response time.

Unfortunately, with Release 1.6 of CICS there is no way to identify the region that initiated a function shipping request. Therefore, using the performance

$$\text{Total CPU Time for TOR} = \frac{\text{KC pathlength} * \#\text{ transactions}}{\text{processor speed}} + \frac{\text{TC pathlength} * \#\text{ transactions}}{\text{processor speed}} \quad (1)$$

Note: The pathlengths were developed by BGS systems using representative benchmark studies.

monitor data, one cannot readily build typical resource profiles for workloads which use MRO or ISC for function shipping. Since the resource profiles will not necessarily be representative, one cannot expect that the models developed to be accurate. However, all is not lost as one can always make some intelligent estimates.

For example, if only two regions are involved, the CSMI transactions will be recorded in the region containing the resource of interest. Prior to Release 1.7, we were not able to identify the initiating transaction ID. However, we would be able to isolate the CSMI transactions into a separate workload and employ the iterative modelling procedure to determine average response times and resource usage for each of the two communicating regions. (In Figure 5 the request handlers would be the CSMI transactions.)

If multiple regions utilize function shipping, it will be extremely difficult to trace the CSMI transaction recorded in one region back to the region that requested the resource. One can attempt to map the CSMI transaction to the initiating region by analyzing the date/time stamps for all transactions executing in these CICS regions.

With Release 1.7, a date/time stamp and region and transaction identifiers will exist in the performance records to facilitate mapping the path of a transaction through the various regions within which it executes.

Regardless of the release level of CICS, if one can identify the amount of resources that a particular transaction consumes within each region, then one can model the system environment utilizing the techniques presented for transaction routing.

The following example illustrates the procedure.

CICS Function Shipping Modelling Example:

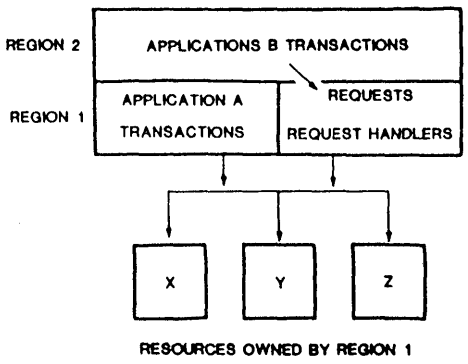

Figure 3.

CICS Region 1: Owns resources X,Y,Z and APPA requests X,Y,Z directly

CICS Region 2: APPLICATION B sends request to Region 1 to access X,Y,Z

The model would contain at least 3 workloads defined as follows:

Workload 1 - corresponds to APPLICATION A

Workload 2 - corresponds to Request Handlers in Region 1 (note: We have assumed that sufficient data would exist to facilitate the identification of these transactions.)

Workload 3 - corresponds to APPLICATION B

Modelling Procedure:

1) Workload 1,2 would be specified as processing in the same (or shared) domain.
2) A delay server, representing the amount of time spent by workload 3 waiting for the request handler to process the request would be required.
3) Iterative modelling technique would be employed.

Function Shipping-Modification Analysis

To determine the performance impact of workload growth, the following steps should be implemented:

1) Adjust the transaction volumes in accordance with the projections obtained.
2) Recompute the Delay servers.
3) Reevaluate all response times.

CASE III. Modelling a CICS interface with another Database

If both CICS and Batch are performing inquiries and/or updates against the database, one must first identify the amount of activity and resources consumed by each of these systems. By analyzing the log tape for most data base products, one can determine the run unit responsible for the activity. For example, with Release 2 of the DB2 product, the data recorded in the accounting records will identify whether the resulting file activity was caused by TSO, Batch or CICS. These records will also contain the number and type of SQL calls performed by each user authorization ID (e.g. signed on user, terminal or transaction ID). Once the amount of activity is reconciled between the various regions (i.e., how much was consumed by BATCH vs. how much was used by CICS), the specific representation of resource usage can be input to the model.

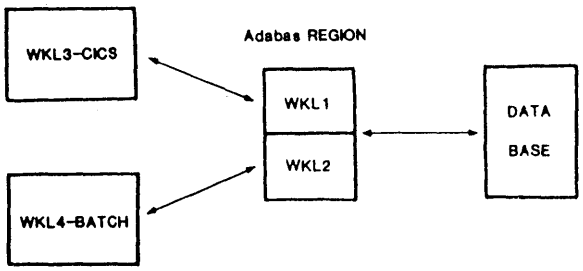

Figure 4.

To facilitate modelling changes to any of the three systems, BATCH, CICS or Adabas, we recommend starting with a baseline model containing 4 separate workloads. This will also enable the analyst to model regions with differing CPU priorities and MPL's.

The specific modelling details are as follows:

1) Form four workloads, where the resource profiles of workloads WKL 1 and WKL 2 are formed as a result of apportioning the original single Adabas resource profile into two distinct profiles according to the number of ADABAS calls issued by each region.
2) WKL1, WKL2 (Adabas workloads) should be placed in a common/shared domain.
3) Determine MAX-MPL's and CPU priorities for each workload (where the MAX-MPL and priority is the same for both Adabas workloads)

4) Add a delay server to the BATCH workload. The value should be equal to the average amount of time required for the Adabas region to perform the file activity requested by BATCH. Therefore, the delay server will be equal to the response time for WKL3 as defined above.
5) Add a delay server to the CICS workload. The delay server will be equal to the response time computed for WKL4.
6) Apply the iterative modelling techniques.

To anticipate the impact of workload growth on performance, the transaction volumes for all workloads which are expected to change should be adjusted. Using the iterative modelling methodology, one can recompute the values for the delay servers and determine the response time CPU and I/O utilizations for each of the workloads.

Summary

As a single address space, CICS has limited opportunity for utilizing a multiple CPU complex, such as an AP, dyadic or MP. By splitting a single region into multiple ones, multiple subtasks can execute concurrently to improve application performance in this environment. As a result, MRO and ISC architectures have become much more common.

We have outlined some of the performance and modelling issues which pertain to CICS applications utilizing this architecture. We have reviewed the general methodology for modelling CICS applications and have proposed several techniques for predicting the performance of CICS systems utilizing MRO and ISC. We have indicated that the specific details for analyzing any of the various implementations of MRO and ISC are similar; iterative modelling techniques are employed to determine the total response time for these transactions which consume resources in multiple regions.

The implementation of MRO and ISC will impact performance, there are costs in terms of CPU overhead and real memory. However, depending upon the business requirements, the particular resource requirements for the application, and the system environment in which that application will execute, the decision to take advantage of the MRO architecture may be the most prudent and cost effective design alternative.

Acknowledgment

I would like to thank Ms. B.J. Hoyt of the Health and Welfare Data Center, Sacramento, California, for her helpful suggestions and numerous discussions concerning the performance impact of an MRO conversion.

ABSTRACT

This paper will show the results of a series of experiments in uniprocessor and dual processor environments. The experiments were designed to show how the Time Sharing Option (TSO) uses the main storage that is installed on the configuration. 48MB to 256MB of main storage will be used in the physical experiment cycles. The Teleprocessing Network Simulator (TPNS IBM Program Product 5662-262) will be used to provide the scripts for the simulated workloads required to drive the measured processors to saturation.

Logical swapping versus physical swapping is studied to show how the operating system uses main storage. The more main storage, the more the user remains in that storage and is controlled by the think time aspects of a session.

A copy of the presentation slides is contained in the appendices. References to the slides are made in the text and cross-referenced for the reader. Photo reduction of the slides would make it difficult for the reader to interpret some of the values.

These results have been developed through measurements of workloads created by Amdahl personnel. These workloads are only for approximation of true production workloads. Estimation of relative performance for a given workload is dependent on the specific application and operating environment.

INTRODUCTION

In the early seventies, simulation techniques were used to show what would happen in a CAD/CAM environment if the user were kept in main storage instead of rolling the working set out to auxiliary storage devices. The operating system (MVT) did not have a "Logical Swap" feature, but if enough main memory or the region size was large enough, the working set could be placed in a dormant state and then be returned to active status on demand (see [1]).

As more of the operating systems entered into the Multiple Virtual Systems (MVS) environment, logical swap became more of an integral part of the operating scene. In short, the user's working set could be marked logically swapped or dormant. If the main storage occupied by one user was not required by another task, the logically swapped user stayed in main storage. If the occupied main storage were required by some other task, the dormant user could be physically swapped to some auxiliary storage device (DASD). The controlling factor would be the amount of think time that a user was allowed to use before a decision was made to recommend that the user be swapped out.

In the last few years, larger main storage sizes have become available and the logical swap condition takes on a more important role in the Time Sharing Option (TSO) online subsystem. The Amdahl Performance Evaluation Center (AmPEC) located in Sunnyvale, California has conducted a series of experiments in various online subsystems to show the effects of increased storage sizes. This paper will document the results of those experiments in uniprocessor and dual processor complexes that employ main storage sizes of 48MB to 256MB.

METHODOLOGY

In today's complex computer centers the USER is required to submit estimates of requirements for resources. (See Figure 2.) The Capacity Planner uses this set of inputs to plan for the user's needs and the physical equipment that would be required as the current workload grows. In most cases the user's inputs can be + or - 30%. Therefore, the capacity planner's output or plan can produce more questions than answers.

Amdahl's approach is to put the yoke on the vendor and supply what the capacity is of each computer configuration as it completes prescribed workloads. (See Figure 3.) AmPEC has produced a series of documents called Planning for Capacity in TSO, CICS, IMS, and VM/CMS environments (see [2 - 8 incl.]). These studies try to illustrate what is the maximum amount of work the tested configuration can produce using a given workload, then compare and contrast what various configurations can produce in uniprocessor and dual processor environments. It is important to find out what the maximum capacity of the computer is in a totally unconstrained environment. In other words, eliminate any storage constraints or I/O bottlenecks that would keep the processor from running at 100% CPU busy.

What are the users' online terminal requirements? (See Figure 4.) Perhaps it might be 500 TSO users or 1000 IMS users that input a workload to the main central processing unit (CPU). It is not economically feasible to have the 500 or 1000 users available for testing. Nor is it feasible to have the 500 or 1000 physical terminals available for testing purposes. Therefore, in the laboratory, this is simulated with the Teleprocessing Network Simulator (TPNS - IBM Program Product 5662-262). In the AmPEC center this simulated workload is relegated to a driver system. The driver system is the host for TPNS that will simulate the TSO or IMS workload. This driver system is called the System Not Under Test (SNUT). The TPNS simulation is placed on the SNUT so that none of the associated overhead would appear on the system that is being measured. This other, or measured system, is called the System Under Test (SUT). The tested application (TSO or IMS) is simulated as a local network so that none of the associated network delays would enter into the measured response times.

The bridge between the driver system and the system being measured is accomplished by a communications front-end processor. (See Figure 5.) When the simulated requests bridge over to the system being measured, they appear as devices submitting work or transactions to TSO, as an example. Let's say that TSO is the only subsystem on the measured processor. Therefore, the operating system and TSO will be coresident or TSO will be running in a dedicated environment. In the experimental cycle, the number of TSO users will be increased on the SNUT until the CPU being measured is operating at 100% CPU busy. Each TSO user will be assigned a script or terminal session to complete. The user will LOGON, do the required work steps, and then recycle through the work steps. This will be repeated over and over again during a measured period of time. As more users are put into the operating environment, it is assumed that the workload remains homogeneous (more of the same).

In order for the device's transaction to reach the processor, the device must be connected to a data path or channel. (See Figure 6.) Each tested configuration can have a different set or maximum number of channels attached. The channel paths are important requirements to keep any I/O contentions from forming. Too few channels for the workload can add wait time to each transaction. This additional time is additive to the request's overall response time. On the other hand, a configuration's maximum channel capability is an important future growth input parameter.

Lastly is the presence of the processor. (See Figure 7.) This is the SUT. The experiment is designed to try to find out what the maximum capability is of this processor with a workload that can be increased until processor saturation (CPU busy = 100%) is reached. The striations on the channel designators will be used to illustrate various amounts of main storage. As device and channel constraints are eliminated, the main storage can be the limiting factor. When main storage becomes the limiting factor, increased paging and swapping functions can lead to increased I/O demands. This can produce a new set of I/O bottlenecks. Therefore, the size of main storage will be increased as more and more users are added to the workload generation schema. An online subsystem like TSO will use as much main storage as there is present in the operational environment.

Before the experimentation cycle begins, it is important to define some of the terms that are used. (See Figure 8.) Suppose we have a measurement interval of one-half hour. Then suppose the CPU is busy 50% of the time, or 900 seconds. Externally, or to the user's eye, the External Transaction Rate (ETR) is the number of transactions divided by the number of seconds in the measurement interval. Internally, the Internal Transaction Rate (ITR) is the number of transactions divided by the number of CPU busy seconds. Unless the CPU is busy 100% of the time, these are two totally different metrics. When the processor is operating at 100% CPU busy, the ETR and ITR will be equal.

(See Figure 9.) In the first column, the processor is a 5870, which averages 61.51% CPU busy. 14,524 TSO transactions were processed in the 30-minute measurement interval. The ITR is 14,524 transactions divided by 61.51% of the 1800 seconds (or 1107.18 seconds) for 13.14 transactions per second. The ETR is 14,524 transactions divided by 1800 seconds (or 8.08 transactions per second).

In the second column the processor is also a 5870, which averages 98.20% CPU busy. 27,392 transactions are processed. The ITR is 27,392 divided by 98.20% of 1800 seconds (or 1767.60 seconds) for 15.50 transactions per second. The ETR is 27,392 transactions divided by 1800 seconds for 15.22 transactions per second. As the processor approaches 100% busy, the ETR and ITR converge and are equal.

A configuration that is not operating at 100% CPU busy is subject to low system utilization effects. This is an operating system phenomenon that is caused by recursive scanning of the work queue. The software thinks that there is always something to do, and if after the first pass of a no-find situation, it goes through a recursive scan. To eliminate the low system utilization effects, an artificial work request called the BR15(s) job is placed in the processor (two jobs in a dual processor). This is a Branch on Register 15 to the same instruction address and creates a loop that is interruptable when higher priority work is in the system.

Consider this first example of a 5870 and a 5860 operating without the BR15(s). (See Figure 10.) The workload used in this set of experiments was the Short Transaction Workload. This workload simulates a program development complex and represents a higher supervisor state than problem state. In other words, there are many more transactions simulated in the measured period, but each transaction requires minute amounts of CPU. The 5860 uniprocessor used 39.74% of the 1800 seconds or 357.66 seconds to process 8879 transactions. The ITR is 24.92 transactions per second. The 5870 dual processor averaged 32.89% CPU busy, or each processor was busy 296.01 seconds to process 8878 transactions. The ITR here was 29.99 transactions per second.

Therefore, the Multiprocessor Ratio is 29.99 divided by 24.92 or 1.21. This translates to the dual processor doing only 21% more work than the uniprocessor. BAD ROI!

Now set up the BR15(s) to run as the lowest priority job(s) in the work queue. Place the BR15(s) in its own reporting period and performance group so that all CPU time(TCB time) for the BR15(s) can be factored out. (See Figure 11.) The measured processors will be running at CPU busy = 100%. Once the BR15 time is factored out, the same number of transactions now takes 157.50 seconds on the 5870 and 269.00 seconds on the 5860. The transaction counts are virtually the same; ITR on the 5870 is 56.33 transactions per second and 32.97 transactions per second on the 5860. The MP ratio is 1.71. In other words, the 5870 is producing 71% more work. Later in the experimental series you will see the effects of the Long Transaction Workload. In this workload the CPU requirements are weighted with heavier problem program state versus supervisor state. In this set of experiments the BR15 is removed and all real work is present. The MP factor will go to the 1.83 to 1.95 range. This then would be the true MP factor if each processor is running at 100% busy.

UNIPROCESSOR

The experimental series starts with a 48MB Uniprocessor (5860). (See Figure 12.) A LONG transaction workload was created to use up the maximum number of CPU cycles, but still meet certain user service level agreements. A LONG transaction workload is defined as a higher Problem State ratio versus Supervisor State. The average response time would be two seconds or less. At least 90% of the transactions would be completed in first period, with a response time of less than 0.50 seconds for trivial transactions. Lastly, the total amount of physical paging would be monitored. In this TSO context, physical paging is the total page and swap rate to and from DASD. Therefore, an artificial limit of approximately 400 pages was set as the paging

threshold. Once the threshold was reached, this would define a memory constraint and some action would have to be taken to satisfy the constraint. As the processor becomes faster, this artificial limit may become meaningless.

If the transaction's working set (occupied pages of main storage) could remain in storage at all times, the overall response time would remain both low and consistent. When a transaction or the user went into THINK mode, the transaction's working set could be marked logically swapped out. In the logical swapped state, the transaction remains in storage, but is just marked dormant. If the occupied storage is not required for any other transaction, the transaction stays in storage. However, if the storage becomes constrained, the dormant request can be physically (swapped) removed from main storage and copied to DASD. This of course requires I/O time to move the image from storage to auxiliary storage and additional time to reverse the process. When the user wakes up and enters the next transaction, the copy on auxiliary storage, has to be moved back to main storage. The I/O time is additive and can become a significant part of response time.

The results of the experimental series are documented in the Planning for Capacity - TSO (see [2]) document. The LONG transaction workload was used because of the heavier Problem State versus Supervisor State. In other words, more of the CPU cycles were doing user work instead of supervisor state functions. (See Figure 13.)

Results:

		Data Source
Processor	5860	
Users	170	(TPNS)
Megabytes	48	
CPU Busy	97.81%	(RMF)
TPNS Avg R.T.	1.93 seconds	(TPNS)
TPNS TRX Total	13,715	(TPNS)
Avg. Response Time	2.29 seconds	(RMF)
TRX Total	15,686	(RMF)
1st Period Response Time	.29 seconds	(RMF)
%Trans. in first period	89.91%	(RMF)
Page Rate	422.66/second	(RMF)
ETR	7.62/second	(Calc)

The attained results showed that at 97.81% CPU busy, the total transaction count was 13,715 as reported by TPNS and 15,686 for RMF. The higher transaction count in RMF is attributed to the inclusion of extra transactions. Every time there is an output terminal wait detected because of an output buffer shortage, RMF considers this a transaction. Therefore the transaction count in RMF is actually inflated. TPNS does not consider this a transaction and all of the ETR and ITR calculations in this paper will use the TPNS transaction count as the base. However, TPNS does not give a breakdown of the response times into trivial and other periods. Consequently, both numbers will be reported here and the reader can make independent calculations.

Notice that the physical paging rate (422.66 pages/second) has exceeded the service level agreement to the simulated user. To alleviate the paging constraint, add more storage. This will reduce the amount of CPU cycles required for page movement and more users can be added until the processor is 100% busy. Caution! CPU cycles will be at a premium and response time can suffer.

Also notice that the response time agreements have just about been reached in TPNS (1.93 seconds) and exceeded in RMF (2.29 seconds). If more users were added to the population, physical paging climbed at an alarming rate and as the physically paging requirements went up, so did response time. Again, more storage will bring down the paging rate and more users will be added to take up the available cycles.

Increase the amount of main storage from 48MB to 64MB. (See Figure 14.) Run with an increased number of terminals until the processor is 100% busy. This will probably exceed the service level agreement for average response time, but find out what it takes to max out the processor.

Two hundred users in 64MB will push the processor to 100% busy. (See Figure 15.) Since there are internal queues for the CPU, user response time goes up. First period or trivial response time stays constant, but the jobs that require a lot of CPU time are taking longer to complete. Reason: The processor is saturated, and there are no more cycles available. 64MB over 48MB with this workload gave a 9% increase in throughput, with about a 17% increase in user population. Solution: No more uniprocessor; look at a dual processor. In this environment, there will be two servers working at the same time.

DUAL PROCESSOR

The major difference in this 64MB environment dual processor environment is the two CPUs. (See Figure 16.) Everything else remains constant. The main memory size stayed at 64MB. Since there are two servers, you would expect response time to improve. Can you add more users?

(See Figure 17.) The 5870 dual processor drops in utilization to 78.49%. If more users are added past the 210 range, paging climbs dramatically. There is marked improvement in overall response time (two engines versus one engine). However, the ETR increases by only 1.6 transactions per second. It would appear that the dual processor is a bad decision. Actually, it was a good partial decision. More main storage will alleviate the memory constraints.

The total main storage size is now 96MB. (See Figure 18.) All the rest of the parameters remain constant. The 64MB 5870 experiments could not use up the CPU cycles because an increase in user population will increase paging beyond the agreed limits. In this environment, the number of users will be increased until the maximum CPU busy can be reached. There is a dramatic increase in user population: 65% - 200 to 330!

(See Figure 19.) Notice, with 330 users the processors are backup to 98.20% busy. Response time is up to 1.44 seconds, but it is offset by the 65% increase in user population. The paging rate is well over the 400 pages per second page rate that was agreed upon. In order to cut this down to a more manageable level, it would require more main storage or a less ambitious user population. However, if you cut the user population, the ETR will decrease and so will CPU busy.

This configuration is the maximum amount of main storage that a 5870 can support. (See Figure 20.) The 96MB configuration supported 330 users but ran into a paging rate of 544.62 pages per second. The additional main storage should reduce the paging rate and allow more users into the operational environment. Let's see if it does!

(See Figure 21.) First of all, the page rate dropped by 50%. This void was then filled with at least 20 more users to a 350 maximum. The processor could not or would not go above 98.63% CPU busy. This release of the operating system used the very top 1% for

interprocessor communication. Perhaps it would be beneficial to review the various environments that have been reported on.

(See Figure 22.) The 48MB uniprocessor had a transaction rate of 7.62 transactions per second and the series reached a peak of 16.19 transactions per second in the maximum 128MB configuration. The interesting columns are highlighted to illustrate that going from a uniprocessor to a dual processor without installing additional storage allowed for 10 more users and a Multiprocessing Factor (MP) of 1.20. In other words, the dual processor was providing 20% more throughput than the uniprocessor. (See Figure 23.) When additional main storage was put on the 5870, the user count went from 210 to 330 - the CPU busy went up dramatically. Consequently, the throughput went from 8.29 transactions per second on the uniprocessor to 15.22 transactions per second on the dual processor. This is an implied MP factor of 1.83 with a 65% increase in the number of users. At maximum configuration, the MP factor is 1.95, with a 75% increase in the number of users.

The next step in the progression would be to replace the 5870 with the new 5890-300 and start with 128MB of main storage. There are other models of the 5890 like the 190 and the 200, but let us concentrate on the 300. (See Figure 24)

Questions of interest:

- How many more users can be supported?
- How much faster is the new processor?
- What is the ratio of performance between the two tested processors?
- What happens when you have a new release of the operating system?

FASTER DUAL PROCESSOR

The results of the set of experiments on the new dual processor are reported in the Planning for Capacity - TSO Volume 2 (see [3]). The first column Run #349 was the results of the experiments with MVS 2.1.2. (See Figure 25.) The second column is the results using MVS 2.1.3. All of the new experiments were conducted using 2.1.3; therefore, the base of the 5870 for comparison purposes had to be repeated and Run # 672 will become the new base. Basically, in 128MB of main storage the 550 users produce 23.80 transactions per second in spite of the 2293.00 pages per second of physical paging. The processors are only 74.41% busy, but adding more users would increase the paging rate and elongate the response time. It is basically a repeat of earlier runs; more main storage would be required to bring down the page rate and improve response time. Therefore, in 128MB the 5890-300 processed 52% more transactions than the 5870 while supporting 57% more users.

The main storage area has been increased to 192MB. (See Figure 26.) More of the transactions will remain logically swapped and stay in main storage. In addition more users can be added to the population and the CPU busy metric will go up. Response time will remain constant. But the overall throughput or number of transactions per second will go up.

(See Figure 27.) As anticipated the page rate decreases by approximately 50%. Another 100 users are added to the population. There is also an increase of approximately five more transactions per second in throughput from the 128MB experiments. In retrospect, the 192MB configuration is processing 82% more transactions per second than the 5870, and is supporting 86% more users at the same time. Again, the 1308.58 Page Rate is constraining the system, which only reaches 86.74% CPU busy.

A 256MB main storage size on the 5890-300 is a maximum configuration point. (See Figure 28.) The last environment (192MB) did not use up all of the CPU cycles. Therefore, how many more users can be added to the population? Will logical swapping continue to be beneficial? Can the page rate be reduced even further?

The primary metric shows that the CPU is busy 98.49% of the time and that the user population has grown to 700. (See Figure 29.) The physical paging rate is down to 731.34 pages per second. When you compare the 5890-300 (256MB) with the 5870 (128MB) you can see that the 5890 is processing 94% more transactions with a user population that is 100% greater. All of the experiments to this point have been conducted in main storage configurations.

CONCLUSIONS

If you look at a graphic presentation of the data representing Response Time versus Number of Users, the differences in the various configurations become apparent. (See Figure 30.) Notice that at 300 users the various configurations are not that far apart. However, as the user population increases, the differences become more significant. What two comparisons become obvious?

The first indicator is a performance difference. (See Figure 31.) The 350 user population gives an average response time of 2.30 seconds. This is 0.30 seconds over the agreed service level agreement. The same user population on the 5890-300 gives an average response time of 0.44 seconds. What about a Capacity Difference?

The Capacity Difference can be illustrated by drawing a horizontal line from the 350 user point on the 5870 line and letting it intersect the 5890-300 line. (See Figure 32.) That intersection is at about 680 users. In other words, the 2.30 second response time on the 5870 can be duplicated on the 5890-300 by adding 330 more users.

Next, what is the effect on the capacity difference when main storage is reduced? (See Figure 33.) Draw a horizontal line starting at the 2.00 second response time point. The line will intersect the 128MB representation at approximately 540 users. In 192MB the intersection represents approximately 620 users. Lastly, the intersection of the 256MB line represents approximately 670 users.

At the end of the experimental cycle, someone asked the question, "How many users doing program development work would be required to max out a 5890-300 that had a 256MB main storage?" (See Figure 34.) Using the short transaction workload, the answer was 1020. Also notice that the number of transactions handled was about 118,000. The interesting point was that the RMF report could not report on a user population that was made up of a value that had more than three characters.

If you were to paraphrase what the entertainer says, TSO would like to thank you for the large main memories. (See Figure 35.) Large main storage sizes can accommodate logical swapping options. Remember that large main storage sizes will have to be tuned differently than the real and ESE combinations. The performance analyst will have to be able to sing different tunes. Be aware of the tuning parameters for THINK TIME.

A CAPACITY PLANNING METHODOLOGY FOR DATA NETWORKS

John Harmon
Lumbermens Mutual Casualty Company

ABSTRACT

Planning capacity requirements for data networks can be a very difficult task. Not only do we deal with several interrelated resources, but we must also work with potentially awkward management structures that have different units responsible for different parts of the network.

This paper presents a hierarchical structure for projecting usage requirements on each of the components in a typical multidomain leased line network. It deals with providing a technique for characterizing data in terms of differing critical time frames for each component; classifying the individual components; defining the relationships between each of the component classes; and showing how this structure can ease the planning burden of those responsible for the individual pieces of the network.

INTRODUCTION

Maximizing an organization's data communications investment involves an organized capacity planning approach. Unfortunately, while mainframe capacity planning seems to have achieved an aura of respectability, network capacity planning is something of an orphan. In fact, the meaning of the phrase "network capacity planning" can have widely different meanings depending on the organization.

For the purposes of this paper, the realm of network capacity planning will be defined to include capacity planning for both the communications lines in our sample network and capacity planning for 3725 Communications Controllers in the network. The paper describes a comprehensive capacity planning sequence in which devices attached to the data network have, as a part of the capacity plan, a description of the data flow going to and from the network. The purpose of this sequence is to improve and coordinate each of several capacity plans.

For the sake of simplification, All examples will refer to an SNA multidomain network where all of the equipment is IBM, and where each 3725 is located at the same datacenter as a host mainframe. This is not to say that this is the only situation where this technique will work, but that it will simplify the explanation. A diagram of this network is in the Appendix.

THE PROBLEM

There are several reasons that network capacity has not received the attention it deserves:

(1) First, network capacity planning involves several different kinds of devices in several different locations. Support personnel knowledgeable in all of the components are spread throughout the company and may seldom get an opportunity to interact.

(2) Responsibility for the capacity of each of the components of a network can be spread across political boundaries within a company. The remote office or an application development team could be responsible for a System 36 at the remote office, the telecommunications department is responsible for the telephone lines and modems, the network software support group is responsible for the communications controller (3725), and the Systems Software unit is responsible for the host mainframe. Even when these groups interact cooperatively, they often have hidden agendas which have the potential to cause problems. A simple example might be a situation where the telecommunications department wants to save the costs of some lines by purchasing some higher speed modems. After the changes are made, the network support group may find that the 3725 is getting errors and belatedly discover that the 3725 can't support the new linespeeds without being reorganized.

(3) Time frames for doing capacity planning on the individual pieces of the network are done at different times of the year. In most cases, mainframe capacity planning and telecommunications capacity planning are geared to complete as the budget cycle begins. Unfortunately, much of what the telecommunications people may need to do adequate planning will not become available until after their capacity plan is done.

Similarly, the network support unit may actually plan 3725 usage, but the Network Control Center may pay for it. In order to do a good job, the network support unit will probably want to use data made available when mainframe and telecommunications planning is done. Their results can be quite good, but anything they produce may be too late for the NCC manager to put in his budget projections.

If the end user does his own planning, as is often the case when all he has is control units and terminals, he, too, will time his requests to feed into the budget cycle, without considering potential impact on the telephone lines. Conversely, if the end user has a minicomputer such as System 36 or an 8100, capacity planning is usually done by either an application support group or a device support group. In either case, capacity planning will probably be done without regard to either telephone line needs or budget cycle timing.

What is needed, then, is an organizational method for performing network capacity planning so that:

(1) There is a uniformity of timing of capacity planning for devices of similar function. These will be defined later.

(2) Capacity Planning information flow must be prearranged so that the input and output requirements for each device are known and agreed to before any capacity planning begins.

(3) All levels of capacity planning must be completed in time to feed into the budget cycle.

ORGANIZATION OF NETWORK LEVELS

The first step of this organizational method is to define the levels of network components. This would be done as follows:

(1) Level One - These devices include end user devices such as control units (3274's), end user minicomputers (System 36's or 8100's), and host mainframes. The common thread is that capacity

planning of each of these devices has as one of its prime inputs, a user estimate of some business activity. While much of what is determined in the device capacity plans feeds into the mainframe capacity plan, as far as the network is concerned, they must be considered as similar devices.

(2) Level Two - These are the telephone lines, but only those which connect Level One devices with 3725's. Input to this level is output from Level One.

(3) Level Three - These are the lines connecting the 3725's in the network. As mentioned before, this assumes that each 3725 in the network is channel-attached to a host mainframe. Input to this level comes from Level One.

(4) Level Four - These are the 3725's in the network. Input to this level comes from Level Two and Level Three.

WHAT INFORMATION GETS TRANSFERRED BETWEEN LEVELS

This approach assumes that at each level, some sort of capacity planning is being done for each and every device. What the method demands is that the capacity plan for each and every device include a document detailing data flow such that it can be used at the succeeding levels. Note that it will save a good deal of trouble if each and every device in the network is given a unique name, preferably with some indication as to what kind of device it is. Keep in mind, however, at some point, someone is going to add (or delete) a component (device, line, or even a 3725). This is fine, just as long as people know how to apply the naming convention.

Input to Level One is the basic user business projection. The driving force for all levels of capacity planning is, of course, how much work is expected to be done. The "hows" of capacity planning at each of these levels will, of course, depend upon cost benefit analyses by whoever is responsible, but, minimally, it will include an output document with certain distinct pieces of data. These are:

(1) The name of the device.

(2) The name of the 3725 to which the device is attached.

(3) The name of the mainframe host which owns it (may be the same as number one).

(4) The name of host on the network to which this traffic estimate applies (need not be the same as number three).

(5) The name of the 3725 to which the host device is attached.

(6) The highest number of characters per second that will be sent to the host named in number four above for each hour throughout the day.

(7) The highest number of characters per second that will be received from the host named in number four above for each hour throughout the day.

(8) For interactive device controllers, the number of transactions initiated by terminals at the remote device.

(9) For batch device controllers, the number of blocks of data sent to or from the remote device.

(10) The number of subsidiary devices (such as terminals) which must be known by the network as associated with number one.

An example of this document is shown in Figure 1.

Note that if this is done for each of 200 devices on a network that contains five host mainframes, it will involve a great deal of paper. However, it lends itself to automation very easily.

Network input to Level Two consists of a simple summation of the output records from Level One by device, by 3725. Whoever does the network design for the boundary networks (remote office to 3725) can then use this information to perform capacity planning. Output from this level also includes a form for each line specifying the following information:

(1) The name of the line.

(2) The name of the 3725 to which the line is attached.

(3) The speed of the line (essentially, the number of characters per second that the line can carry).

(4) The number of primary devices.

(5) The number of subsidiary devices (terminals).

(6) The highest number of characters per second that will be sent to the devices on this line for each hour throughout the day.

(7) The highest number of characters per second that will be received by the 3725 on this line for each hour in the day.

An example of this document is shown in Figure 2.

Network input to Level Three consists of a summary of those input records from Level One in which the attached 3725 and the destination 3725 differ. This indicates that they need to be connected by an internetwork node link (3725 to 3725) rather than by a boundary link. Notice that this will include host to host traffic such as dataset transmissions. This information will probably be given to someone in the telecommunications and/or network support unit to determine what circuits will be necessary to support this traffic.

It may seem that Level Three is similar enough to Level Two to combine the two steps. Resist this approach. First of all, planning Level Three links (INN links) is more complex than planning Level Two links, so you would want to keep the distinction between the two levels for as long as possible. Secondly, the 3725 (which is configured in Level Four) handles boundary links (Level Two) differently than it handles INN links (Level Three). Thirdly, many companies which have only one datacenter will not have to worry about Level Three at all. To try to include Level Three information where people are not familiar with it might introduce a confusion which is not necessary.

In addition to putting out changes in the backbone (INN) network, whoever plans at this level will produce a document for each INN link indicating the following information:

(1) Name of the link.

(2) Speed of the link.

(3) Name of the "A" side 3725 ("A" side is arbitrary).

(4) Name of the host mainframe that owns the 3725 in number two.

(5) Name of the "B" side 3725 ("B" side is arbitrary).

(6) Name of the host mainframe that owns the 3725 in number four.

(7) The highest number of characters per second that will be sent from the "A" 3725 to the "B" 3725 by each hour of the day.

(8) The highest number of characters per second that will be sent from the "B" 3725 to the "A" 3725 by each hour of the day.

An example of this document is shown in Figure 3.

Network input to Level Four consists of the documents produced by both Levels Two and Three. What is essentially provided is data that can be passed to the proper person, probably in the network support area, who will plan for the capacity of the 3725's. There will be no output documents from Level Four, other than the 3725 capacity plan.

Figure 4 shows each of the steps in the network capacity planning process, along with the associated outputs.

It is important to keep in mind that the suggested data flow documents may be inappropriate for your network. However, they can serve as a starting point for discussions with the people who have to determine exactly what it is that they do need.

MAKING IT WORK

This methodology will not, in and of itself, solve all of your network capacity problems. The key to making it work is to have an informed person serve as an overall Project Manager. The primary roles of the Project Manager are:

(1) Identify and name all of the components (devices, lines, 3725's) in the network. The Network Support Unit can provide much of this information with the NCP source code.

(2) Categorize these devices as to where they fall in the levels described above.

(3) Determine who is going to have primary responsibility for the capacity plan for each network component.

(4) Interview each of those people and determine how long it will take them to (a) complete all of their capacity plans and (b) complete their specific Network Data Flow documents. In most cases, the Data Flow document can be produced first.

(5) Lay out the time line for the Project so that you give each of the planners sufficient time to produce their Data Flow documents and so that all capacity plans are complete in time to serve as input to the budget process.

(6) Monitor the process and make sure that people and technical deficiencies are dealt with as quickly as possible.

I would anticipate that, as with any new method, there would be opposition to this procedure. People planning for the remote devices may have new demands put on them. People doing mainframe planning may not appreciate the imposition of a new schedule. Nevertheless, there are some major paybacks to the effective use of this process:

(1) The timing of the process enables more complete budgeting for network costs.

(2) The flow of the process allows for capacity plans that are more accurate, and more internally consistent.

(3) The preplanning involved makes it less likely that one or more components will fall through the cracks. Because of the hierarchical nature of this method all of the parts must be looked at. This may generate some surprises.

(4) The existence of such a process will help justify the tools necessary to do adequate planning.

(5) Centralized management of the process will assure continuity, standards, and timing of the production of all of the capacity plans which are connected with network planning.

CONCLUSION

In order to provide for adequate input into a network capacity plan, those people who provide the necessary information for each of the parts must be coordinated if the final product is to reach its maximum potential as a management tool. This paper has outlined a way that I believe this coordination can be performed.

If an organization has the basic tools needed for capacity planning and network design; if it has a management desire for and commitment to improved resource planning; and if it has a person with the skills to "ride herd" on the process; the result should be not only improved planning for the telephone lines and communications controllers, but increased effectiveness of resource planning throughout the company.

NETVIEW AND NETVIEW/PC TUTORIAL

Dr. Kornel Terplan - Communication Networks Consultant

Performance Navigation, Inc. - 28 Summit Avenue
Hackensack, New Jersey 07601

ABSTRACT

The integration of logical and physical network management becomes one of the challanges for managing communication networks. There are several instruments providing support to main- and sidestream network management, including network, modem, application and software monitors, data bases, and analytical, emulation and simulation models. The major limitation of all of the above is that none of them provide an integrated solution. The tutorial offers an in-depth technical review of NetView and NetView/PC for addressing integrated network management. This include such areas, as support of the SNA products NCCF, NLDM, NPDA, LPDA, TARA, NMPF, ALERT, TAF, VNCA within NetView. It also includes the integration of LENs, LANs, PBXs and third party architectures utilizing alert, operator, host data and services point command facilities of NetView/PC. In addition, application program structures, panel hierarchy, code and command customization, files architecture and management, selection of information exchange alternatives, concert of real-time and PC-DOS components of NetView/PC are also addressed. To maintain objectivity, the paper also discusses the limitations of NetView and NetView/PC due to APPC, NMVT, DDM and CICS constraints. Other issues discussed are the cooperation of third party vendors, experiences yielded by the initial implementations as well as future trends.

1. INTRODUCTION

The need for adequate service levels in complex communications networks drives the demand for fast, consistent, expert-quality response to network management problems. Effective, flexible automation of both routine and creative activities would satisfy this demand by improving network management productivity.

Network management means deploying and coordinating all the resources necessary to plan, operate, administer, analyse, evaluate, design, and expand communication networks to meet service level objectives at all times at reasonable costs with optimal capacity.

In order to improve network management quality, there is a definite need for the integration of different information sources, products and procedures. The present status of network management can be characterized as follows:

- Fragmentation by products (communication software, modems, matrix switches, local area networks, multiplexers, private branch exchanges)
- Separate logical and physical network management
- Lack of correlation of different information sources
- Separation by network architectures
- Gateways do not yet support network management
- No adequate control of end user service level
- Too much information collected
- Redundancy in products
- Lack of powerful configuration data bases.

NetView and NetView/PC may mean the first important step towards centralized, standardized and integrated network management for multiple communication forms.

Although IBM has offered network management applications software packages for many years, NetView represents the first time that these separate SNA host network management packages have been put together in a single product. NetView consists of the NCCF, NLDM, and the NPDA network management products, and also includes functions from the VNCA and NMPF products. IBM products currently supported by NetView include the 3720 Communications Controller, the 3725 NCP Token-Ring Interconnection, the 3728 electronic matrix switch, and the 586X modems.

IBM's other recent announcement is NetView/PC, a multitasking personal computer subsystem that can be used in conjunction with NetView to provide services that extend Communication Network Management (CNM) support to non-IBM communications devices. CNM support will be extended to IBM Token-Ring Networks, non-SNA communications devices, and voice networks (CBX/PBX). The basic services provided by NetView/PC include services available to IBM or Rolm device-dependent applications, services to a user-written IBM PC-DOS program, and services to a technician/operator.

2. NETVIEW

NetView uses IBM`s SNA Network Management Architecture that supports the capabilities of new device attachments and permits flexible network growth. Architectural capabilities include Alerts, Session data, and Response time measurements. NetView supports any terminal in the IBM 3270 family with a minimum 24-line by

80-character display that is used as a NetView operator station when logged on through VTAM. The databases of the NetView components can use any IBM Direct Access Storage Device supported by VSAM.

2.1 NETVIEW ARCHITECTURE (Figure 2.1) (DATA87)

The functions of NetView are seen in the components that make up NetView, which include the following: (TERP87)

- Command facility - includes and enhances the functions of the Network Communication Control Facility (NCCF)
- Session monitor - contains the functions of the Network Logical Data Manager (NLDM)
- Hardware monitor - includes the functions of the Network Problem Determination Application (NPDA)
- Status monitor - allows network operators to look at the status of network resources and to choose commands to be sent for any displayed resource
- Online Help facility - supplies data about NetView commands and many of the NetView Display panels
- Help Desk facility - offers an online guide about network problem diagnosis techniques
- Browse facility - allows operators to look through libraries and the network log

2.2 NETVIEW SUBSYSTEMS

The most important subsystems of NetView are discussed in some depth (TERP87).

The virtual telecommunication access method (VTAM) has its own command language and operator functions that allow commands and messages to be issued and received via the system console. In the past, the sharing of the system console for VTAM and operating system messages created operational problems for IBM customers with large networks. To alleviate this problem and to separate network messages from host-system messages, an interface called the programmed operator interface (POI) was made available in VTAM.

The network communication-control facility (NCCF) is the current IBM product that uses POI. With this interface, terminals defined to NCCF can issue any command to VTAM that can be issued from the system console. The terminal can also receive messages from VTAM and output them to the NCCF terminal. In addition, NCCF uses the communication network-management interface (CNMI) provided by the SSCP.

NCCF allows grouping of individual commands into lists, called CLISTs, that can be invoked with one short command. NCCF provides program-based services for user or IBM-written applications. These services can be used for communication network-management applications or to tailor operator control functions.

In multiple system networks (MSNF), NCCF provides for communication across domain boundaries. Coordination and control of the network can be assigned to NCCF operators in any or all of the domains in the network. NCCF may become the central point for analyzing and filtering all SNA-related messages.

The VSE/OCCF (operator communication-control facility) extends the control capability of NCCF for the inclusion of DOS/VSE control, operated at remote locations. MVS/OCCF allows one or more remote MVS systems to be operated from a host MVS system. It resides in the remote systems and optionally in the host. ROCF resides in the remote facility.

Network operational control is frequently over loaded by supervising various applications (IMS, CICS), various systems (MVS, DPPX) and network-related information (NETVIEW, NCCF, NPDA, VNCA, NLDM). Until recently, for each area indicated, different display devices were required for continuous control. To address the access-to requirement, terminal-access facility (TAF) connects to a variety of display-oriented network-management tools that reside in a variety of software bases. It ensures that messages are not lost while the screen is dedicated to a specific application. Both solicited and unsolicited communication are supported, and a correlation of requests to replies is provided. But, TAF is restricted to the use of operator control sessions only. Multiple application single screen (MASS) allows an operator to have up to eight sessions to different VTAM applications at a time. Screen support may be provided by 3290, or Series/1 or 3270 devices.

NPDA assists network operators in performing network-problem determination by collecting and interpreting records of errors detected within a network and by recommending possible resolution. NPDA is a NCCF IBM-written command processor with access to the accumulated error-data and statistics-data base. This data is presented as follows:

1. Error counts associated with communication controllers, channels, modems, terminals, and links.
2. Specific data, an error description, and a probable cause associated with each class of errors collected. Recommended actions to resolve the displayed errors are provided.

Two new protocol commands have been implemented via the communication network-management interface: request maintenance statistics and record-formatted maintenance statistics.

Request maintenance statistics are forwarded by the system service control point to an SNA node upon request of NCCF. NCCF issues a request when directed by the NPDA command processor. NPDA sets up the request sequence whenever an NCCF operator requests, via network node name, to view the problem-determination data for a specific SNA physical unit. This request is issued from a terminal connected to NCCF.

NPDA provides error-description and probable-cause statements on displays to the NCCF operator. The error descriptions and probable-cause statements are derived from an analysis of network error data stored in the NPDA data base. The problem-cause definition identifies the most likely network component or group of components that caused a failure of hardwa-

re or software.

NPDA allows the NCCF operator to receive advanced warning when a communication-controller data link connecting a specific station exceeds an error-threshold rate on the link. The operator is alerted if the ratio between traffic and temporary station errors exceeds thresholds, specified by the user, on a line basis. The alerts are designed to flow unsolicitedly from the network elements using record formatted maintenance statistics (RECFMS) Type 00 response unit.

The alert originator communicates the alert to the alert processor, which forwards it to the alert manager. The originator and processor may be combined in the same network resource. The manager may or may not coreside with the alert processor. Besides physically oriented alerts (e.g., stations, lines, etc.), application alerts generated by customer-specified error-performance limits being exceeded are also included.

Via the event-statistical recording filter, irrelevant events grouped by unit name and type can be supressed. The alert-generating filter enables operators to classify certain types for alarming. These are stored in a separate part of the NPDA data base, accessible for operational control at any time. The NCCF operator-viewing filter enables network management to set up authority levels for operational control. Finally, the NPDA customer-viewing filter assists operational control to customize the filtering characteristics for the specific tasks under consideration. NPDA provides a data base for further processing by other tools, such as Information/Manager, SMF, Statistical Analysis System (SAS), or MICS. The data copied onto performance data bases are very valuable in supporting diagnosis in on-line or off-line modus.

Until recently, the stations attached to a controller were not explicitly known to the SSCP. For satisfying the downstream requirement for subnetworks, a threshold analysis and remote access (TARA) program was developed as an additional NPDA feature. Information may be solicited by the operator but more frequently is driven by automated procedures. This information can be centrally displayed in a hierarchical form, consistent with NPDA. Interfaces for management reporting via Service Level Reporter (SLR) and Info/System are supported as well. Recently MICS offered an NPDA interface as well.

In order to faciliate and simplify the network operational control activities, VNCA (VTAM node control application) offers additional features under NCCF to NPDA. It provides full-screen color displays to monitor the status and current activity of all resources in the domain under consideration. Customer-friendly interfaces have been designed for easy communication with the network. More importantly, certain routine-reactivation sequences are automated, allowing network operational control more time to handle unexpected, more serious network problems.

Network logical data manager (NLDM) was designed in response to logical problem-determination requirements. NLDM is an application under NCCF for collecting SNA session-related information, correlating data related to SNA sessions between network-addessable units, and displaying relevant information at an NCCF operator station. The intent is to establish session awareness and provide session-trace capability. By collecting relevant activities in progress at and just prior to failure, central problem determination can be significantly faciliated.

The principal NLDM features are

- NLDM is an on-line, interactive software monitor that extracts information from the telecommunication-access methods (e.g., VTAM or TCAM) and from the network-control program in single and multiple domains for supporting logical network management.
- Data are displayed in full-screen mode, utilizing color support.
- It provides useful data (SNA protocol, data flow, Path Information Units (PIUs) and selected NCP control information) when network problems (e.g.,"hung" sessions and stopped applications) occur that otherwise might not produce problem related information about physical networking resources.
- The operator can select the session(s) to be traced prior to and during the sessions.
- Active session data is maintained in virtual storage. When the session is terminated, the data are transferred to a VSAM data base for further processing and later reference for accounting, problem determination, availability reporting, and capacity planning.
- NLDM provides information for local or remote resources in the same domain or in cross-domain sessions.
- Reduction or elimination of the need to recreate software problems or to run dedicated traces because of the ability to collect and store relevant SNA information in progress and prior to a failure.
- Support for the response time monitor (RTM).

NLDM information may be further processed and reported by MICS.

2.3 NETVIEW INTERFACES

In order to improve end user productivity, NetView is expected to provide interfaces for:

- Info/System (IBM) for supporting problem, configuration and change management
- Service Level Reporter (IBM) for supporting service level evaluation and reporting
- MVS Integrated Control System (Morino) for contributing to standardizing the performance data base, reporting and for faciliating correlation among various information sources
- Teleprocessing Network Simulator (IBM) for supporting script generation for quality

testing new applications and stress testing communication networks

- SNAP-SHOT (IBM) for providing input data on traffic volumes for improving the accuracy of simulation runs

- Best/1-SNA (BGS Systems) for supporting network wide modeling.

At the moment, it is still early to say what systems and in which sequence are going to be supported.

2.4 NETVIEW BENEFITS TO USERS

Besides combining separate functions into one program, NetView also offers enhanced capabilities in the following areas:

- Terminal Access Facility support of large screen and color applications

- CLISTs driven by application messages

- Disk log enhancements

- Modem support of IBM 586X Models 2 and 3 and IBM 5812

- New and generic alerts

- New "Purge Attached" command

- Token-Ring network support

- Virtual route blockage indication

- Session setup failure notification

- Extended Recovery Facility in MVS/XA

- Automatic operations and recovery

- Realtime update of the domain status panel

- Important message indicator

NetView also provides improved support of network management functions through learning aids, consistent use of color, common program function keys and procedural conventions, and ease of movement between components. Learning aids consist of an Online Help Facility, a NetView Operation Primer and the NetView Operation Scenarios publications, and an IBM PC diskette tutorial.

To simplify installation of NetView, customized procedures and installation aids for all NetView components are available, such as the 4700 support facility on MVS. An installation "cookbook" and a post installation verification procedure are also provided.

2.5 PROBLEMS AND RISKS

Besides of substatial benefits toward integrated network management, there are still certain drawbacks with the NetView implementation:

- NetView does not eliminate or reduce the information capturing overhead of subsystems, such as NLDM and NPDA.

- Network Performance Monitor (NPM) is no part of NetView. Thus, relevant information on NCP-slow-down, Byte count, Line utilization statistics, and the TPNS-Interface are missing.

- End user response time measurement is by means of RTM and NLDM, only.

- Continuous threshold supervision via NPDA requests too much resources.

- The LPDA-related functions require the use of IBM modems.

- No message filtering.

- Lack of interfaces to other products, such as Info/System, SLR and modeling instruments.

- NetView is not yet user-friendly at all.

- Help-desk support leaves a number of unanswered questions:
  x Is expert system support expected ?
  x How easy is to interrogate the existing documentation ?

- Netview is not unexpensive; all software around Netview require the latest version.

- It is not yet clear, how independent products, such as Mazdamon, Netspy, Net/Master, application monitors and host monitors are able to communicate with Netview.

2.6 COMPETITION OF NETVIEW

The only product available at the host level for doing similar jobs is Net/Master (CINC84). It is a multicomponent system designed to assist in managing and optimizing the performance of complex SNA networks. Every node can be connected within the network, and information can be shared by hundreds of end users. Net/Master is a multitasking, multithreading VTAM application that is designed to support a large number of concurrent users with minimum system overhead. Net/Master has been designed to be easy to install and is extremely user-friendly, utilizing a large number of full-screen panels and menus to facilitate function selection as far as possible. The product solves the problems of managing multiple applications on the same mainframe, supporting a mainstream approach. NCCF is not a prerequisite for running Net/Master.

Net/Command (AVAN87) uses a sidestream approach for integrating different information sources, such as application, software, communication, network, modem monitors and LAN/PBX servers, offering virtual operating and filtering features. Similar integration options are supported by other companies such as AT&T, Codex, Infotron and Timeplex.

3. NETVIEW/PC

NetView/PC is a multitasking personal computer subsystem that supplies the facilities to support communication of network management data between a personal computer and NetView on a host. NetView/PC was designed to be used in conjunction with NetView to provide servi-

ces that permit user-written programs to extend Communication Network Management (CNM) to non-IBM communications devices. Using NetView/PC, CNM support can be extended to non-SNA communications devices, voice networks (CBX/PBX), and IBM Token-Ring Networks. It offers the basic services needed by a device dependent CNM application program and a network operator.

3.1 NETVIEW/PC ARCHITECTURE (IBM87)

NetView/PC is a new product designed to extend IBM's network management into new customer environments and to help provide, in more and more networks, total enterprise-wide network management. NetView/PC can perform important functions and, at the same time, communicate information to NetView so that it can execute additional functions. NetView/PC supports stand-alone network management as well as complementing NetView to extend the scope of centralized network management.

NetView/PC applications support IBM Token-Ring Networks and voice networks. In addition, the Application Programming Interface/Communication Services (API/CS) functions provided by NetView/PC will enable customer-developed applications to support a variety of other devices not supported by IBM's current network management.

Netview/PC provides a diverse set of functions. The capability to execute different tasks concurrently enables foreground and backgound processing to share a processor's resources, increasing its total capacity. A co-processor communication card and supporting software provide both synchronous (SDLC) communication with the IBM host and asynchronous communication with ROLM voice network devices, while off-loading a significant amount of work from the PC processor.

Local problem determination provides management of device and software alerts (errors) at the Netview/PC console. Host alert transfer to NetView extends centralized network management to devices not currently supported within the SNA network. File transfer between NetView/PC and the IBM host, using LU 6.2 protocols, enables a wide range of information to be exchanged with the IBM host CICS/DDM (Customer Interface Control System/Distributed Data Management) product and thus made available to host application programs for reporting, billing, or other processing.

Local operator control of NetView/PC allows operator access to various functions. Using remote console support, NetView/PC can be controlled from another NetView/PC, or a remote operator can review the keying of the local operator. The DOS partition support enables most DOS programs to execute concurrently with some NetView/PC tasks. Finally, a command facility provides a command-response capability between the NetView operator and applications running on NetView/PC.

Three NetView voice-network accounting programs reside and execute in the host (Figure 3.1).

One of the critical challenges facing the NetView/PC product was how to provide all of the NetView/PC functions, including host communication, and still meet certain storage and performance requirements. To provide host communication, it was necessary to support LU (Logical Unit) 6.2 sessions for sending data files, and PU (Physical Unit) 2.0 sessions for alert processing. This requirement was met by using the functions in the Advanced Program-to-Program Communications for Personal Computer (APPC/PC) program in the co-processor card.

APPC and the remaining NetView/PC functions could not be loaded in DOS memory, however, because of storage requirements. The solution chosen was to off-load all the communication software, such as LU 6.2, PU 2.0, SDLC (Synchronous Data Link Control), and ASYNC (asynchronous protocol) to a co-processor. For this, A Realtime Interface Co-Processor (ARTIC) card was selected (Figure 3.2). This provided NetView/PC with the storage and operating cycles needed to execute all of the input and output processing without drastically affecting PC performance.

The Realtime Control Program (RCP) is an IBM supported program that executes on the co-processor. The multitasking operating system can control up to 253 concurrent tasks, each task executing on any of 255 possible priorities. The Realtime Control Program also provides various other functions that simplify the writing of tasks such as:

- First-level interrupt handlers. The program receives all software and hardware interrupts, which are then passed to the task interrupt handler.
- Resource handler. The program manages various resources provided by the co-processor, such as hardware and software timers, queues, memory, communication ports, DMA (Direct Memory Access) channels, and interrupt vectors. A task can request temporary control of these resources.
- Interface functions. These routines allow any application task running on the co-processor to interrupt the PC in order to exchange data and control bytes.

In addition, there are various program functions provided that run on the PC for support of the co-processor, including system initialization (power-on, self-test, interrupt vectors, and hardware timer initialization), loading, PC tasks to the co-processor interface, and asynchronous error handling.

3.2 NETVIEW/PC SUBSYSTEMS AND COMMUNICATION WITH NETVIEW

The support of open application programming interfaces allows customers to use the services provided by NetView and NetView/PC to provide consistent management of network devices, enhancing their ability to manage a multi-vendor network. Figure 3.3 illustrates the open application programming interfaces that NetView and NetView/PC support.

NetView/PC provides a set of open application programming interfaces known collectively as the Application Programming Interface/Communication Services (API/CS). Four

functions are supported to assist customer and vendor-supplied applications in providing SNA network management support for non-SNA devices, such as terminals, modems, PBXs, multiplexors, LANs, other architectures and matrix switches. The four separate functions in API/CS are Host Alert Facility, Operator Communication Facility, Host Data Facility, and Service Point Command Facility.

The Host Alert Facility (HAF) allows an application running in NetView/PC to build an generic "alert", based on information received from the machine the application is monitoring, and route it to the NetView/PC. The Alert Manager passes the alert to the local NetView/PC operator and sends it to NetView in the host, where it may be displayed or used to initiate a recovery.

The application uses the Operator Communication Facility to signal the local NetView/PC operator. This is particularly important when more than one application is executing in NetView/PC and one of the background applications needs to communicate with the operator.

The Host Data Facility permits NetView/PC applications to transfer DOS files to a CICS/DDM (Customer Information Control System/Distributed Data Management) facility. A CICS/DDM application may then alter or transfer the contents of the DOS files.

Conversely, the CICS/DDM application may send files to the NetView/PC application.

Three types of communications using an SNA host are supported by NetView/PC. The first type is the forwarding of alerts from NetView/PC to NetView in a focal-point host. The application creating the alert provides the routing instructions; NetView/PC then routes the alert to the NetView/PC operator or to Net View. This alert structure follows the NMVT (Network Management Vector Transport, a subset of SNA) format and flows over an SSCP-PU 2.0 session path to NetView.

The second type of host communications is the transfer of data files between the host and NetView/PC, using a Logical Unit 6.2 session. This session is supported at the host end by a Customer Information Control System/Distributed Data Management (CICS/DDM) transaction program. Files can be transferred in either direction, which can be initiated by the NetView/PC operator or by any application in NetView/PC.

Finally, the Service Point Command Facility allows a command issued from NetView to be routed to an application running in NetView/PC, where the command will be executed. The functions supported by the application via this facility are determined by the application developer and the capabilities of the device that the application manages.

3.3 NETVIEW CUSTOMIZATION

Most of the open application programming interfaces in NetView were present in the earlier IBM network management products. However, these interfaces, in combination with the NetView/PC API/CS facilities, permit extension and customization of network management for all devices in the user's network.

NetView supports open application programming interfaces via four major sets of facilities: command lists (CLISTs), user exits, command processors, and alert screen customization.

The Command Processor Facility allows a customer to supply additional commands that may be invoked by NetView operator or CLISTs. Command processors can communicate with non-IBM and non-SNA network devices via the NetView/PC Service Point Command Facility. It is through this facility that customers and vendors can extend various command and response facilities to non-IBM and non-SNA devices.

The CLIST Facility allows a customer to define a set of NetView and access method commands to be executed based on some triggering event, such as an operator command, message, alert, or expiration of a timer. The CLIST can issue a command that invokes a command processor to communicate with a NetView/PC application. In this way, a device`s operations can be automated.

User exists allow a customer-written routine to supress data that is not useful in this environment, put device-specific data into a form that may be worked on by NetView or a supplied application, and tailor the user interface by changing the commands and displays available to the operator. Exits also have the capability to initiate CLISTs or command processors in response to events reported to NetView.

An important function provided in NetView is the Screen Customization Facility, which allows a customer to define alert screens for non-IBM devices. In addition, a customer can change or delete specific alert screens for devices that are supported by NetView.

Through these four facilities, NetView can be used to centralize the control of vendor devices, integrating the management of both SNA and non-SNA devices. The command processor facility communicates with the customer`s devices. The exit and CLIST facilities allow the operation of these devices to be automated, while the alert-screen customization facility displays events about devices.

The application programming interfaces in NetView and NetView/PC complement one another. An alert issued by a NetView/PC application and sent to the host using the Host Alert Facility may be displayed using the alert-screen customization facility. Alternately, the alert could trigger a customer-defined action using the user exit and command processor facilities of NetView.

The emphasis of open application programming interfaces both in NetView/PC and NetView allow NetView's view of the network to be expanded. As customers participate in IBM's Open Network Management structure, NetView, NetView/PC, and customer applications will provide better enterprise-wide management of customer networks.

3.4 INFORMATION EXCHANGE BETWEEN NETVIEW AND NETVIEW/PC

This chapter demonstrates how alerts are escalated by Netview/PC to Netview and how Netview reacts. File transfer capabilities are addressed as well. The numbers of the steps in Figure 3.4 relate to the numbers in the following list.

An error is detected.

1. A User supplied network management application, executing in the DOS partition of NetView/PC, recognizes an Alert condition and calls DCJVAOO to send an alert to the hardware monitor.

2. NetView/PC logs the Alert and sends the Alert NMVT to the host.

3. NetView passes the Alert NMVT to the Hardware Monitor executing in NetView.

Reacting to the Alert.

4. The operator enters the user defined command with the target (NetView/PC application) name.

5. The command is recognized by NetView and the user supplied Command Processor (CP) is given control and passed the parsed input.

6. The CP checks that valid data is passed and then calls the user supplied subtask with the DSIMQS macro.

7. NetView passes control to the OST with the passed data.

8. The subtask checks the input and then builds an NMVT. The subtask then issues the DSIZCSMS macro to send the NMVT to NetView/PC.

9. NetView sends the NMVT to NetView/PC.

10. NetView/PC passes the message to the API/CS.

11. The user application calls DCJVCOO (API/CS call to receive a command) and the API/CS passes the message to the user application.

12. The user supplied application uses DOS to perform required communications with the device.

13. The user application processes the command and prepares a reply message and calls DCJVCOO (API/CS call to send a reply).

14. The user application calls DCJVO00 to notify the operator that the DOS Partition requires operator communications.

15. The API/CS turns on the DP icon on the NetView/PC operator display.

16. The API/CS sends the reply message to NetView/PC.

17. NetView/PC sends the reply to NMVT to NetView.

18. NetView passes the reply NMVT to the user supplied subtask. The subtask processes the reply and prepares a message to send to the NetView operator.

19. The subtask issues the DSIMQS macro to send messages to the user supplied CP to display to the NetView operator.

    Note: The subtask may display messages directly by issuing the DSIMBS macro.

20. The user supplied CP issues the DSIPSS macro to display the message data.

Transferring file data.

21. The user application calls DCJVO00 to transfer file data.

22. The API/CS passes the request to the Host Data Transfer program in NetView/PC.

23. The HDF initiates the transfer with the host CICS DDM application. The file data is sent to or received from the host.

3.5 APPLICATION DESIGN OVERVIEW

Using the API/CS

This segment describes the general applicability criteria of using API/CS. All further examples, however, will show the specific criteria for the Host Alert Facility, only.

An Application Request Block (ARB) is required for all calls to Application Program Interface/Communications Services functions. Storage for the ARB must be provided by the application program. An ARB should be dedicated to an API/CS function from the 'OPEN' to the 'CLOSE' of that function.

External Declarations (ie. EXTERN DCJVA00: FAR) for the API/CS library calls must not be in the application's code segment. All calls to API/CS subroutines are FAR calls.

To use an API/CS function, the application should be coded to:

1. Provide storage for an ARB for each API/CS function that the API/CS will use. The storage for the ARB should be dedicated to the ARB from the 'OPEN' of the API/CS function to the 'CLOSE' of the API/CS function.

   Each Application Request Block (ARB) is identified by an ARBID, ARBn, where n is a numeric character that identifies the function for which the ARB will be used. It is used by the API/CS to verify the start of the ARB and serves as an 'eye catcher' in a storage dump.

2. Check the address of the ARB in the AX and DX register pair when the API/CS returns control.

   The API/CS checks the ARBID and if the ARBID (ARBn) in the ARB is incorrect for the subroutine called, the ARB address is assumed to be invalid. The API/CS makes the AX and DX pair zero and returns immediately to the calling application. The

application must check the AX and DX pair for non-zero before they are used.

3. Open each API/CS function that the application will use.

4. Call each API/CS function as required.

5. Close each of the API/CS functions the application has opened.

The functions should be opened as part of the application's initialization process and all opened functions should be closed by the application's termination process. The application may call an opened interface as many times as is required by the application until the application closes the (API/CS) function.

The ARB contains a two byte request code field (in hexadecimal) that the application sets to indicate the function desired. The two byte Request Codes and descriptions are:

Request Code Description

Alerts

0101H Open the Alert API/CS

0102H Send an Alert

0104H Close the Alert

Host Alert Facility Example

This example shows design requirements and still open questions about processing alert messages third party devices by NetView/PC. The steps include:

- Generating unsolicited alerts by the third-party device; the format is completely different from each device, and from the required NMVT-format

- Transmission to NetView/PC

  The following items should be clarified:

  x Address of NetViews/PC port
  x Transmission medium
  x Transmission protocol (synchronous, asynchronous)
  x Transmission speed

- Receive by NetViews/PC

  x Allocation of receive parts and buffers
  x Syntax check
  x Allocation of internal message id.
  x Storing third-party alert

- Processing Alert in NetView/PC by the application program

  x Branching to the appropiate subsystem - (in this case: Host Alert Facility)
  x Format conversion onto NMVT
  x Storing NMVT and identifying the pointer to the NMVT

- Transmission to NetView by using SSCP-PU-services

  x Open alert API/CS
  x Send alert
  x Close alert API/CS

For successful management, building the NMVT plays the principle role. NMVT-s are referenced in the ARB-s (Application Request Blocks) A four byte field (Position 15, name: MVADDR) defines the printer to the Alert Major Vector which may represent multiple NMVT-s.

NMVT (Network Management Vector Table) has the following structure for Alarm Management:

- X`01` Date and time
- X`03` Hierarchy name list
- X`10` Product classification
- X`91` Basic alert
- X`00` Text message
- X`A0` Detail qualifier
- X`9F` Netview/PC alert subvector

One example shows the following structure:

Length X`0000`	X`01`	X`03`	X`10`	X`91`	X`10`
X`00`	X`9F`	X`A0`			

X`91' gives information on alert type such as permanent or temporary, on cause (e.g. hardware, software, microcode), on components impacted (e.g. control unit, modem, link, line) PBX, device.

For implementing NetView/PC, X`9F` subvectors have to be constructed very carefully. X`9F` contains all information about third-party-components.

The target records include:

- Alert description records
- Probable cause records
- User cause records
- Installation cause records
- Failure cause records and
- Recommended action records

This classification follows the existing NPDA-formats. These records are the targets for third-party-alarm-message-conversion.

As an example, the Alert Description Records for X`9F` subvector will be shown. The first step in application design investigates how third-party alarm records match with those shown in Table 1. As an example, Infotron 992 multiplexers are considered with the list of alarms (Table 2).

3.6 NETVIEW/PC BENEFITS TO USERS

Users, centralizing and integrating network management can benefit in many ways:

- Services available to IBM or Rolm device-dependent applications:

  x File manager, multitasking facilities, communications manager

  x Panel, keyboard facilities, display

- Services available to a user-written IBM Personal Computer DOS program:

  x Host file transfer and communication with NetView

- Services available to a technician/operator:

  x Operator control, remote console, general help

  x Problem management, service reminder, alert management

- Consolidation of alerting, billing and traffic information within one product running in an application host or a dedicated computer such as CMC

- Standardization of all alerting messages of various measurement and management instruments

- Correlation of information from various sources
- Opportunity of supporting one single interface towards modeling, reporting and data base systems.

3.7 PROBLEMS AND RISKS

Besides benefits of centralization and integration, there are still many unanswered questions. The most important open problems include:

- IBM may become - without any serious competition - the network management market leader controlling practically all third-party-devices

- Dependency of users from too many parties, including IBM, third-party-vendors (quality of network management) and who has implemented Netview/PC

- Request for implementing new software and customization of existing software

- Lead time up to the integration of all third-party-devices may take too long

- NetView/PC is no integrator, but just an intelligent protocol converter

- Third party vendors may decline of being controlled by IBM

- NetView/PC means redundancy, because the most third party vendors have been utilizing some degree of network management that may even be much richer than the NetView/PC functionality (e.g.: INMS from AT&T and UNMS from Timeplex)

- NetView/PC is not yet bidirectional; the question whether IBM permits third party vendors to gain access to control and/or to information

- Netview/PC may be overloaded when mass data processing is required.

- NetView/PC has serious storage and communication throughput constraints

3.8 IMPLEMENTATION EXAMPLES

The first two implementation examples are discussed in some detail.

- Voice Network Management

IBM and ROLM announced two communication network management software products that extend IBM's open network management architecture to voice networks. These new programs, which run in NetView/PC and in the host System/370 (Figure 3.5), allow central site operations to produce billing reports for telephone calls, choose cost-effective configurations for voice traffic, and trouble-shoot ROLM Computerized Branch Exchanges (CBXs).

The ROLM Alert Monitor offers network-wide alert monitoring and problem management at the IBM NetView host. A single Alert Monitor can serve a combination of up to 10 CBXs and CBX II 9000 nodes. The Monitor detects problem conditions, collects error and alarm infomation from the CBXs, and translates the information into one of the four types of alerts, categorized by degree of severity. These alerts are then passed to the NetView/PC alert manager for local problem management and can be passed on to NetView for centralized problem management. The Alert Monitor also can use information obtained from the ROLM Automatic Facilities Test System (AFACTS) to report changing trunk conditions.

The ROLM Call Detail Collector collects information from up to 10 CBXs or CC3 pollable storage devices connected to remote CBXs or selected non-ROLM PBXs.

The Call Detail Collector provides site collection, multisite polling, and host transfer of data, which may be used for billing, capacity planning, and network analysis. Information can be stored and later forwarded to an IBM host for processing, using NetView/PC's File Transfer Facilities (via Logical Unit 6.2).

The NetView/PC can be locally attached to the ROLM CBX via an asynchronous connection for collecting call detail records, and error and alarm data. This information can also be collected and stored by a locally attached storage device and later forwarded to NetView/PC via a dial connection initiated either by NetView/PC or the locally attached storage device. The connections initiated by NetView/PC can be scheduled to occur at regular intervals while connections initiated by the storage device will occur when storage capacity thresholds are exceeded.

The NetView Network Billing System is a host System/370 application that provides customers with a clear accounting of CBX costs and usage by departments, long-distance carriers, and equipment. The input for this application are the Call Detail Records generated by CBX, collected and forwarded to the host by NetView/PC. Tariff information is provided by the NetView Tariff Data Base for U.S. long-distance carriers.

The NetView Traffic Engeneering Line Optimization System is a set of five host application

programs that allow users to analyze Call Detail Records received from the ROLM Call Detail Collector program. These programs help determine cost-effective ways to configure a site's telecommunication system and also help identify problem areas within a customer's configuration.

- Token Ring Network Management

The IBM Token-Ring Manager Version 1.1 (Figure 3.6) is a program that assists the user in problem determination and error recovery on the Token-Ring Network. It can operate as a standalone application or using such NetView/PC applications as alert forwarding to host and remote-console support to provide total system network management. The Token-Ring Network manager monitors the token-ring network for hard and soft errors.

A soft error is recorded when an error threshold for transient, recoverable errors is exceeded. Soft errors may indicate a possible loss of a network resource. Hard errors may indicate faults in the token-ring network cabling system access units, or attached network adapters. Up to 260 devices on one ring are supported.

Network errors are recorded by the Token-Ring Network Manager in an event log on a disk or diskette. Other network events, such as stations joining and withdrawing from the network, can be recorded in the log to assist the user in network problem determination. Events logged may be displayed and printed for a specified station or period of time.

An alert condition is immediately signaled to the NetView/PC operator by an audible alarm and a highlighted indicator on the operator display. At the same time, an alert message can be transmitted over an SDLC link to NetView in the SNA host, using NetView/PC's alert manager and host communication services.

NetView/PC's remote console support allows an operator at a remote IBM PC to operate the token-ring network manager. The remote NetView/PC communicates with the PC attached to the token ring through an ASCII asynchronous link.

3.9 COMPETITION OF NETVIEW/PC

There are just few products on the market offering similar functionality. Examples are:

- INMS (Integrated Network Management System) from AT&T
- UNMS (Unified Network Management System) from Timeplex
- NMS (Network Management System) from Nixdorf
- INM (Integrated Network Management) from Infotron
- CONTROLNET from Unisys
- NM (Network Manager) from Codex
- Net/Command from Avant-Garde Computing.

The majority of the products provide value added characteristics in the particular domain and encourage third party vendors to accept the protocol for integration. Usually, the integrator offers an interface to NetView/PC or directly to NetView.

4. FUTURE EXPECTATIONS

With the introduction of NetView and NetView/PC, IBM is finally offering an integrated compatible line of software products. One of IBM's goals is connectivity among its products as well as non-IBM products. By opening up its communications architecture, it is allowing users to attach other vendors' products to the SNA network. A centralized source of control is another goal that IBM is striving for with these announcements. Previously, its network management packages were not necessarily compatible with each other and operators would have to jump from one application to another to gather information.

If NetView is the success that IBM hopes it will be, vendors of both hardware and software network management systems will face a major new player. Previously datacomm managers who had an IBM shop may have used another vendor's network management system to get statistical information on the network. IBM hopes to stop this by offering an integrated package that meets the users' needs. Vendors with independent network management systems may have to find new markets or go after the smaller shop.

One area that remains unclear is NetView's report-generating capabilities. Information on this ability remains sparse. Another potential problem is cost. NetView is expensive; it runs only on IBM mainframes, whereas other packages can run on less costly mini- or microcomputers. NetView/PC runs on the IBM Personal Computer, but to bring together all of the network management components, users will need a number of these personal computers. One other thought is that this is just the first step in integrating network management. Some of the products are not even available yet. What is currently available permits network managers to monitor the alarm conditions but diagnostic tests and reconfigurations cannot be done yet.

In summary, it is expected that the majority of third-party-network-management-vendors will seriously consider the implementation of the NetView/PC-gateway. In certain cases, users or external software companies will implement the gateways.

A SURVEY OF PERFORMANCE APPLICATIONS OF THE TELEPROCESSING NETWORK SIMULATOR(TPNS)

Richard C. Burke
Duke Power Company

ABSTRACT

The Teleprocessing Network Simulator(TPNS) is recognized as a tool for preparing accurate pre-production response time estimates of major new application systems, and for simulation of complex network configurations. This tutorial will describe how the flexibility of the TPNS architecture and the scripting language make TPNS also suitable for a variety of other performance applications.

This tutorial begins with a brief introduction to TPNS, followed by a survey of some of its performance related applications. Descriptions of actual simulations and summaries of the results are also provided.[1]

1. INTRODUCTION

IBM's Teleprocessing Network Simulator(TPNS) is software that provides simulation for many different network/ terminal types and configurations. TPNS can be run in essentially two modes. The direct attached configuration allows for the complete simulation of the terminal response time(host response time and all network and VTAM response times). The VTAMAPPL configuration is used when only the stressing of the host application environment is required. Executing TPNS with the VTAMAPPL configuration requires only the installation of the TPNS software on a host computer. However, executing TPNS with the direct attached configuration also requires one or more standalone 3705/3725 network processors, and additional TPNS software on each 3705/3725. Defining a TPNS simulation using the direct attached configuration can be extremely complex and time consuming. However, defining a simulation configuration for a VTAMAPPL simulation is relatively simple. Our company runs TPNS exclusively with the VTAMAPPL configuration.[2]

When run with the VTAMAPPL configuration, TPNS uses multiple VTAM application programs(actual VTAM APPL statements), which establish one or more LU to LU sessions between secondary logical units(SLU - usually the terminals being simulated), and one or more primary logical units(PLU - usually the application(s) under test, such as a CICS Terminal Owning Region or a PROFS system). The VTAMAPPL configuration also permits simulation of the PLU allowing actual network terminals to logon the SLU. The scripting facility of TPNS generates the input transactions that are sent to the system under test. TPNS monitors the send and receive timestamps, allowing computation of an approximate host response time. Figure 1.1 is a simplified schematic diagram illustrating a view of the VTAMAPPL configuration for a simulation for 10 terminals and three applications under test. The "VTAPX" units designate actual VTAM APPL statement(s) defined to the TPNS VTAM system(VTAMA). A one to one correspondence between the SLUs and the VTAM APPL statements is only required if the PLU(s) do not support parallel sessions. The dotted line between the two processors illustrates that TPNS and the application(s) under test can run on the same processor. However, if the simulation is a stress test, TPNS should run on a different processor.

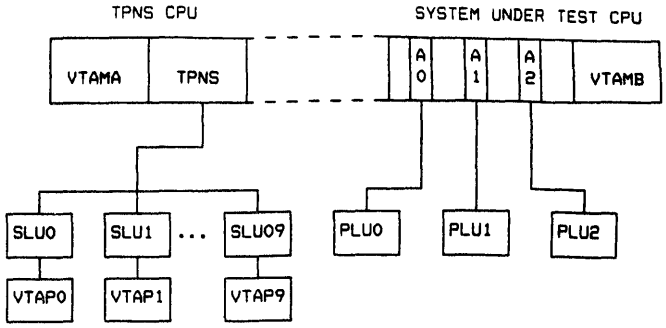

Figure 1.1

The specifications for a TPNS simulation are contained in the TPNS script. The script is made up of two primary components, the network definition(generally one per simulation), and the message text definitions (many per simulation). The network definition defines the environment for the test. This might include the attributes of the VTAM APPL ids, the attributes of the SLUs and PLUs(screen size, logical unit type, logmode entry, etc.), table data to be used in generating the input messages, the order in which the message text definitions will be executed, and overall parameters of the simulation(such as the default transaction think time). The message text definitions define the logic for generating the transaction input, testing the validity of the output, and controlling the flow of the test.

2. PERFORMANCE APPLICATIONS OF TPNS

The flexibility of the TPNS architecture makes TPNS suitable for a variety of performance applications. These applications include:

1. Stress Testing of Application or System Software
2. Performance Testing of Application Software
3. Performance Testing of System Software / Benchmark Creation
4. Functional/Regression Application Testing
5. Application Prototyping
6. Creation of an Expert System

---

[1] The views expressed in this paper are those of the author, based on his experiences using the TPNS product. They do not reflect the official policy of Duke Power Company.

[2] All performance related applications of TPNS discussed in this tutorial assume the VTAMAPPL configuration.

2.1 STRESS TESTING OF APPLICATION OR SYSTEM SOFTWARE

The objectives of a well designed application stress test are to determine the impact of a given application at peak arrival levels on the performance and capacity reserves of the system as a whole, and to determine if the application will adequately meet standards. There are two methods for meeting these objectives without the use of TPNS. The first method is to perform a stress test with the clients who will be using the system when implemented into production. Although this method does work on occasion, lack of adequate client training, lack of adequate test planning, and most importantly lack of test repeatability make this method prone to failure. The second method is to create an analytic model of the application under test with performance data from a similar production application, performance data from the test environment, or with an application modeling package, and model the impact of bringing the new or modified application into production. This method also can be very successful, at a relatively low cost, given the correct circumstances. However, for a totally new major application, a critical operational application, or a change in an environment with very low capacity reserves and margin for error, a well designed stress test performed with TPNS is often the best way to prevent major unexpected performance problems.

To ensure that the TPNS test actually simulates the production usage of the application, it is essential that the script be developed with the assistance of the application development and primary client areas. After thorough testing in a test environment, the stress test should be run in the production environment (production configuration, production DASD, etc.) in a stand alone mode. If the results from this test are successful(i.e., response of the application meets standards), an analytic model of the application should be built, and merged with a baseline model of the production system. If the resulting model demonstrates that the complete production environment will meet standards, a final stress test should be run with the application under test running with all other production workloads. The analytic model should then be calibrated with the arrival rates from the stress test. The model can then be confidently used for future capacity planning studies. This methodology applies equally to the stress testing of a new version of system software(operating system, subsystem, etc.), except the testing must take place in a standalone environment, and must simulate all significant workloads of the system/subsystem under test.

2.1.1 EXAMPLE. In this example, an application stress test was designed to determine if a newly developed corporate online payroll entry application could be successfully implemented into production within the service level specifications. The application was designed to run in the CICS 1.7 environment, using the DB2(primary DBMS) and ADABAS DBMS. The design of the application called for a peak transaction rate of 2 to 4 transactions per second from 250 to 400 terminal operators. The requirement that the entry of payroll data be completed within a short time window made tuning the response time of the utmost importance(the guideline was 96% of all transactions be completed with an end user response time of less than five seconds). The TPNS simulation called for the simulation of the entry of time sheets(one or more transactions for each employee), a summarization/balancing transaction, and a posting transaction. Performance issues discussed during the design of the script included concerns about possible delays due to the use of two DBMS systems, delays due to the possible overloading of an already loaded CICS Application Owning Region, and the possibility that the addition of this application would overload the cpu processor. Since this was the first major on-line DB2 production application to be installed, it was critical that a thorough simulation of the production environment be performed. These concerns identified the key points in the simulation design(simulation of a representative sampling of all data base files, simulation of the many entry formats, and a gradual increase in the transaction arrival rate over the duration of the test). Since the development of the TPNS script was performed by a performance analyst with no background in the application, close cooperation with the application team was essential. The primary impediment to the rapid testing of the script was conflicts between the TPNS script tester's need for a stable application environment and the application tester's need to make final changes to the application.

2.1.2 RESULTS. A dry run of the stress test was scheduled the night prior to the planned production test. Minutes after beginning the test, it was apparent that performance was unacceptable. Host response, that should be in the 1 to 2 second range, was averaging close to 10 seconds with as few as 10 transactions per minute. The problem was determined to be in the performance of some of the DB2 plans.[3] Changes were made to the DB2 plans, the application was rebound, and another dry run of the stress test showed that the changes were successful. The full production test was then begun, and gradually the transaction rate was increased to approximately 1.5 transactions per second. Suddenly, TPNS appeared to stop. Analysis of the TPNS logfile revealed that the application had returned an unexpected response, and TPNS had hung in a loop. Fortunately, the problem was quickly resolved, and the test was restarted.

Over the test period of almost an hour and thirty minutes, the number of simulated terminals was increased to nearly 200, at which point the one minute transaction rate was over three transactions per second. However, as illustrated in Figure 2.1.1, the transaction rate dropped significantly at several points during the test(indicating a serious performance bottleneck). Figure 2.1.2 shows a corresponding dramatic increase in response time at these same points. Although the response time was generally stable(except at the bottleneck points), it was clear that the application would not meet performance standards.

SAS code was developed to analyze the collected performance data from THE MONITOR FOR CICS(Landmark Systems Corp.). This analysis identified the following breakdown of the host response time:

TRANSACTION	DB2	ADABAS	RPL	MISC CICS
Primary Transaction	25-50%	40-50%	10-20%	10-15%
Average of Remaining Transactions	70%		25%	5%

From this data, three primary bottlenecks were apparent:

- o Delays due to DB2 processing
- o Delays due to ADABAS processing
- o Delays due to excessive CICS relocatable program loads(RPL)

---

[3] A DB2 plan is the control structure produced during the bind process and is used by DB2 to process the SQL statements required for execution of the application. The bind process includes compilation of the SQL statements, selection of the optimal access path, and output of the DB2 application plan.

Subsequent analysis revealed that considerable DB2 delays were caused by DB2 deadlocks resulting from locks being placed on an obsolete DB2 object; 50% of ADABAS delays were caused by duplicate opens and closes being performed on ADABAS accounting files; and the CICS RPL problem was resulting in considerable delays to the existing CICS workload. As a result of the information gained from the stress test the following performance recommendations were made:

- Remove the lock requests for the obsolete DB2 object
- Redesign the ADABAS routines to optimize the file I/O logic
- Set up a new CICS Application Owning Region for this application

Due to resource constraints, the ADABAS modifications were deferred. The other two changes were made and plans were readied for a second production stress test.

The results of this test were more encouraging. The peak transaction rate was consistently maintained between six and seven transactions per second (considerably higher than the estimated peak) with approximately 380 terminals. The host response of the most important transaction was consistently between 1.0 and 1.3 seconds. Some executions of the summarization transaction ran in excess of 30 seconds due to its selection of up to 5,000 DB2 rows. This was judged to be insignificant due to the low frequency of this transaction. During the execution of the test, the processor requirements of the application caused the processor to be consistently utilized at levels in excess of 100%, resulting in a significant backlog in the production batch and TSO workloads. A subsequent analytic model of the new production environment provided justification for the early upgrading to an IBM 3090/400 processor.

2.2 PERFORMANCE TESTING OF APPLICATION SOFTWARE

TPNS can be very useful in the identification of the component(s) of an application responsible for the highest level of resource consumption. This is especially valuable in an application such as PROFS where no response time data by transaction name is available. Scripting for this type of simulation is accomplished by coding several identical message text decks for the application. The decks are then altered to terminate at successively later stages in the deck. Subsequent analysis of the performance data will identify the component(s) in the application responsible for the performance problems. This technique was used in the "DW/370 vs. DCF" comparison described below.

2.2.1 EXAMPLE. In this example, the relative resource requirements of the two PROFS document text processors (DW/370 and DCF) are compared. The purpose of the simulation was to determine if the installation of DW/370 as an alternative document text processor would have a significant effect on the resource consumption of the PROFS workload. The values of several resource measures(transaction count, trivial to non-trivial transaction ratio, cpu time(virtual and cp), paging reads, non-paging I/O, working set size, response time, etc.) were collected to create a benchmark of the resource requirements of each text processor in a completely controlled environment. The script consisted of the PROFS input required to create or update, proofread, correct errors, review, print, and return to personal storage, one of three different documents(a 1½ page document, a 1½ page table, and a 5 page document) for both text processors. The script was designed using realistic think times and attempted to minimize the number of terminal interactions(use of the "ENTER" key). Each simulation benchmark (combination of document type, text processor, and text action such as create or update) was executed on a separate VM id to permit a clean analysis of the performance data. The computation of the resource benchmark was done by running the reduction and user classification phases of the IBM VM Performance Planning Facility(VMPPF) modeling software.

2.2.2 RESULTS The results of the simulation demonstrate that usage of DW/370 requires significantly more processor capacity, non-paging I/O, and considerably reduces the non-trivial to trivial transaction ratio(resulting in a corresponding increase in the number of non-trivial transactions). The increased resource levels are much more pronounced for the larger document(five pages) than for the smaller documents(1½ pages). Figures 2.2.1 and 2.2.2 illustrate the differences in processor and non-paging I/O(VIO) for the three simulated document types.[4] Although it was expected that DW/370 would consume more processor resources, the large increases in the non-paging I/O and non-trivial transaction counts were puzzling. To determine the cause of the unexplained resource increases, the TPNS script was modified by creating duplicate TPNS message text decks for the different benchmark simulations. Each deck was altered to terminate at a different point in the document conversation, to identify the resources required for each component. The simulation was rerun only for the long document, with unexpected results(Figures 2.2.3 and 2.2.4). The primary difference in resource consumption was in the document proofread and correction script(DW/370 consumed almost three times as much processor time and almost five times as much non-paging I/O as DCF). Finally the simulation was rerun with seeks analysis turned on. The results(Figure 2.2.5) again show that the proofread function was the primary performance bottleneck. The ratio of DW370 seeks to DCF seeks for the proofread/correction function was approximately 2.5:1 for the product mini-disks, but a whopping 27:1 for the user A disk.

2.3 PERFORMANCE TESTING OF SYSTEM SOFTWARE / BENCHMARK CREATION

TPNS can be successfully used as a vehicle for testing system performance tuning parameters. The major difficulty in this form of TPNS testing is the large number of workloads that must be simulated to create an accurate benchmark of typical system activity. One notable exception is a stand-alone VM system for office automation(PROFS). If a realistic benchmark can be created, the complete repeatability of TPNS can be used to study the impact of changing various system tuning parameters in a totally stand-alone environment.

2.3.1 EXAMPLE. In preparation for the installation of a new operating system for a production VM system (nearly 100% of usage is PROFS), a requirement was identified to perform a stress test on the new operating system, and create a performance benchmark, to assist in tuning the new operating system. The objective of the benchmark study was to design a script that when run would exhibit similar performance characteristics of the production system(in terms of processor utilization, paging/swapping, and non-paging I/O). Scripts were already available for several of the typical PROFS functions(document creation, calendar update, mail read, etc.). These scripts as well as several new ones were combined to form a PROFS benchmark script. The script included such features as realistic think times, wait scripts(to simulate periods

---

[4] For a more extensive analysis and listing of the results of the initial simulation, see reference [1].

of complete inactivity), and selection of the function script(open the mail, check calendar, etc.) based on the expected probability of that activity occurring in production. The completed script was run in a test environment with 50 PROFS ids in order to compare the processor utilization, non-paging I/O rate, and command rate per PROFS id with that which was occurring in the production PROFS system during peak activity. Based on the results of this comparison, new transaction think times were computed to allow for resource activity comparable to that expected for our production system 6 to 9 months from now. The final TPNS script was then run with 800 PROFS ids for a period of approximately 45 minutes under both the current and the new operating system. Based on the results of the test, initial tuning objectives were established. In the future, an expanded version of this benchmark script will be used to perform additional tuning, to predetermine the effects of the expanding PROFS community on the VM virtual storage constraint, to determine the break point(in terms of number of logged on users) of the GCS VTAM virtual machine, and to conduct other performance studies.

2.3.2 RESULTS. Available at presentation in December

2.4 FUNCTIONAL/REGRESSION APPLICATION TESTING

TPNS can be used in the application development functional testing process to ensure that all documented expected results are achieved. After all functional testing is complete, the functional test scripts can be modified and reused during the stress test phase, and whenever regression testing is required(operating system/subsystem changes or minor changes to the application). The major difficulty in this type of testing is providing the development staff with the required level of training to code the initial functional testing scripts. This difficulty can be overcome by the creation of a functional script generation program. The input for such a program would be the documented application expected results. The program would then output a runnable TPNS functional test script.

2.5 APPLICATION PROTOTYPING

It is possible to simulate the primary logical unit(the actual application) as well as the secondary logical unit(terminal input). Simulation of a PLU with TPNS provides the capability to allow a client to logon from any VTAM terminal and view the current version of the design of the application. Furthermore, the simulated primary logical unit can be used when developing the stress test script, so as to avoid conflicts between the development of the application and the development of the stress test script. This basic concept was used when developing a prototype of an "OMEGAMON Monitor Database" application that is described below.

2.5.1 EXAMPLE. The purpose of this example is to demonstrate the powerful capabilities of the TPNS prototyping concept, not necessarily to recommend the development of this particular example. This example demonstrates the methodology for the creation of an "OMEGAMON Monitor Database" application that was developed with the TPNS prototyping concept. The idea evolved during the development of several VM/PROFS performance simulations. The need was identified to document detail performance data from the OMEGAMON/VM (Candle Corp.) performance monitor over the duration of the simulations. This requirement was met by designing a script to logon a simulated terminal to OMEGAMON/VM, and logging the results to the TPNS log file. This script was then included in the actual VM/PROFS performance script to be run. Although this method permitted the retention of the desired OMEGAMON/VM displays for later analysis, the performance analysts viewing the simulation also needed to view the same displays. Although each analyst could logon to separate VM ids and invoke OMEGAMON/VM, this might result in a stress test of OMEGAMON/VM. It was decided that the prototyping feature of TPNS could be used to allow any analyst to logon to a TPNS simulated PLU which would display the last received OMEGAMON/VM status screen. This method would place no additional overhead on the system under test. The development with TPNS of a simulated PLU requires only a basic knowledge of TPNS scripting and a general knowledge of 3270 programming concepts(TPNS takes care of the SNA protocols of sending and receiving data between the simulated PLU and the actual terminal). An implemented version of this methodology was used during a benchmark test of a VM/PROFS system(described in more detail in section 2.3). An expansion of this methodology was used to build a prototype of a system-wide "OMEGAMON Monitor/Database".

2.6 CREATION OF AN EXPERT SYSTEM

The scripting features of TPNS that allow checking for application expected results make TPNS especially well suited for use in the rules testing phase of an expert system. The advantages of this concept are that an expert system for any complex software can be built by simply defining the rules base, providing a mechanism for collecting input(an ISPF panel, etc.), and coding the rules base within a TPNS script.

2.6.1 EXAMPLE. The purpose of this example is to demonstrate the broad concepts of producing an expert system from any existing software product that solicits input in a full screen mode. In this example, a prototype of an expert system for the IBM VM Performance Planning Facility(VMPPF) is described. VMPPF is software used for modeling performance and capacity planning configuration changes in the VM environment. VMPPF is quite adequate for occasional usage by an experienced VM analyst. However, for developing numerous models or for usage by an analyst with limited VM expertise, the use of an expert system would be very desirable. The primary objective for developing this prototype was to develop a methodology that would eliminate all repetitive procedures, encode the knowledge base within the system, and permit the development and production of the results for multiple models with a minimum amount of analyst interaction time.

A basic flow of the expert system is as follows:

Invoke the system under either TSO or CMS

The primary ISPF panel is invoked(Figure 2.6.1)

The ISPF panel allows for the selection of the desired model building/execution options for this execution of the expert system(panel options 1-4), which produces a TPNS table file to be used in simulating VMPPF.

The execution of VMPPF via TPNS is requested. This marks the end of the user interaction with the system until execution of the VMPPF software is complete.

The execution of the TPNS simulation is begun. TPNS will simulate the requests for tape mounting, input of all predetermined data for VMPPF, and use of the rules base for determination of all other input to VMPPF.

After all requested VMPPF models are computed and reports are generated, the primary ISPF panel is reinvoked.

The selection of display or printing of the previously generated modeling reports/graphics is made, and the requested information is provided.

The expert system is terminated.

Figure 2.6.2 illustrates the expert system flow:

3. GENERAL TPNS SCRIPTING DESIGN RECOMMENDATIONS

Determine the objectives of the test before any work is begun on the script. The TPNS scripting language is extremely flexible. If one understands the major concepts of TPNS scripting, practically any realistic testing scenario can be simulated. TPNS also supports an extremely open EXIT architecture for options that the scripting language does not support.

Design the simulation on a "macro-level" instead of on a "micro-level". In other words, determine what level of system activity should take place. Do not be concerned with the specific transaction mix(and specific input) of one terminal. This allows all terminals to execute one set of message text decks. Judicious use of path distributions and data tables will enable a script to simulate the proper transaction and data mix respectively.

Design as much **flexibility into the script** as possible. Designing a script with only one set of message text decks permits the addition of any number of terminals without defining additional decks. This design substantially minimizes the complexity of the overall simulation. Another method for adding flexibility into the script is controlling the simulation with one "Master LU" deck. The script is made flexible by coding all possible control actions in "ON EVENTS", determining which LUs should be affected by a given control action with one or more network/device counters, and specifying which control action is to be performed next by signalling the required ON EVENT from the console.

Design as many **self-checking and recovery** features into the script as possible. Considering the substantial investment made in the development and testing of the scripting process, it would be disastrous if the test failed for lack of one of these features(a definite possibility).

Build a script library, so that scripts and techniques that have worked successfully in one test, can be reused in succeeding tests. This is especially important if a benchmark of a production system may be desired in the future.

Only use the **script generator facility** if there is a good reason for doing so. Using the script generator facility causes the test designer to in most cases lose control of the content of the script(one of the primary advantages of TPNS). Also, use of the script generator facility limits the addition of terminals to the test (added terminals will be executing exactly the same transactions with exactly the same input data as defined in the captured script).

Monitor the results of the test with the normal application monitors. Although TPNS captures data that permits computation of an approximate host response time, its value may differ considerably from that computed by the application monitors(especially for VM).

4. SUMMARY

The effective use of TPNS in the CPE area has the potential for giving definite answers to questions that without its use are left to educated speculation and qualified answers. This tutorial has identified six major performance applications with examples, for the use of TPNS with the VTAMAPPL configuration. Specific recommendations for the effective design of TPNS scripts have also been provided. It is the hope of the author that this tutorial will provide the incentive for more CPE professionals to make use of the less traditional applications of TPNS in the solution of complex CPE issues.

I/O Tuning in the MVS/XA Environment

Rich Olcott
Schering-Plough Corp
3022 Jackson
Memphis TN 38151
(901) 320-2867

After a brief consideration of tuning strategies and MVS/370, we explore the major performance-impacting innovations of the IBM XA hardware and MVS/XA software. We then apply the general principles to specific cases in locating and correcting performance problems arising in MVS/XA-managed DASD and tape subsystems.

The phrase "I/O tuning" covers a multitude of activities and concerns, ranging from planning the acquisition and configuration of hardware to the correction of design flaws in an application program. All of these center on the fact that waits for I/O completion are the largest source of delay in most computer systems. Speeding up user response time generally reduces to eliminating unnecessary I/O and then making sure that the remaining activity proceeds as expeditiously as possible. IBM's introduction of Extended Architecture (XA) hardware and software have changed the way I/O delay is measured, and thereby have enabled I/O tuners to adopt new methodologies for managing their systems.

Systems tuners have developed three general strategies for determining what changes should be made to improve performance. Explicitly or implicitly, most practitioners use all three at different times. For lack of better names, we will refer to them as bottom-up, top-down, and middle-out. The bottom-up strategy depends on "Rules of Thumb", sets of thresholds which on the average separate satisfactory and unsatisfactory systems. For instance, one time-honored rule of thumb is that no path element between CPU and device should be run at greater than 30% utilization. A performance analyst using the bottom-up strategy might generate an RMF/370 channel report, scan the "%busy" column, see no numbers larger than 30, and conclude that the system was healthy during the interval covered by the report.

That conclusion is based on several hidden but system-specific assumptions. The first has to do with the Rule of Thumb itself, the second has to do with the report, and the third has to do with the system the analyst is monitoring.

The 30% rule derives from the M/M/1 queueing equations [1]. These equations describe the steady state of a system with a single server. Their solution allows us to calculate how long an arriving customer will have to wait for that server to finish with a prior customer:

$$QT = ST * U / (1 - U)$$

where QT is the average queued wait, ST is the average service time, and U is the server utilization, the average fraction of its time spent busy with a customer. (This equation makes certain assumptions about the customer and server behavior. Those assumptions appear to have about equal degrees of validity for both MVS/370 and MVS/XA so we won't go into them here.) The behavior of QT/ST is shown as the solid line in Figure 1. At low utilizations waiting times are small. As U approaches 1 QT approaches infinity. Despite the appearance of the graph, there is no "knee of the curve", no special point where a sudden rise begins. The location of the apparent knee depends upon the vertical scale used in making the plot. On a graph with equal horizontal and vertical scales, the function has a 45° tangent at U = 0 and rises with an increasing acceleration from there. However, QT turns out to be exactly half of ST when U = 1/3. Thus, the U = 30% rule attempts to keep the queue wait below half of the service time. As we shall see, M/M/1 queueing does not necessarily apply to MVS/XA DASD or tape.

The RMF/370 channel report, like the RMF/370 device report, conceals another system-specific assumption. RMF/370 [2,3] is a sampling monitor, activated at regular intervals. At sampling time, the I/O data collection routine checks the device and I/O control blocks, noting the current state of each. U for a device is calculated as the ratio of "busy" samples to total samples taken during a reporting interval. The problem is that the calculated U may be biased if the sampling interval is at all synchronized with the activity being measured. Consider the school child who believes that Teacher lives at school, because Teacher is in the classroom whenever the child checks. In a system as complex as a running MVS/370, it is difficult to assay one way or the other whether such a bias exists.

The third assumption in the Rule of Thumb strategy is to assume that if the over-all system appears healthy, then all the applications are delivering acceptable performance. When it is put so bluntly, the risk in this assumption is immediately apparent. It is easy to write a scenario in which, for instance, a production PROCLIB and a CICS-active ISAM file are on the same DASD volume as a page data set. When a CICS region encounters a page fault, all of its activity ceases until the fault is resolved. If fault resolution must wait until completion of a long PROCLIB directory search or an ISAM overflow area update, then many CICS users will experience poor response time even if the DASD volume in question delivers nominal performance.

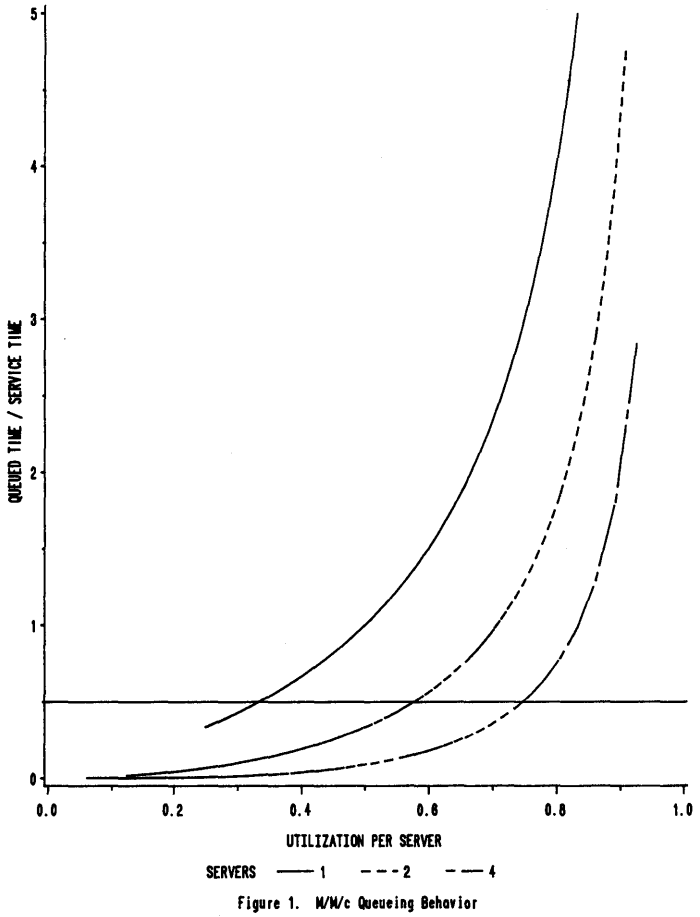

Figure 1. M/M/c Queueing Behavior

The bottom-up strategy concentrates on the device statistics: a performance problem is defined to exist only when some device-level Rule of Thumb is being violated. In contrast, the top-down strategy defines a performance problem in terms of objectively measured service level goals: "Is the 90th percentile TSO trivial transaction response time less than our published threshold?" If so, there are other projects to work on. The performance analyst starts studying the I/O subsystem only if some component of the installation's workload is not fulfilling its goals, and then only if measurement shows that I/O is the major source of delay.

The middle-out strategy attempts to finesse performance problems before they occur. The heart of this strategy is a model of the I/O subsystem, built from known device characteristics and expected workload levels. The model is used to calculate expected service delivery at the application level. If the modeled service levels do not meet the installation's service goals, the I/O subsystem is re-configured on paper (or silicon) until goals are met, at which point the modeled subsystem is translated to real devices and cable connections. The model's use is not over, however. One of its by-products is a set of expected device performance statistics. These statistics then become installation-specific Rules of Thumb. Significant deviations between measured and modeled device and path element activities are danger signals, to be investigated and addressed before application-level performance problems appear.

A strategy is no better than its implementation and the quality of the supporting quantitative data. "You can't manage what you can't measure", and conversely, how you manage is determined by what your measurements represent. The introduction of XA hardware and MVS/XA software have changed the implementation of all three strategies by changing the information upon which they depend.

XA Hardware Innovations

The most dramatic innovation in XA hardware [4] is undoubtedly the 2 GB virtual address space. The Dynamic Address Translation facility ("DAT box") transforms a virtual address to a pointer referencing a real main storage location. An XA DAT box can handle a maximum virtual address 31 bits wide, giving an addressable range 128 times larger than the S/370 16 MB maximum. However, this change's impact on the I/O subsystem has been minimal, reflected mostly in an increased load on the paging volumes.

The other major XA innovation [5] has had a much greater effect. S/370 I/O is managed from the CPU. Channels are directly attached (logically and physically) to the central processor. CPU time is spent choosing a path for each I/O request, adjudicating contention for path elements, monitoring I/O request progress, and recovering from errors. The XA architecture places a dedicated subsystem between the I/O equipment and the CPU. The internal structure and nomenclature of this channel subsystem (CSS) vary with the hardware. The CSS contains one or more microprocessors and serves as the connection point for all I/O cabling. Microcode running in the microprocessor(s) has taken on all of the above responsibilities for I/O management. The host operating system need only pass an I/O request to the CSS and then accept an interrupt after the CSS has completed the indicated transfer to or from main memory.

The most important implication of this architectural change appears when we look at contention in the I/O subsystem. Consider the cabling diagram in Figure 2. Looking downstream, the CPU or CSS communicates through a channel [*] to a DASD control unit (CU), which can manage up to four strings of DASD devices. Each string contains up to 8 actuators and is under direct control of a head-of-string (HOS). Looking upstream, the HOS contains a string-switching feature so that connections can be made to two CUs. Similarly, the CU has a channel-switching feature that allows it to connect to up to four channels.

Contention arises because a transmission must gain exclusive control over an entire path (channel, CU, HOS) between CPU (or CSS) and device. None of the path elements is able to support transmission of multiple control or data streams, in S/370 or XA architectures. Suppose a system needs to read a block from DASD. For the moment we simply assume that the resident operating system has already ensured that the device is not already busy. The I/O's lifetime begins with the outbound transmission of positioning information to the device. If any intermediate path element (CU or HOS) is busy with another I/O operation, the attempted transmission is thwarted. Our read request must be queued for retry at a later time.

In fact, the exposure to path contention occurs at least twice for each DASD I/O request. Because of the channel contention problem, all current S/370 and XA rotating-media devices support a protocol called Rotational Position Sensing (RPS). RPS allows the device to disconnect from the channel during periods of mechanical delay, thus freeing at least some of the path elements for other work. No freedom comes free, however. When the device is ready to transmit the designated block, it must gain control of a path back to the central system. If some intermediate path element has become busy on another I/O during the interval since disconnect, the reconnect fails. Again the request is queued for retry, but in this case the retry cannot occur until the platter completes a full rotation and is again positioned properly to read the desired block of data. We have just witnessed an RPS miss.

Herein lies the I/O advantage of XA over S/370. Recall that S/370 channels report directly to the CPU. S/370 software identifies each outstanding I/O with the channel upon which it started. S/370 architecture requires that all the subsequent activity for that I/O (initial responding interrupt, any necessary redrive activity, initial data transmission, and any later command and/or data transmission) take place via the same channel. S/370 upstream I/O thus fits the definition of a single-server queueing system, no matter how many channels physically connect the device to the CPU.

XA's introduction of the CSS changes that picture. The CSS is able to manage I/Os at the device level (see below). A reconnect can exploit any available path from the device back to the CSS, not just the path used to initiate the I/O. In terms of queueing theory, the reconnect follows M/M/c statistics (where c is the number of servers). In an M/M/c system,

$$QT = ST * C(c,U) / (c - U)$$

where C(c,U) is Erlang's formula for the probability that a new customer will find that all c servers are busy if the average server is U/c percent busy. The dashed lines in Figure 1 show

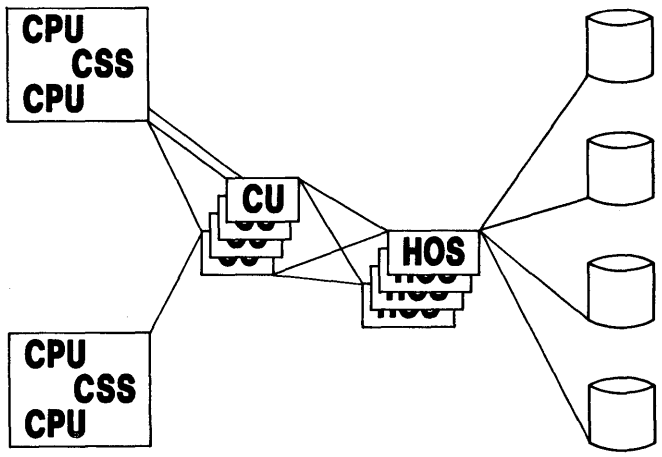

Figure 2. Typical DASD Cabling Diagram

---

* - IBM uses "channel" to refer to the S/370 physical and logical connections between CPU and control unit, and "channel path" to refer to the XA physical connection alone. We will use "channel" for both architectures, at the risk of losing this subtle distiction.

the behavior of QT for 2 and 4 servers. It is clear that XA's Dynamic Path Reconnect (DPR) capability has significantly eased constraints on path element busy for DASD. The XA equivalent to the S/370 30% path element Rule of Thumb can be as high as 70% for equivalent performance. Note well that the device itself is a single server in both architectures. The 30% device Rule of Thumb is unchanged.

Another important implication of the CSS architecture has to do with I/O measurement. Recall that RMF/370 is a sampling monitor, counting I/O requests but estimating time spent satisfying them. The I/O-dedicated resources in the CSS can measure delays and active times directly. For an analogy, consider measuring airplane in-flight time. The S/370 method would start with more-or-less regular satellite photos of a sample region. Count planes in the air in each picture. The estimated flight time is is the total number of in-air images, times the duration of the sampling interval, divided by the total number of flights as determined by a separate census. The XA equivalent would be to have each airport's control tower log the take-off and arrival time of each flight.

The XA I/O management subsystem is organized around a set of control blocks that interface mainframe software and CSS microcode. Each I/O request is represented by an Operation Request Block (ORB), and each interrupt by an Interruption Response Block (IRB). The subchannel is the CSS microcode's image of the device. Each unique device is represented by a Subchannel Information Block (SCHIB). The SCHIB contains, among other things, a list of paths that service this device, an indicator if timings are to be kept for this device, and a pointer to the device's Channel Measurement Block (CMB).

We need one more definition. Recall that the S/370 channel is the highest bottleneck in its I/O architecture. If the channel is busy, than the S/370 I/O request must wait until the channel is free. The most efficient way of managing the wait is to construct a FIFO queue of I/O requests against each channel. The mainframe software does this by maintaining what in MVS/370 is termed the Logical Channel Queue. XA has no channel per se, or rather has so many that they are rarely the bottleneck. The new heir to that throne is the CU: if the CU is busy than an XA I/O request must wait until the CU is free. Again the solution is a FIFO queue, this time headed by the set of control units that can connect to a device, or better yet, a common set of devices. We have just described the Logical Control Unit (LCU): the queue formed in the CSS to represent each set of devices that shares a common set of physical control units.

We can best understand subchannel operation by following an I/O request [6]. Activity at this level starts when the mainframe software issues a Start Subchannel (SSCH) instruction whose operand is a pointer to the SCHIB for, say, device 5A2. The subchannel (really, the combination of general microcode routines and the specific SCHIB) starts a timer and places the ORB on a queue of requests destined for 5A2's LCU. This first timer measures the Pending time, the delay until the request gains access to a specific channel path. At that point, the Pending time is recorded in 5A2's CMB and a second timer is started. This timer measures the Connect time, during which control information and data pass along the channel path. The Connect timer also runs during error correction activity. For some devices, function may allow or require the device to relinquish path control during the period that the ORB is being serviced. Whenever that occurs, the Connect timer is stopped and a third timer, for Disconnect time, is started. When path control is regained, Disconnect is stopped and Connect is restarted.

Activity continues until 5A2 signals Device End, signifying the completion or suspension of the ORB-specified operation. The subchannel stores the accumulated Connect and Disconnect time totals in 5A2's CMB, fills in an IRB, and passes an interrupt back to the mainframe software. Some processor models go so far as to record separate total delays for each level of path element. In principle, then, the software is aware of the exact amount of time that each I/O spent waiting for a path, transferring control or problem data, and holding a device but not doing data transfer.

There are some data integrity problems in the CMB interface. Each of the accumulators (Pending, Connect, and Disconnect) can overflow during the servicing of a given I/O. The overflow threshold varies with the processor class; the limit for 308x equipment, for instance, is 8.3 seconds during any single channel program. However, the hardware system only detects and reports on Connect and Disconnect overflows; reported Pending time measurements should always be treated as lower limits on the true value.

MVS/XA Software Innovations

All of the aforementioned activity takes place at the hardware and microcode levels, available to any program or operating system running on an XA processor. How does MVS/XA in particular exploit the XA CSS architecture and measurement facilities?

We have already described the advantage obtained from DPR, which reduces the likelihood of DASD RPS miss by increasing the number of paths from the device back to the host. We have also alluded to the potential advantage to be gained from offloading much of IOS's processing load to the CSS. We should note the relief of a constraint to I/O subsystem growth. The S/370 architecture defined the device address as a one-hex-digit channel-id followed by a two-hex-digit sequential unit number. In effect, this limited the S/370 I/O subsystem to 16 addressable channels, each with a maximum of 256 units. The XA architecture has removed the channel-device ratio constraint entirely and its almost-4-hex-digit device number in principle allows a maximum of 32K devices.

XA's direct measurement of I/O timing has changed the complexion of MVS/XA system measurement tools and has altered strategies for using them. The major art in using MVS/370's tools was in tracing state percentages and EXCP (EXecute Channel Program) counts back to delay sources. In MVS/XA, we can look at the delays themselves, because each timing measurement corresponds to a unique set of delay causes. We will return to this point for specific device types after considering the MVS/XA tools themselves.

The heart of the MVS/XA I/O measurement subsystem is the CMB, the interface between the CSS microcode and the mainframe operating system. The CMB's are constructed by the System Resource Manager (SRM) at IPL time. SRM automatically builds enough CMBs to account for all DASD and tape devices declared in the active IOCDS. If the analyst wishes to track times for other device classes, they must be requested using the CMB= parameter in the IPL-time IEASYSxx PARMLIB member. The device(s) of interest must be attached to a block channel: byte multiplexor channels are not equipped to measure or report device time data.

The System Management Facility (SMF) [7] software provides data on resource utilization by each batch job, TSO user, and started task. Its complete XA benefits are only available for workloads subject to Type 30 recording, and then only for devices for which CSS measurement is active. The Type 30 record for a step contains connection time data at two levels. At the lower level, the record contains one EXCP section for each unique device allocated to a DDNAME, whether by JCL or dynamically. The section contains several fields that relate to that device, including the IOGEN/MVSCP-derived device number and the allocated DDNAME. If multiple datasets are allocated under a common DDNAME to a single device, the quantitative data are consolidated into a single EXCP section. Three fields describe the I/O that took place to the device:

- SMF30BLK - the number of blocks transferred to/from the device
- SMF30BSZ - the largest blocksize observed for the dataset
- SMF30DCT - the device Connect time for that I/O

Much of performance management consists of searching for anomalies, and here is our first opportunity. The product of SMF30BSZ and SMF30BLK is an upper limit on the number of bytes transferred, equal to the byte count for fixed and VSAM record formats. The product of Connect time and channel speed should also be equal to the number of bytes transferred. If the latter measure is significantly larger than the former, we may have an indication of serious inefficiency in the I/O for that dataset. We will return to this point below.

Field SMF30TCN in the I/O Activity section contains the total device Connect time for all I/O (except paging I/O) done on behalf of this step. The difference between SMF30TCN and the sum over SMF30DCT thus represents I/O to datasets that are not explicitly device-allocated: linklist libraries, security dataset, catalogs, JES spool, etc. It also includes I/O done by OPEN/CLOSE (for instance, to VTOCs or tape labels) that does not result in transfer of dataset content. Note that neither paging I/O nor VIO is included in SMF30TCN or SMF30DCT totals: the corresponding physical I/O is done by the Auxiliary Storage Manager and is not charged to individual address spaces.

There is another, very important datum in the Type 30 I/O Activity section. Bit 0 of field SMF30MFL is set to 1 if channel measurement was disabled for any I/O (DD or system level) in this step. There is no indication as to which individual statistic is in error. Thus, any records with this bit set should be rejected in preparing an I/O report.

Resource Measurement Facility (RMF) is the other major IBM-supplied MVS performance tool. Originally written to feed performance data to the SRM, it is the central source for system-level utilization and delay data. Other vendors have produced similar monitors, all of which use the same underlying hardware facilities and produce similar sets of data elements. They compete on the output side, vying for the analyst's favor on the basis of summarization strategy, ease of use, and presentation formats. We will describe only the IBM product here, but the analyst would be well-advised to consider the market before settling on any particular product.

There are actually three different RMF monitors that can operate in a running MVS/XA system. Monitor I, still closely coupled to the needs of SRM, generates SMF Type 70-77 records as a by-product. The records are generated periodically and contain summaries (usually totals) of system resource statistics. Record Types 73 (Channel Activity) and 74 (Device Activity) are the most relevant to our discussion here. They are used by the RMF Post Processor to inform the corresponding RMF reports. They can also be reduced by other programs to generate custom reports or load a database for ad hoc queries.

Monitor II is used for close scrutiny: traces of specific data elements for short periods, snap-shot reports of system status, and on-line queries. Monitor II is an offshoot of the Monitor I facility, and there is a good deal of overlap in their orientation and the data elements they present. In particular, both Monitor I and Monitor II track device activity in terms of I/O rates and mean Pending, Connect and Disconnect times. Furthermore, both support an additional statistic that cannot be measured by the CSS: I/O queueing time within the mainframe.

We have said that Pending time represents path wait. However, that wait only begins when MVS's I/O Supervisor (IOS) passes the ORB to the CSS. An I/O request's life cycle passes through several stages before CSS ever sees it. The application program first issues, say, a GET request against a particular dataset. The GET request is directed to Access Method (AM) software which builds a channel program designed to satisfy the request. The AM uses EXCP (or an equivalent call) to pass the channel program to IOS. IOS will connect the channel program to an ORB and notify CSS, but only after issuing a Test Channel (TCH) command and checking the device's Unit Control Block (UCB) to see whether or not the channel or device is already busy to this processor. There is nothing to be gained by overloading the CSS queues. If IOS knows that the request will encounter a busy condition downstream, IOS queues the request in the mainframe until the blockage is cleared. This additional delay, IOS Queue time, is measured by sampling the IOS queue length and then calculating from Little's Law:

$$IOSQ = \frac{\text{(Mean sampled queue length)}}{\text{(I/O rate)}}$$

Monitor III adopts a different perspective on the system workload. The philosophy implicit in Monitors I and II is to concentrate on the system's resources, diagnosing delays by asking which resource is overcommitted and then which tasks are competing for that resource. Monitor III concentrates on the workload itself. The monitor periodically samples the state of each task in the system. If the task is in a wait state, the monitor records what the task is waiting for. The data are summarized once each reporting interval (commonly either 60 or 100 seconds). The entire matrix (task by delay source by report time) is maintained in virtual storage for online reference. Monitor III's presentation side is designed to offer quick answers to fire-fighting questions like, "What workload is suffering the greatest delay?" and, "Which tasks are competing with job BVSD4000 for DASD volume MVSA01?"

Before leaving the software tools area, we should mention several measurements that are not XA-specific but are no less important in the XA environment. The EXCP count is a still vital datum. Technically, EXCP is but one of several I/O drivers supported by IOS. ASM, VSAM, VTAM, OLTEP, JES3, and program fetch all have their own specially-tailored interfaces. Nevertheless, each invocation of IOS is referred to as an "EXCP".

Because I/O quantification in earlier versions of OS was limited to EXCP counts, a "one EXCP, one block" interpretation has arisen. That interpretation is not necessarily correct and has generated some confusion. Channel programs can be of arbitrary complexity: one EXCP can result in the transfer of one, several, or no blocks of data. Recent versions of IOS have attempted, unsuccessfully, to clarify the situation. For the sequential access methods (QSAM, BSAM, BPAM), true block counts are reported as "EXCP counts" and true EXCP counts are not reported at all. This explains why attempts to tune an application by revising the channel programming (specifying an increased buffer count, for instance) seem to have no effect. There may indeed be a reduction in IOS invocations, but the transferred block count remains the same.

The EXCP ambiguity is the reason that one should use the "Connect time per EXCP" ratio cautiously. The ratio may be high because of very "expensive" I/O, but it may also be biased in either direction by non-transfer EXCPs. High Connect time may be due to error correction activity for the device or any other device-specific activity that elicits no data transfer but yet does not release the path. No-data EXCPs may be used to release a RESERVE, force a rewind, or carry out some other device management task that must be directed from the mainframe.

The other important non-XA I/O metrics are network-oriented. Unfortunately, network measurement is an even less mature discipline than mainframe device measurement. The ideal metric is one that can be economically and reliably evaluated, easily understood, and readily compared to some straightforward measure of capacity. None exists.

Part of the problem is that "the connection" is complex, possibly comprising communications and terminal controllers, protocol convertors, multiplexors and modems as well as wires and microwave beams. Each component of "the connection" is a potential bottleneck. Part of the problem is that "the message" itself has different sizes when viewed by different levels of the system. Each layer may use compression techniques to reduce data length, may slice the message into smaller packets or merge multiple packets into longer transmission units, and may add header and trailer

information for message routing and identification. Part of the problem is that network connections have much poorer reliability than do local connections. Message integrity requirements have forced protocol designers to work with short transmission blocks and several layers of redundancy, all of which reduce effective connection capacity. Part of the problem is that network management itself requires network time for its function. All network protocols include provision for control transmissions before and after data transmissions.

Part of the problem is historical. "Growth at need" of existing networks have led to a variety of protocols and message structuring techniques used even within a single network discipline. Consider the range of "LUs" available under VTAM, for instance, and ponder on the measurement consequences of a gateway between a bit-stream system like SDLC and a packet-oriented system like X.25. Part of the problem is cultural. Computer communications networks are at the interface between two industries that each have developed tightly reinforced ideas of "the right way" to do things. Part of the problem is instrumental. Even given satisfactory metrics for message size and transmission channel capacity, there is no current technology for accurate measurement of transmission time.

XA itself has no solution for the problems. Many of the phenomena that affect network capacity are beyond the purview of any single CSS or set of CSSs. My purposes in raising the point are to warn the new XA user that networks are still untamed, and to encourage those who are seeking solutions.

System-level I/O Tuning Facilities

Before turning to the treatment of specific device types, we should note several I/O-related system-level parameters that are either new or enhanced in MVS/XA.

I/O in S/370 (classic and XA) is an asynchronous process. The CPU passes a channel program to the I/O subsystem and then takes up other business. The subsystem posts an interrupt to the CPU when the I/O requires the CPU's participation. Any deviation from a one-to-one SSCH-to-interrupt relationship is an error. A waiting I/O that does not receive a timely response is said to be suffering a missing interrupt. A device that generates repetitive unsolicited interrupts is displaying a hot I/O. Both types of errors have performance impacts. A missing interrupt stops the application that is waiting for the I/O in question. Responding to the repeated challenge of a hot I/O may so dominate the CPU that no other work is accomplished.

IOS contains a subsystem, the Missing Interrupt Handler (MIH), dedicated to detecting and coping with both types of error. MVS/XA's MIH covers a wider variety of phenomena that does MVS/370's. Furthermore, MVS/XA's designers have allowed the system tuner to specify parameters that control MIH's vigilance. After all, some device types have inherently slower responses than others. Why spend resources recovering from a missing interrupt that is tardy but not AWOL?

The parameters may be placed in a new PARMLIB member, IECIOSxx [9], selected by an IOS=xx start-up parameter. For missing interrupts, one can specify device-specific surveillance intervals. If the device is pending at both the start and end of an interval, and its I/O count has not changed, then a missing interrupt is diagnosed and MIH logs the event and attempts to recover, for instance, by redriving the attempted I/O. For hot I/O's, the system programmer is invited to specify how many unsolicited interrupts over what interval are to be considered "hot" for each general device type, and what automatic actions should be taken in response to the first and later misbehaviors.

There is an interaction between the MIH expiry time and the accuracy of reported Pending times. SRM has taken advantage of the fact that there are two timers measuring I/O delays. The MIH timer runs in the mainframe and senses when any particular I/O has lingered beyond the limits prescribed in IECIOSxx. The Pending timer runs in the CSS and can overflow. Because the MIH subsystem inspects each the state of each device once each MIH interval, SRM treats the MIH timer interval as an effective maximum Pending time. The RMF/XA-reported Pending times have been adjusted to include MIH-sensed outages, but note that the resolution of that adjustment is limited by the MIH interval for the device in question.

I/O load balancing operates somewhat differently in MVS/XA, but retains the same basic concepts as the MVS/370 version. SRM has three load balancers, for I/O, CPU, and real storage. Each attempts to ensure that its particular resources are properly loaded. Early versions of the I/O balancer simply considered the overall usage of the I/O subsystem. Later versions keep separate accounts for subsets of the total activity. MVS/370's load balancer subsets by logical channel, defined as the set of devices that share a common set of physical channels. The busy-ness for a logical channel is measured by the fraction of its I/O requests that have been deferred because of physical channel busy. If any logical channel %busy exceeds an installation-specified system-wide threshold, then the load balancer looks for the heavy users of the devices on that logical channel. The load balancer then recommends that SRM swap-out that user or users.

MVS/XA's I/O load balancer [8, chapter 5] is very similar. Of course, "channel" is a non-word in XA so one speaks instead of physical and logical channel paths. From the tuner's point of view, SRM's "logical path" is identical to IOS's "logical control unit". MVS/XA logical path %busy is calculated from measured connect times rather than request deferrals. The truly novel element in MVS/XA's I/O load balancer is separate treatment of logical paths serving tape, DASD with dynamic reconnect capability, and DASD without dynamic reconnect. MVS/XA has recognized that the performance of the three device classes respond differently to a given level of channel utilization. Each class of logical paths has its own algorithm for calculating path %busy and its own overload threshold. The algorithm parameters are set out as a new set of keywords in the active IEAOPTxx member of PARMLIB.

Selective enablement is SRM's subtlest response to the innovations in XA architecture. The placing of CSS between CPU and peripherals broke the bond between I/O request and channel and thereby led to DPR. It also broke the bond between I/O request and CPU. There is no longer a requirement that the interrupt be serviced by the CPU that issued the I/O request. Consider the activity that must occur when an I/O interrupt is presented to a CPU running problem code. First, the status of the currently running task must be saved. The current contents of the high-speed cache(s) and the instruction pipeline must be flushed. The high-speed cache must be loaded with the code to be executed in response to the interrupt. The new instruction stream must be started through the pipeline. Machine cycles are stolen while the CSS accesses real storage for data transfer. First-level interrupt handling (FLIH) code and possibly some other routines must run before interrupt disabling can be released and control returned to the dispatcher. Meanwhile, some of the first application's favorite virtual storage may be paged out before the application regains control of the CPU.

Now consider the benefit to be gained in a multi-processing complex if one CPU services all the I/O interrupts. On the one hand, the I/O server spends a higher fraction of its time in IOS code and therefore is less liable to context switching. On the other hand, the other CPUs are also less burdened by context switching so a higher fraction of their time is spent in problem state. Everybody wins.

The situation as described would dedicate 50% of a dyadic processor to interrupt servicing, clearly an untenable strategy. The XA SRM provides a dynamic control instead, based on IOS's use of the Test Pending Interupt (TPI) instruction. IOS plays the odds by issuing a TPI just prior to

the end of its FLIH routine. If another I/O interrupt is waiting, IOS can return to the top of FLIH and service that interrupt with no context switch. The SRM selective enablement algorithm responds to the fraction of all interrupts that are serviced by this TPI tactic. If the fraction is too low, then too many processors are doing I/O servicing; SRM refuses to pass any more I/O interrupts to one of those processors. If the fraction is too high, then too many interrupts are kept waiting for service; SRM makes another processor eligible for I/O interrupt activity. The installation defines "too low" and "too high" in the CPENABLE= parameter of the active IEAOPTxx PARMLIB member.

Application to DASD

DASD I/O management is the most mature CPE discipline. The waits within the DASD subsystem are well understood, instrumentation is in place and dependable, and the literature [10] and the marketplace provide bridges between symptom and treatment.

Refer again to Figure 2 and recall the operational definitions of:

IOSQ time - delay waiting for control of the UCB.
Pending time - delay in the CSS waiting for control of the path.
Connect time - time spent transferring control information or data, or error correction time.
Disconnect time - time during which the device is dedicated to an I/O request, but not connected to the CSS.

How is the tuner to translate reported wait times into recommendations for action? Let us first describe each in terms of specific DASD device and path activities. We can then turn to tuning strategies.

First a rapid review of DASD operation in S/370. A simple DASD channel program might be made up of the command sequence "SEEK, SET SECTOR, READ". For 3350 and earlier technologies, each of these commands must be transmitted separately. The CSS-to-device link is connected for the SEEK and then disconnected. The DASD actuator moves to the requested track. The link is reconnected for SEEK success acknowledgement and SET SECTOR transmission and then disconnected once again. When the platter has rotated to the proper sector, the link is reconnected yet again for READ command trans-mission and data transfer, followed by a final disconnect. For 3380 (and, one supposes, later) devices, the SET SECTOR command can piggyback on the SEEK transmission, thus avoiding a reconnect delay exposure.

The low-level logic in the hardware includes substantial error detection and correction capability. If an uncorrectable error is detected in any step of the I/O cycle, the CSS connects to the device and steps through an extended retry procedure until either an error-free transmission is completed or a repetition threshold is exceeded. There is a sustained connection to the device throughout this procedure, so Connect time is accumulated and the path is unavailable to other transmissions until it completes.

DASD Connect time is thus made up of protocol time for each connect and reconnect, command transmission time, data transmission time, and error correction time. Connect time is more important as a performance determinant of paths than devices. For a single DASD I/O operation, the Connect time is often less than 10% of the response time. However, a higher path element's utilization is the sum of the Connect times for all transmissions through it. A CU managing 8 devices, each of which is connected 10% of the time, is itself 80% busy.

DASD Disconnect time is mainly attributable to reconnect path delay and waits for mechanical events (SEEK completion and platter rotation). As we have seen, DPR has essentially eliminated reconnect path delay. For reasonable path utilizations, reconnection waits average 10% or less of the delay for each of the mechanical waits.

DASD Pending time is pure path contention. An I/O starts accumulating Pending time when the CSS first accepts the corresponding ORB. Pending time stops accumulating when the first connection to the device is accomplished. Along the way, the request may have to wait for access to the channel path, to the CU, and to the HOS. Each looks like a M/M/1 server, extending the response time by a factor of [U / (1 - U)], where U is the fractional utilization of the corresponding path element. The U for the channel path and CU are directly calculable as

$$U = \frac{[\text{SUM (Connect times)}]}{\text{(Measurement duration)}}$$

where the summation is over all I/O using that path element during the measurement interval. HOS utilization is a tougher nut. Recall that an S/370 CU may contain a channel switch that allows upstream connection through up to 4 channel paths. There is no requirement that all four paths lead to the same system. If in fact they connect to different systems then the CU, the HOS, and the devices behind it are said to be "shared" among those systems.

Sharing DASD leads to some problems in system measurement and data management [11]. One must be especially wary of write integrity exposures. Suppose, for instance, that a device is shared between two systems. TSO users in each system are running a common application that updates records in a file on that volume. If both users happen to access the same block of data, the second one to rewrite the block will overlay the updates made by the other user.

S/370 and XA architectures address this exposure with the RESERVE and RELEASE channel commands. When a system issues the RESERVE command against a device, all other sharing systems sense that device to be busy at HOS. That condition persists until the holding system issues the RELEASE command. In MVS/XA, Pending time includes delays waiting for a device RESERVEd by another system. HOS U must thus include both Connect time (from all sharing systems) and that portion of Pending time that is actually RESERVE-but-idle time. Unfortunately, the latter is not directly measurable. The closest equivalent is a field in the SMF Type 74 record, SMF74UTL. This field reports "dog in the manger"-hood: the sample count for which the reporting system had RESERVEd the device but had no outstanding I/O against it. The analyst has the task of calculating

$$\text{HOS } U = \text{SUM}\left(\frac{\text{SUM (Connect times)}}{\text{(Measurement duration)}}\right) + \text{SUM (SUM [(SMF74UTL) / (SMF74SAM)])}$$

where the inner SUM is over all devices on the string, and the outer SUM is over all RMFs reporting on the string. Of course, U for a shared CU must also be calculated by double sums, but that expression does not require the terms in SMF74UTL.

IOSQ time is peculiar to sharable devices. A DASD device is sharable because it can service one application's requests independently of another's. However, that sharing is really serial control, not concurrency. The actuator arm cannot move in two directions at once. IOS recognizes this limitation by queueing I/O requests against a device or path it knows to be busy, giving rise to IOSQ time. Hence, IOSQ time represents competition within a single system for a given device or path. The analyst can easily diagnose the difference from the IOSQ times alone. If many devices on a path show high IOSQ time per SSCH, it's a path problem; if one device does, it's that device's problem.

Armed with an understanding of the meaning of the reported times in the DASD context, we can turn to their application in tuning. The bottom-up strategy, remember, starts with the assumption that if all the device statistics look good ("happy numbers"), then the system is probably working well. What RMF "happy numbers" apply to DASD in an XA environment? How should one approach an RMF Direct Access Device Activity report?

Dev Num	Volume Serial	LCU	Device Activity Rate	Avg Resp Time	Avg IOSQ Time	Avg Pend Time	Avg Disc Time	Avg Conn Time	% Dev Conn	% Dev Util	% Dev Resv	Avg DS Open

Figure 3. Direct Access Device Activity Report

There are at least as many ways to read an RMF report as there are people willing to tell about it. Some authors [12, 13] have developed extensive lists of threshold numbers for different devices and situations. I prefer to scan the report as a whole, simply looking for numbers that are out of line with their neighbors. After all, the odds are overwhelmingly against an entire DASD farm being uniformly out of tune. Usually the bottleneck volume or string will advertise its presence by numbers that stick out like a sore thumb. The tuning problem then reduces to understanding the behavior of that volume or string and then taking appropriate action.

For example, consider the partial report in Figure 3. The figures worth noting are the IOSQ time of SYS001, the Connect time of LIB100, and the Pending times of the entire 860 string (compared to the farm average, 0.4 msec). The Disconnect times are also a bit high for 3380 volumes. As it happens, SYS001 contains a very popular catalog and LIB100 is mostly batch program and PROC libraries. The SYS001 IOSQ time represents application and TSO allocation activity; the tuner's recommendation was to split the catalog across two volumes.

Long connect times on LIB100 are the result of extended SEARCH KEY EQUAL operations against PDS directories, combined with FETCH's use of chained scheduling to transfer a multi-block load module with a single EXCP. The question is, do these long Connect times lead to a performance problem elsewhere in this system?

Apparently they do. Notice that LIB100 is on the string with the long Pending and Disconnect times. LIB100's long connections have so tied up the HOS that I/O to the other volumes is being impeded (the "skew effect"). The effect is not large, yet, but could grow. That observation leads to a recommendation that the datasets on LIB100 be spread over several strings.

The top-down strategy [14] views performance from the application side. Figure 4a shows a summary of SMF data averaged over several runs of the SQRC jobstream. SUB_WAIT is the interval between the end of one job in the stream and the submission of the next. INITWAIT is the delay between submission and acceptance by a JES initiator. ENQ_WAIT is the delay due to ENQ interference. ALC_TIME is time spent in allocation, either tape drive assignment or DFHSM dataset recall. CPU_TIME is the total TCB and SRB time. DASDTIME and TAPETIME are the total durations of I/O to the named device types, estimated by EXCP count multiplied by system-wide DASD and tape response times. (XA Type 30 recording provides Connect times but not response times.) ???_TIME is the difference between the observed execution time and the sum of ENQ_WAIT, ALC_TIME, CPU_TIME (times an average MPL for that time-period), DASDTIME, and TAPETIME.

Jobname	SUB_WAIT	INITWAIT	ENQ_WAIT	ALC_TIME	CPU_TIME	DASDTIME	TAPETIME	???_TIME

Figure 4b. Job Step Timing Statistics

The biggest single block of time in the entire stream is clearly the DASD time in job SQRC024M. Figure 4b summarizes DASD I/O (taken from SMF Type 14, 15, and 64 records) for that job in the study runs. The largest EXCP counts are those to the data and index components of a VSAM file, SQRC.PC1274CL. According to the application programmer responsible for this jobstream, the file is usually accessed patchwise sequential, that is, each read or update usually starts with a randomly distributed record but then proceeds through a short series of the first record's successors. The tuner's recommendation was to increase the index and data buffer allocations for that file, by adding

AMP=('BUFNI=10','BUFND=5')

to the PC1274CL DD's in jobsteps SQRC0241 and SQRC0244. The recommendations were put into effect, index read activity essentially went away, and SQRC024M's execution time dropped from 252 minutes to 5.

The middle-out strategy uses modeling to estimate expected device performance and then compares observed to expected performance. Deviations from the model are investigated and diagnosed as either errors in the model or opportunities for performance improvement. This approach has been extensively discussed with respect to MVS and VM paging subsystems [15]. We shall consider another example, an application that makes heavy use of a two-cylinder checkpoint file.

The file consists of several tracks of header information (blocked 4K), followed by a large number of 4K blocks of detail data. A typical access consists of a partial header read, several random detail reads or writes, and a partial header rewrite. The file resides under the fixed heads of a 3350 volume, thereby avoiding any delays due to SEEK commands and reconnects. The rest of the volume contains data that is essentially inactive. The relevant device constants are channel speed (1.2 MB/sec), protocol time (about 2 msec per SSCH) and rotation time (16.7 msec). On the average, a target block is halfway around from the current head position so the mean rotation time ("latency") is half a rotation. For single-block data transfers we calculated

Connect time = 2 + 4K / (1.2 MB/sec)
= 5.3 msec
Disconnect time = 2 + (16.7 msec) / 2
= 10.3 msec

The RMF-reported values (24-hour average) per SSCH for this device were Connect time = 11.4 msec, Disconnect time = 24.4 msec, and Pending time = 0.7 msec. We clearly had something to investigate.

We started with the Connect time made up of error correction, control and data time. SYS1.LOGREC showed no error recovery charged against this device, so the Connect time is all control and data transfer. Command transfers, measured in bytes, are negligible relative to data measured in thousands of bytes. Apparently the application is moving [(11.4 - 2) msec * (1.2 MB / sec) / 4K] = 2.82 blocks with each SSCH. Further investigation showed that the application does indeed use chain-scheduled EXCPs against this dataset, and that 2 - 4 blocks per EXCP was not an unreasonable activity rate. Therefore, the single-block I/O assumption in the original model was in error.

We next turned to the disconnect time, which comprises SEEK time, rotational delay, and reconnect wait. SEEK time should be zero if the file is indeed under fixed heads. We double-checked the volume location and, with the IBM CE's help, made sure that the device in question was equipped with the fixed-head feature. An IEHLIST LISTVTOC report confirmed that the file occupied cylinders 1 and 2, the fixed head location. SEEK time thus was eliminated as a contributor to that 24.4 msec. Reconnect wait is a function of path busy. The 0.7 msec per SSCH Pending time applies to the downstream path (M/M/1 statistics) and is already a low number. Upstream queueing for this configuration follow M/M/1 statistics at HOS and M/M/4 statistics at the CU, so upstream path wait should be somewhat below 0.6 msec. We must still account for roughly 24 msec of rotational delay per SSCH.

The original 8.3 msec estimate was based on the assumption that the platter would have to rotate halfway around, on the average, to reach the target block. If that same latency applies to each block in a 2.8-block chain-scheduled I/O, we should see a Disconnect time of [(2.82 block) * (8.3 msec / block)] = 23.4 msec per SSCH. This is almost too good an agreement with the observed time when we add in an expected reconnect delay.

To sum up, roughly 2/3 of the response time to this file is taken up by rotational delay. That delay exists because there is no correlation between the rotational positions of two successive target blocks within any EXCP. Suppose the file uses TTR addressing. The R value for block 2 in a transmission has equal odds of being higher or lower than the R value for block 1. The process could be made more efficient by pre-sorting the blocks to be transferred. By arranging them in increasing order of R (except that duplicate R values pass to the end of the list), one increases the odds that the next delay will be of less than 1/2 rotation, and thus reduces the mean Disconnect time to less than 8.3 msec per block transferred. The tuner recommended that the application be so altered, but is still waiting for the results.

Application to Tape

Tape I/O management is in much poorer shape. Indeed, many of the relevant statistics are still ill-defined. The very meaning of some of the reported numbers varies with the tape device technology. The original definitions of the CSS variables still hold: Pending time is path wait, Connect is control and data transfer, and Disconnect clocks "device dedicated but not transferring". However, the operational definition of "device" gets a little blurry with the 3480 tape subsystem.

Let's take the simpler case first. The oldest currently supported generation of tape equipment, 3420-class devices, runs under a 3803-class control unit. The 3803 is strictly a pass-through facility. Suppose the CSS attempts to start an I/O to a 3420 drive. If a path is available straight through, connection is made and data transfer starts immediately (Connect time accumulates). If no path is available (device not READY or CU busy with another drive), then the I/O is queued in the CSS (Pending time accumulates). Disconnect time accumulates during periods when the device is executing a command that requires no data transfer (rewind, forward/backward space, etc.).

The more recent equipment, IBM's 3480 architecture [16, 17], uses a microprocessor-driven control unit with buffers that are dynamically dedicated to individual drives and I/Os. Early-ship CUs were equipped with 512K of memory, partitioned by the firmware into 64K buffers. IBM has since announced 1MB units and has even offered no-cost upgrades for the smaller memories. The buffers serve a speed-matching function. Data transfer from CSS to CU buffer takes place at channel speeds (3 MB/sec in current models). The rate from CU buffer to device depends on block size and specific function, but in general is substantially lower. The CU accepts a high-speed burst bound for drive 1, for instance, and then uses the CSS-CU path for drive 2's traffic while using a downstream path to dole out data at lower speed to drive 1.

WRITE operation starts with a channel command and data passing from the CSS to the CU's buffer(s). Pending time accumulates only if no CU buffer is available to accept the data. Connect time accumulates during the transfer to the buffer. The CU returns Channel End when the transfer to the buffer is complete. Disconnect time accumulates while the CU empties the buffer downstream. The CU returns Device End and Disconnect time stops when the transfer to the tape is complete.

READ operation is the converse. Pending time accumulates from receipt of the ORB until the I/O command can be passed to the CU. The CU frees the path (Disconnect time

accumulates) until the tape drive has loaded the CU's buffer. Then the CU reconnects (timer function switches from Disconnect to Connect) for data upload to the host.

From the CSS's viewpoint, the "device" in these operations is the CU buffer, not the target tape drive. This becomes even more apparent when one considers chain-scheduled transfers. In a WRITE, for instance, the CU may be filling buffer 2 from the CSS while simultaneously draining buffer 1 to the tape. The CU's Channel End signal is deferred until there are no vacant buffers to accept new data. CSS-measured Connect time overlaps what would otherwise have been Disconnect time.

The picture is muddied by the fact that rewind and mount wait time both register as Disconnect time for 3480, whereas they appear as Pending time for 3420. To summarize, in the context of tape devices:

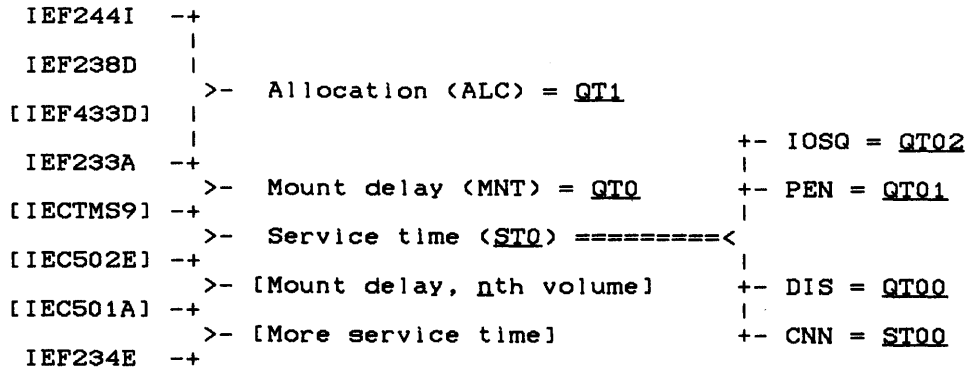
- IOSQ time - delay waiting for control of the UCB (should be none) or as a result of path sensed busy by IOS's TCH channel command.
- Pending time - delay in the CSS waiting for control of the path:
  - 3420: includes rewind and mount time.
  - 3480: CSS-to-CU path contention and buffer waits only.
- Connect time - time spent transferring control information or data:
  - 3420: to the device.
  - 3480: to the CU buffer.
- Disconnect time - time during which something is dedicated to an I/O request but not connected to the CSS:
  - 3420: "something" is the drive - time for forward or backward space by file or block.
  - 3480: "something" is the CU buffer - time waiting for buffer fill or release or allocation (which may involve rewind and/or mount waits).

The somewhat anomalous treatment of rewind and mount time points up a fundamental difference between DASD and tape. A DASD device is sharable: it can support concurrent access to one or more datasets by multiple applications. A tape device is dedicated to a single dataset and a single application: a current user must release the entire dataset before any user may access any other dataset via that device. Tape data access is thus necessarily subject to two levels of queueing. A user application must first wait for exclusive access at the dataset level. Gaining that, it must wait again for each block or burst of blocks. The two levels of queueing have timescales that may differ by a factor of a thousand or two.

Consider the effect of a design decision made early in the history of RMF. The designers worked on the assumption that the only relevant variable for tape drives is time-in-use. The device is obviously dedicated to a user during rewind or tape mount wait, so RMF tallies together all times that the device is not idle. That decision leads to collection of data that is usable for very little else than time-in-use management.

For example, suppose that allocation for batch job APRECAP has issued a message, requesting that tape volume 024978 be mounted on 3480 drive 2C4. Processing in APRECAP's address space proceeds after the mount request has appeared. Control is eventually passed to application code which attempts to OPEN the tape file. When OPEN gets control, it issues a READ against 2C4 to begin label processing. If 2C4 is not yet READY, its CMB will accumulate Pending (for 3420s) or Disconnect (for 3480s) time until the tape is mounted and made READY. Furthermore, this tape mount request is not satisfied in less than 8.3 seconds, so it is accompanied by a Disconnect time overflow. Attendant action by MIH estimates the "true" Disconnect time as some number of MIH interval expiries. RMF at current levels takes no notice of the mount wait status but accumulates all of these timings into the totals for "real" I/O. The resulting reports average together a 2-minute mount wait and a few dozen 50-millisecond READ waits and incorrectly show enormous queueing delays per I/O.

Similar logic leads to inflated tape device %busy figures from RMF/370. The numbers are so obviously improbable for block-level queueing activity that most analysts simply ignore RMF's Tape Device Activity Report, even though some of the numbers on it are valid and useful. IBM has announced that a future release of RMF will address the confounding of mount wait with I/O activity queueing times. The change will likely involve more than simply discarding active-but-not-READY times, because time-in-use is still an important capacity metric. We should see a complete recast of the report, with



Dataset response time (R1) = QT1 + ST1
= ALC + Dedicated device time
Dedicated device time (R0) = ST1 = QT0 + ST0
= MNT + Device service time
Device service time (ST0)
= Host time + SUM (IOS response time)
IOS response time (R02) = QT02 + ST02
= IOSQ + CSS response time
CSS response time (R01) = QT01 + ST01
= PEN + Subsystem response time
Subsystem response time (R00) = QT00 + ST00
= DIS + CNN

Figure 5: Tape subsystem queueing

separate columns for dataset- and block-level metrics.

If the RMF reports do not speak clearly to dataset-level delays, where can the analyst turn for data? SYSLOG is a good source for both MVS/370 and MVS/XA. Interesting data can be developed by using SAS or similar software to scan SYSLOG, looking for specific tape-related messages. The following discussion is specific to JES2 in a system with no tape-sharing software, but similar analyses can be carried out for JES3 and STAM (a shared tape drive management product of Duquesne Systems, Inc.) systems.

Each step in the mount cycle is signaled by a specific message, and each message is timestamped. All of the following messages are prefixed with the requesting job's JES job number, and all after the IEF433D message carry the device number (address) of the drive in question. The variable to be tracked is the difference in timestamps between successive messages for a given mount (see Figure 5).

Suppose all drives are in use and a new allocation request appears. Allocation issues an IEF244I message, "Unable to allocate unit...", followed by an IEF238D message, "Reply device name, wait, or cancel". There are no drives available and the job cannot be cancelled, so the operator replies "Wait". The system responds with an IEF433D message, "Wait requested -- Reply Hold or Nohold" asking whether it should release any devices the job has already received. Either way, the job sooner or later obtains a drive and issues an IEF233A message, requesting a mount of the desired volume on that device.

It would be nice to know the mount delay, the period between the IEF233A message and the moment the system senses that the correct volume is READY. Some subsystems, notably DFHSM, keep their own records of tape mount waits. IBM system software does not provide a "mount satisfied" message. However, mount time usually is very close to the time of OPEN completion. An OPEN timestamp appears in the corresponding SMF Type 14 or 15 record. SYSLOG receives an IECTMS9 message at OPEN time if (1) the tape is OPENed for output, and (2) the installation is running the UCC-1 (TMS) software (a product of UCCEL, Inc.). OPEN-for-output mount delay is a potentially useful estimate of general mount delay, but it can be biased if the system's operating procedures include special racks for scratch tapes or if Automatic Cartridge Loaders are installed on 3480s.

The dataset I/O cycle completes with a final IEF234A message, issued when the tape is demounted. The period between the IEF233A and IEF234A messages is the dataset-level service time, which is itself divisible into a series of queue and service times at the EXCP level. Figure 5 summarizes the entire sequence and makes plain the complexity of the nested queueing structures.

Before going on to consider tuning strategies applied to tape performance, we should say a few words about what can be tuned in a tape subsystem. Many of the DASD tuning options (dataset or volume reorganization, etc.) are responses to generic problems that are peculiar to DASD equipment (head movement delay, etc.). There are fewer generic problems in a tape subsystem, which is just as well because there are fewer tuning options as well.

The major options are equipment-oriented. Technology choice is one of the basics. Moving from 3420- to 3480-class equipment should affect all of the components of ST1. Reference [17] offers a particularly lucid discussion of the 3420/3480 issue with regard to performance expectations. Doubled channel speed does not necessarily yield proportionally decreased turnaround times, but one can at least expect reduced Connect times. The person making equipment decisions must recognize other concerns as well: interface requirements with other equipment, financial terms, media and storage costs, etc. Of course, the tuner is usually faced with an overriding constraint: the enterprise must work with what is on the floor.

The next tuning "parameter" is the subsystem configuration. Insufficient drives lead directly to allocation delays (QT1). Long strings of tape drives behind a small number of CUs will in general lead to greater path contention delays (QT01 and QT02). Contention problems could be addressed by adding one or more CUs to the mix and shortening the strings. Tape device waits could be addressed either by reducing service time per request or by adding more device to the existing configuration.

The 3480 CU is nearly a black box, tuning-wise. "Tuning" is the management of a scarce resource to minimize the effects of the scarcity. The scarce resource in the CU is the buffer memory. Insufficient CU buffer space leads to elevated Pending and Disconnect times (QT00 and QT01). The CU firmware has the responsibility of managing that resource. The user cannot measure CU buffer usage, but neither is there a way to influence how many buffers are to be dedicated to any drive. The only available tuning option is to ensure that the CU is equipped with the largest available memory.

Tape mount wait (QT0) is one of the most important sources of delay in the tape subsystem. Machine room geography can have a major impact on mount delay: how close are the most active tape drives to the media storage, especially for scratch tapes?

The SELTAPE= parameter in the active IEAOPTxx PARMLIB member can also have an impact on tape mount time, at least for very large tape farms. This parameter gives policy to SRM on which tape drive should be selected for the next mount. SELTAPE= RANDOM guarantees maximum exercise for the tape libarians. If device numbers are assigned with the lowest being closest to the tape console, SELTAPE=LOWEST will concentrate activity near that facility. SELTAPE=NEXT will concentrate mounts into a band that starts at low device numbers and sweeps across the farm in a regular procession.

The final option finesses the rest: reduce tape waits of all sorts by reducing tape I/O. The combination of decreasing DASD cost and increasing sophistication of data management software (IBM's DFHSM, Sterling's DMS, Innovation's ABS, etc.) has made feasible the wholesale migration of short tape datasets to DASD. Schering-Plough's Memphis Computer Center, for instance, adopted a 20-MB low threshold for tape residence. As a result of that policy, the installation was able to reduce its tape drive count by 60%, with attendant reductions in batch work delays [18].

How, then, can our tuning strategies be applied to the tape subsystem in an MXS/XA environment? The bottom-up strategy is of little use, mostly because the measurement difficulties noted above have hindered our development of useful Rules of Thumb. Some authors have proposed rules hinging on ratios of Pending or Disconnect to Connect time, but the 3480 CU's ability to overlap upstream and downstream operations limit their effectiveness. Because a tape device is dedicated to a single user (at any one time), it works perfectly well at utilizations near 100%. The 30% path busy rule is still of some use, except for a 3480 subsystem with the Dual Control Unit Communications Coupler (DCUCC) feature. The DCUCC in essence converts the 3480 subsystem from an M/M/1 to an M/M/2 server downstream and as high as M/M/8 upstream. Such a configuration can withstand path utilizations as high as 70% and still deliver as well as an M/M/1 server at 33%.

Similarly, the middle-out strategy is of limited value because of the difficulty of modeling the complex interactions of the electronic, mechanical, and human timescale queues. The M/M/c relations do offer a way to estimate drive count requirements, starting with an estimated mean dedicated device time (ST1) and a desired mean allocation wait (QT1). Figure 6 shows a family of QT1/ST1 versus AT1/ST1 curves (calculated with the code in Appendix 1) for different values of c (tape drive count), where AT1 is the mean mount request arrival rate. Dividing both interarrival time and queue time by service time allows the same set of curves to be used for any

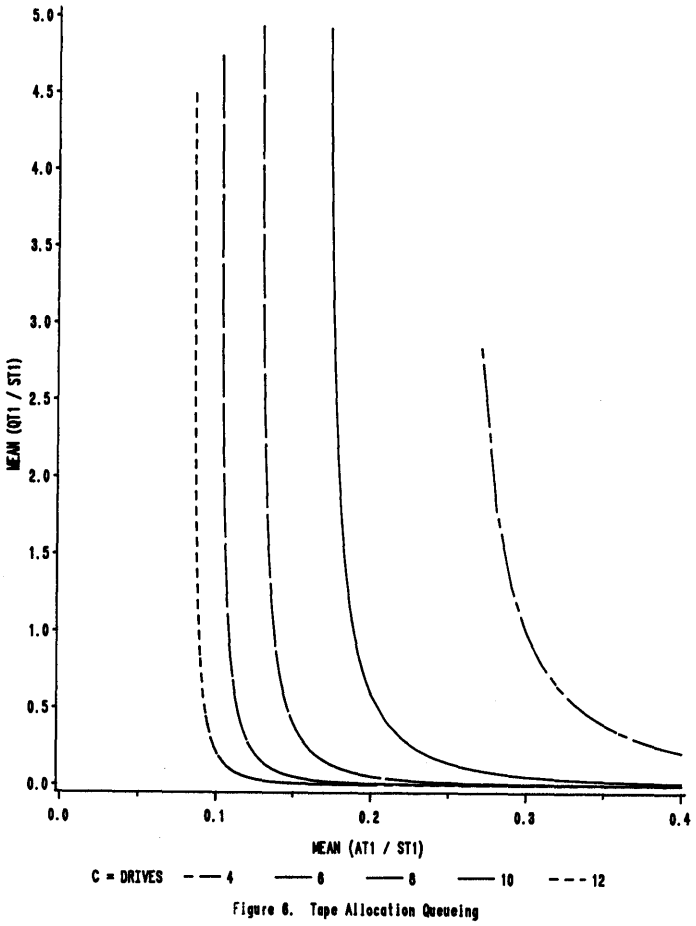


Figure 6. Tape Allocation Queueing

average service time. For instance, the curves say that if an installation's mean ST1 is 5 minutes and its mean AT1 is 1 minute (AT1/ST1 = 0.2), 4 drives will be unable to handle the load, 6 would give a mean (but risky) QT1 near 2.5 minutes (0.5 * ST1), but 8 or more drives should provide acceptable service.

These predictions should be taken with a good deal of salt. The major problem is that the M/M/c model assumes that arrivals and service times are each Markovian, that is, no arrival or service time depends upon any other arrival or service time. This is not the case for real batch workloads, which usually mount two or even three tapes simultaneously for the length of the same job step. The correlated activity of n servers effectively reduces the server count by (n - 1).

The top-down strategy is the most useful here, because it concentrates on locating problems as perceived by the user. During the SQRC subsystem performance analysis of Figure 4, for example, the analyst noticed that one job step had an unusually large disparity between the total execution time and the total of allocation, ENQ, CPU (expanded by the mean Multi-Programming Level), DASD and tape times. Further probing showed that one tape DD's Connect time per EXCP was only a tenth that of the installation mean for tape datasets.

Short Connect time indicates a small block size, and sure enough, this dataset had 800-byte blocks instead of the installation-standard 20K blocksize. Some relevant numbers are collected in Figure 7. The small block size means that only a small number or records are transmitted with each EXCP. Since each EXCP carries an overhead penalty (the sum of IOSQ, Pending, and Disconnect time, averaging to 20 msec per EXCP system-wide exclusive of mount and rewind time), small block size also means high overhead. The last entry in the "Prior" column shows that only 6% of the I/O time against this dataset was actually spent transferring data.

	Expression	Prior	Future
File size, MB	F	26	26
Block size, KB	B	0.8	20
Channel speed, MB/sec	S	3	3
KBytes per 5-block EXCP	5B	4	102.4
EXCPs to read file	E = 1000 * F / 5B	6500	254
Connect msec per EXCP	C = (5B / S) + 2	3.3	32
Total Connect sec	C * E / 1000	21.6	8.1
I/O msec per EXCP	T = 20 + C	23.3	52
Total I/O time	T * E / 1000	151	13.2
I/O efficiency	100 * (5B / S) / T	5.6	57.7

Figure 7. Improving I/O by Reblocking

Suppose the dataset were reblocked from 10 to 256 records per block (blocksize 20480). The expected I/O timings are shown in the "Future" column of Figure 7. The reblocking would raise the I/O efficiency to nearly 60% and we would expect to reduce the job step's run time by over hundred seconds. (The actual magnitude of the reduction would depend on how much of the job's I/O to this dataset overlaps other processing.) The file was reblocked on the analyst's recommendation, and the job step's execution time in fact dropped by 170 sec. Expediting the tape I/O so sped up processing that the job suffered far less paging and swapping than it had with the smaller blocksize.

Summary

The advent of XA moved MVS's I/O measurement philosophy from resource measurement to time measurement. That reorientation has facilitated the performance analyst's ability to apply the top-down tuning strategy, the most efficient way to locate and relieve performance bottlenecks. Relative levels of measurement sophistication make systematic tuning most applicable to DASD subsystems, less applicable to tape and network problems.

FROM SIMPLE REGRESSION TO ANALYSIS OF VARIANCE AND BEYOND--PAINLESSLY

Ann C.Pool
Planning Research Corporation

ABSTRACT

An understanding of the theory of simple linear regression and confidence intervals can be expanded to gain invaluable additional information. In a few steps an analyst can go from a conceptual understanding of linear regression to an understanding of analysis of variance and analysis of covariance. This paper attempts to demystify linear regression models and addresses some of the its applications and common misapplications. The general linear regression model and its assumptions, confidence intervals and prediction intervals, and the formulation of linear regression models that can be used for prediction, classification of data, and modeling growth are discussed.

1. INTRODUCTION

Often one hears "I tried every test in the book" or " I don't use statistics, because I don't trust them ". What both of these people are saying is that they do not understand statistics. Generally in statistics only one or two tests or series of tests are appropriate in a given situation. Statistics can be a powerful tool if the underlying assumptions and restrictions are understood. Perhaps one of the greatest weaknesses of many computer and business professionals is that they do not understand statistical methods and procedures. The purpose of this paper is to demystify linear regression models and to address some of its applications and common misapplications. This paper does not set out to suggest computational methods or the abandonment of standard computational procedures.

Linear regression can be used as a statistical model of a given situation. Linear regression offers a rich and full language for interpreting relationships into mathematical equations and statistical procedures. Regression analysis allows formulation of models that can be used to explore the functional relationships, and to predict future conditions. Just like any other modeling process, using linear regression requires definition of the problem, identifying appropriate input and output variables, finding appropriate mathematical representation of the relationships, and testing the model.

2. STRAIGHT-LINE REGRESSION

Linear regression divides all variables into two types: independent variables and dependent variables. Independent variables are the predictor variables. Independent variables can be set or observed but not controlled. They drive the equation. Dependent variables are the response variables. These variables represent the consequence of independent variables. They are the result of the equation. For example, in the equation:

$$Y = \beta_0 + \beta_1 X + \beta_2 X^2 \qquad (1)$$

Y is the dependent variable and X is the independent variable. Equation (1) is a second order (in X) linear (in the β's) equation.

Equations which are not linear can be transformed into a linear equations or approximated by one.

Consider, the following equation:

$$Y = a\, X^b \qquad (2)$$

Y and X represent known values, a and b are unknown values. This equations is not linear, because b is an unknown. However, it can be expressed in linear form as

$$\log(y) = \log(a) + b \log(X) \qquad (3)$$

Equation (3) is a first order (in log(X)) linear equation. log(a) and b constant parameters that can be calculated using linear regression.

2.1 ASSUMPTIONS OF LINEAR MODELS

Like any statistical test or model there are certain assumptions associated with linear regression. If X represents the independent variable(s) and Y is the dependent variable, the assumptions can be stated as follows:

1. For any fixed value of the variable X, Y is a random variable with a certain probability distribution.
2. The Y values are statistically independent of one another.
3. The mean value of Y is a straight line function of X.
4. The variance of Y is the same for any X.
5. For any fixed value of X, Y has a normal distribution.

Each of these assumption has an important implication for linear regression models. Consider each of the assumptions individually.

1. For any fixed value of the variable X, Y is a random variable with a certain probability distribution. The mean of this populations is denote by $m_{X|Y}$ and $s^2_{X|Y}$ is the variance of the population. "Y|X" means the random variable Y depends on the value of X.
2. The Y values are statistically independent of one another. This means that information about one value of Y gives no information about other values of Y. For example, consider the amount of disk space used on a system measured at various points in time. If there is no procedure

in operation to remove old files from the system between the two measurements, then the amount of disk space would not be statistically independent. This assumption is often violated. Special techniques for handling these situations include time series analysis and growth curve analysis.

3. The mean value of Y is a straight line function of X. This assumption can be written as

$$m_{Y|X} = \beta_0 + \beta_1 X \qquad (4)$$

where β_0 and β_1 are the intercept and slope of the regression line respective. An alternate form of this equation is

$$Y = \beta_0 + \beta_1 X + E \quad \text{or} \quad E = Y - (\beta_0 + \beta_1 X) \qquad (5)$$

where E is a random variable which has a mean 0 at a fixed X. The variable E describes the distance from an individual values of Y to the regression line. E represents the residual of the linear regression.

4. The variance of Y is the same for any X. This is the assumption of homoscedasticity or the "same scattering". This assumption is written as

$$s^2_{Y|X} = s^2 \qquad (6)$$

Since $\beta_0 + \beta_1 X$ is a constant for a given value of X, s^2 is also the variance of E.

5. For any fixed value of X, Y has a normal distribution. This assumption makes it possible to evaluate the statistical significance of the relationship between X and Y. It is important to note that there is a certain amount of leeway in this assumption. This is called the "robustness" of the regression analysis. This assumption also implies that E has a normal distribution with a mean of 0 and a variance of s^2. If this assumption can not be met by the original data the values of Y can be "transformed". Common transformations include using logarithmic functions, reciprocals, and square root functions.

2.2 CONFIDENCE INTERVALS AND PREDICTION INTERVALS

Confidence intervals and prediction intervals are very useful tools. They allow the analyst to evaluate the value of a parameter or calculated value and the quality of the estimate. The center of a confidence interval or prediction interval is generally the calculated value of the parameter. The width of the interval represents the quality of the estimate. The wider the interval for a given level of confidence, the less certain the estimate. Confidence intervals consists of boundaries between which there is a particular level of confidence that the unknown value will actually lie. For example, a 95% confidence interval for a fixed, unknown value w consists of an upper limit and a lower limit so that, there is a probability of 0.95 that the true value of w is contained in the interval. A prediction interval is used to predict a value of the function under consideration that was not part of the original computation.

In considering linear regressions, confidence intervals are associated with the calculated parameters (the β's) and the calculated estimates of Y. Table 1 shows confidence intervals for a simple regression of the form

$$Y = \beta_0 + \beta_1 X \qquad (7)$$

Notice that in Table 1 there is a confidence interval for $m_{X|Y}$ and one for Y_{x_0}. The confidence interval for $m_{Y|X}$ is for use with values of X that were used in the calculation of the regression. Y_{x_0} is used with values of X that were not used in calculation of the regression. This confidence interval is sometimes called a prediction interval. Notice that these equations are very similar. The confidence interval for $m_{Y|X}$ is

$$Y = m_{Y|X} \pm t_{(n-2,\ 1-a/2)}\ S_{X|Y} \sqrt{\frac{1}{n} + \frac{(X_0-\bar{X})^2}{(n-1)S_X^2}} \qquad (8)$$

The confidence interval for Y_{x0} is

$$Y = Y_{x0} \pm t_{(n-2,\ 1-a/2)}\ S_{X|Y} \sqrt{\frac{1}{q} + \frac{1}{n} + \frac{(X_0-\bar{X})^2}{(n-1)S_X^2}} \qquad (9)$$

where q is the number of Y values expected at X_0. That is, if at X_0 there is to be one value of Y, then the confidence interval of Y_{x0} is much wider than the confidence interval of $m_{Y|X}$. As the number of Y values expected the X_0 increases, the confidence interval of Y_{x0} approaches the confidence interval of $m_{Y|X}$. Figure 1 shows the plots of a regression line, and the associated confidence intervals for $m_{Y|X}$ and for Y_{x0}.

Often it is more important to know the values of the independent variable associated with a confidence or prediction interval. For example, if time is the independent variable (X) and cost is the dependent variable (Y). It may be useful to know the earliest and latest points in time when a certain cost might be expected. The interval between these values is a fiducial interval. Fiducial intervals for a confidence interval and a prediction interval are shown in Figure 1. The fiducial interval associated

with the confidence interval is given by

$$X = \bar{X} + \frac{b_1 (Y_0 - \bar{Y})}{b_1^2 - \frac{t^2 S_{x|y}^2}{S_{xx}}} \pm \frac{t_{(n-2,\ 1-\alpha)} S_{y|x} \sqrt{\frac{(Y_0 - \bar{Y})^2}{S_{xx}} + \frac{b_1^2}{n} - \frac{t^2 S_{x|y}^2}{n S_{xx}}}}{b_1^2 - \frac{t^2 S_{x|y}^2}{S_{xx}}} \quad (10)$$

The fiducial interval associated with the prediction interval is

$$X = \bar{X} + \frac{b_1 (Y_0 - \bar{Y})}{b_1^2 - \frac{t^2 S_{x|y}^2}{S_{xx}}} \pm \frac{t_{(n-2,\ 1-a)} S_{y|x} \sqrt{\frac{(Y_0 - \bar{Y})^2}{S_{xx}} + \left(\frac{1}{n} + \frac{1}{q}\right)\left(b_1^2 - \frac{t^2 S_{x|y}^2}{S_{xx}}\right)}}{b_1^2 - \frac{t^2 S_{x|y}^2}{S_{xx}}} \quad (11)$$

These intervals do not exist for every linear regression at every value of the dependent variable. To be of practical value β_1 must be significantly different from 0, that is 0 is not in its confidence interval, and $(t^2 S_{x|y}^2)/S_{xx}$ should be smaller then about 0.20.

In looking at the regression parameters, it is important to note that since the estimate of the β's are not independent, one cannot combine directly the confidence intervals of b_0 and b_1. The joint confidence interval for b_0 and b_1 is the confidence interval for the combinations of the β's. Using matrix notation, the joint confidence interval has the form

$$(\beta - b)' X'X (\beta - b) \leq p s^2 F(p, v, 1-a) \quad (12)$$

This interval results in a elliptical confidence region for two parameter equations. Figure 2 shows the 95% confidence interval for b_0 and b_1 and the joint confidence region for b_0 and b_1. The point A is in the confidence intervals for both b_0 and b_1 . Point A is clearly satisfactory when considering only b_0 or only b_1. However, when considering both b_0 and b_1, point A is not satisfactory.

3. LINEAR REGRESSION MODELS

Any modeling, including statistical modeling, is an ongoing process beginning with a question or an idea, simplification of the idea to a mathematical form, evaluation of the mathematical form, and analysis of the results. In the case of statistical models, each model is associated with at least one statistical test which may disprove a hypothesis. Linear regression models can be used to model, among other things, the differences among groups and the relationships among variables.

In developing a linear regression model the first steps are generally to graph the data, examine the graph and hypothesis one of the primary relationships among the variables examined, and then test the hypothesis. A simple regression model is first constructed and tested. Other factors are then added to reduce the residual error (E) until either the remaining factors do not significantly reduce the error or all hypothesises have been tested. This process will require several iterations. For example, consider a computer system with four disk drives that are run during 3 shifts. The users are complaining about slow disk access. One of the questions that must be answered is "Is the disk access time related to the drive on which the file being accessed is found or to the shift when the file is accessed?" At least three tests are required: one relating access time to the drive, one relating access time the shift, and one relating access time to both shift and drive.

3.1 MODELING RELATIONSHIPS AMONG GROUPS

Linear regression models can be used to examine the difference among some continuous variable such as a measurement made on groups of individuals. The model can include information on nominal factors, such as membership in groups, and continuous factors. Nominal factors contain categories or groups called levels. Factors may be either fixed or random. A fixed factor is one in which has all of the relevant levels of interest. A random factor is one which has only a sample of the levels available from some larger classification. For example, suppose a manufacturer conducts a test of a sample series of disk drives selected at random. If the measurements are grouped by the drive, and the information is applied to all disk drives manufactured, the disk drives represent a random factor. If the same test is run on all drives at a site and the results are only applied at that site, the disk drives represent a fixed factor.

The problem is now how to represent the relationships as in a linear equation. Since there is no restriction on the selection of the independent variables (X's) in a linear model, they can be used to represent membership in a group. Since the outcome a linear model is the mean of the dependent variable (Y) under the conditions in the model, i.e.,

$$m_{Y|X} = \beta_0 + \beta_1 X_1 + \ldots + \beta_{k-1} X_{k-1} \quad (13)$$

it is possible to choose the values of X so that the β's represent the means of the groups. That is, the mean response of any group is a linear combination of the β's. The responses of the groups 1 to k-1 are explicitly represented. The kth group is implicitly represented. If the kth group had been explicitly represented, the

computation of the linear regression would have been impossible.

The regression model can be re-written as

$$Y_{i,j} = \mu + \sum_{i=1}^{k-1} \beta_i X_i + E \quad (14)$$

where $Y_{i,j}$ is the dependent or response variable. It is often a measurement made under known or controlled situations. $Y_{i,j}$ is the "jth" element of group i. μ is the true value of the mean of some fixed group. β_i represents the difference between μ and the mean of the $Y_{i,j}$'s in group i. X_i represents membership in group i. E is the random error or the difference among individuals. There are a number of ways of coding membership in a group. In one scheme uses the following:

$$X_i = \begin{cases} 1 \text{ if group } i \\ 0 \text{ otherwise} \end{cases}, \quad i=1, 2, \ldots k-1 \quad (15)$$

In this coding scheme, the means of the groups are compared to a base group. For example, if there are 4 groups, the equation (14) can be interpreted as shown in table 1. In this example the base group is group 4. In an alternative coding scheme

$$X_i = \begin{cases} 1 \text{ if group } i \\ -1 \text{ if group } k \\ 0 \text{ otherwise} \end{cases}, \quad i=1, 2, \ldots k-1 \quad (16)$$

This coding scheme compares the means of the individual groups to the over all mean or the grand mean. An example of this coding scheme for four groups is shown in Table 2.

The are two different tests associated with this modeling depending on the type of factor being investigated. If the factor under consideration is fixed, the null hypothesis is H_0: $\beta_1 = \beta_2 \ldots = \beta_k$ versus H_1: not so. The English translation of this hypotheses is: the assumption to be disproved is there is no differences among the means of the groups versus, at least one means of the groups is different from the others. The results of an analysis of variance are generally analyzed through an ANOVA table such as the one shown in Figure 3. The table shows the error associated with different portion of the model. The table shows the degrees of freedom (df), the sum of the squared errors (SS), and the mean squared error (MSE). The degrees of freedom are the number of independent pieces of information involving k independent numbers. The sum of the squared error shown between groups

$$SS_b = \sum_{i=1}^{k} J_i \ (\hat{Y}_i - \bar{Y})^2 \quad (17)$$

represents the error that is introduced by estimating the mean of the measurements for each level in the factor by the mean of all of the measurements in all of the levels.

The mean squared error for the groups or variance

$$s_b^2 = \sum_{i=1}^{k} J_i \ (\bar{Y}_i - \bar{Y})^2/(k-1) \quad (18)$$

is the sum of the squared error divided by the degrees of freedom with k-1. The error within groups

$$SS_w = \sum_{i=1}^{I} \sum_{j=1}^{J_i} (Y_{ij} - \hat{Y}_i) \quad (19)$$

in found by comparing the actual measurement to the measurement estimated by the model $\hat{Y}$ and the actual measurement.

The mean squared error within groups

$$s_w^2 = \sum_{i=1}^{I} \sum_{j=1}^{J_i} (Y_{ij} - \hat{Y}_i)/(n-k) \quad (20)$$

is the variance associated with the model. The question becomes which is larger, the average error associated with using the overall mean or the average error associated with using the model.

These two numbers are compared by forming a ratio (a test-statistics)

$$F = \frac{s_b^2 \Leftarrow \text{mean error for the model using only the grand mean to represent the mean of each group}}{s_w^2 \Leftarrow \text{mean error for the model using mean of each group to represent each measurement}} \quad (21)$$

If there is more error associated with the model including the factors then with a model including only the means then the ratio will be greater than one. In order to determine how much greater than one is significant, the ratio is compared to be statistical distribution called the F-distribution. This distribution takes into account the number of parameters being estimated and the number of measurements used in the estimation. If the factor is random, it is assumed that the β's are distributed in a normal distribution with a mean of 0 and variance of $\sigma\beta$. The null hypothesis $\sigma\beta = 0$. This hypothesis implies that there is no difference among the groups. To make this test, the same ratio is compared to the the ratio $F = s_b^2 / s_w^2$ (test-statistic) to the suitable percentage point of the F(k-1, n-k) distribution (F-statistic).

Both of these schemes will give exactly the same test statistic (F-statistic) . The difference lies in the interpretation of μ. In the first scheme μ is the mean of a base group that is used to compare with the means of the other groups. In the second scheme μ is the grand mean and all group means are compared to it.

If the first scheme is used, additional information about the relationship to some base group is gained. If the second scheme is used, then information relative to the grand mean is gained. Additional information can be gained from either scheme by examining the confidence intervals of the calculated parameters (β_i's). Both schemes are suitable for fixed factors.

There are two methods of reporting the results of a statistical test. Traditionally, a predetermined percentage point is chosen from the appropriate distribution and a comparison is made. In the alternate method of reporting, the results of the test are reported as the percentage point of the distribution associated with the ratio. This allows the reader to access the risk that he is willing to take in accepting the hypothesis. This second approach is not recommended for use with a audience who is not familiar with statistics or who is not willing to accept the responsibility for the interpretation. However, many managers are willing to accept more than the traditional 5% error on a test and this allows them the opportunity to make the decision to reject or accept the hypothesis.

This model in equation 14 is called a One-way Analysis of Variance. The groups which are different can be determined by examining the confidence intervals associated with the parameters that contribute to the mean of the group. If the confidence interval contains zero (0) then the group mean is not statistically significantly different from μ. However this method has some draw backs. First making a number of tests and combining the results to reach a conclusion, reduces the significance(meaningfulness) of the group of tests. Secondly, the parameters are not strictly independent. It becomes difficult to make multiple comparison confidence intervals. Alternatively, post priori tests can be performed to determine which group is different. These tests include LSD (least significant difference) approach, Tukey's method, Scheffé's method, and orthogonal contrasts. Each of these tests combines into a single hypothesis the relationships among the means of the groups. These tests reduce the amount of overall error used in evaluating the relationship among the groups.

3.2 MODELING RELATIONSHIPS AMONG TWO GROUPINGS OR FACTORS

Often one grouping will only partially explain the relationships among the subjects under consideration. If two groupings of the subjects are used then the groupings may be called row and column factors or blocks and treatments. In either case each individual is defined by one and only row factor and one and only one column factor or by one block and one treatment. The intersection of a row factor and a column factor is call a cell. The individuals in a cell have some measurable characteristic that is partially due to the row factor and partially due to the column factor. The mean value of the measurements in a cell has a component or part that is due to the row factor, a part that is due to the column factor, and a part due to the interaction between the two factors. For example, in evaluation disk access time, not only the drive may be important, but the shift during which the measurements are made may be important. The relationship between the shift and the drive may vary from drive to drive and shift to shift. This relationship may be modeled as two factors and an interaction. The factors are the disk drive and the shift. This model is called a two-way analysis of variance. This relationship is shown schematically in Figure 4.

The basic model for this situation is

$$Y = \mu + \sum_{i=1}^{k-1} \alpha_i X_i + \sum_{j=1}^{b-1} \beta_j Z_j + \sum_{i=1}^{k-1} \sum_{j=1}^{b-1} \gamma_{ij} X_i Z_j + E \qquad (22)$$

where X_i represents the membership in the group with the row factor of level i and Z_j represents membership in the group with the column factor. α_i and β_j are the components of the mean of Y due to the factors. γ_{ij} is the component of the mean due to the interaction between the two factors. One scheme used to represent membership is [1]

$$X_i = \begin{cases} 1 \text{ if level i of row factor} \\ -1 \text{ if level k of row factor} \\ 0 \text{ otherwise} \end{cases} \qquad (23)$$

$$i = 1, 2, \ldots k-1$$

and

$$Z_j = \begin{cases} 1 \text{ if level j of column} \\ -1 \text{ if level b of column factor} \\ 0 \text{ otherwise} \end{cases}$$

$$j = 1, 2, \ldots b-1$$

This scheme compares each cell to the grand mean. This is illustrated in Figure 5.

There are three null hypothesises to be tested in this model:

1. H_o: The row factor has no effect.
2. H_o: The column factor has no effect.
3. H_o: The interaction has no effect.

The testing process is further complicated by the fact that a factor may by either fixed or

[1] The first scheme shown with the One-way ANOVA may be used if the interaction term is not included in the model.

random. This leads to the following possible scenarios:

Both factors are fixed

Both factors are random

The row factor is fixed and the column factor is random

The row factor is random and the column factor is fixed.

Thus there are four series of tests that might be performed. The analyst will choose the series of tests based on the situation. For example, in considering the disk access time problem for a given site, the drives are a fixed factor, and the shift may be either a fixed factor or a random factor. If the information from the test is to be applied to historic situations only, then the factor may be fixed. However, if the information is to be applied to all situations, past and future, the factor is random. There are different test-statistic used depending on the type of factors involved. These tests are summarize in Figure 6. Notice that there is a difference in the test statistics for fixed and random effects. Also note that the sums of squares are calculated for cells with the same number of members in each one.

3.3 ANALYSIS OF COVARIANCE

At times discrete factors are not enough to explain the relationships among variables. Continuous variables can be added to an ANOVA to account for such relationships. This model is call an Analysis of Covariance. The linear regression representation of this model is

$$Y = \mu + \sum_{i=1}^{p} \alpha_i X_i + \sum_{j=1}^{b-1} \beta_j Z_j \qquad (24)$$

where X_i is a continuous variable and Z_j represents membership in a group. Since this model represents only a one-way analysis, either scheme for representing membership could be used. If a two-way analysis with interaction is used only the second scheme could be used. It is important to note that this test is used under two conditions. First, if groups appear to significantly different under conditions where it is hypothesized that they should not. Alternately, it may be used if groups do not appear to be significantly different but should. For example, if the access time appears to be significantly different when grouped by shift, adding the covariant of disk location to the model may make the grouping not significant.

Analysis of this model is performed in two steps. First the relationship between the dependent variable (the Y) and the covariants (the X's) is confirmed by testing the statistical significance of the model

$$Y = \mu + \sum_{i=1}^{p} \alpha_i X_i \qquad (25)$$

This is confirmed by comparing the model in (25) with p=1 to the model with p=0 using a F-statistic similar to the process discussed before. Then compare the model with p=2 to the model with p=1. This process is continued until the test results do not lead to the rejection of the null hypothesis or all of the hypothesized convariants have been added to the model. The second step is to compare the modeling including the factors (25) to the model not including the factors (26). If the null hypothesis is rejected then the groups are said to be significantly different when "controlling for covariants".

3.4 THE COMPLICATIONS OF ANALYSIS OF VARIANCE

There are several issues in using analysis of variance models. The first is the number of subjects or measurements in a cell. The examples shown above assume an equal number of subjects per cell. There are computation methods used for models with unequal cell size. These methods are discussed in the references. Many statistical computer packages provide analysis of variance routines which may or may not deal with unequal cell size. Sometimes an analyst can use the regression routines to preform analysis of variance. Another issue is the number of factors and covariants to be used. The number of variables used to explain dependent variable should be held to be minimum.

3.5 GROWTH MODELS

Growth models deal with change over time. They can be approached in the same manner as the analysis of variance models--observe, hypothesize, test. There are two important questions to be answered:

Can the relationship be modeled under the restrictions of linear regression?

Can the shape growth curve be modeled using linear regression?

Often the second principle of regression (The Y values are statistically independent of one another.) is often violated in using a model, for example

$$Y_i = \mu + \beta t_i \qquad (26)$$

If Y_2 can be predicted by knowing Y_1 then some change must be made in the model. This condition can be eliminated by using $Y_2 - Y_1$ as the dependent variable. Then the model is

$$(Y_2 - Y_1) = \mu + \beta t_i \qquad (27)$$

Under many conditions, growth is not a straight line. Under these condition a transformation of the data may be used. For example, if the data can be model as

$$Y = bt^a \qquad (28)$$

This model can be transformed using the logarithmic function to

$$\log(Y) = a \log(t) + b \qquad (29)$$

Either of these models may be expanded to include other independent variables.

4. SUMMARY

It is possible to model many situation using linear regression models including the relationships among groups, growth, and logarithmic relationships. Independent variables may be either discrete or continuous. Linear regression models can be used for the applications discussed in this paper as well as such diverse applications as discrete multivariate analysis and time series analysis. The modeling process using a statistical approach is the same as using any other modeling process. All linear regression can be reduced to the comparison of a model to a simpler one. Knowledge of the methods lead to predictions, understanding of relationships, and the ability to evaluate statements and claims.

HIGH PERFORMANCE I/O SUBSYSTEMS

Anthony G. Mungal.

ABSTRACT

It is readily apparent that major breakthroughs in technology coupled with the evolving and shifting trends of the data processing industry will necessitate revolutionary methodologies for the configuration and classification of data. As the quantity of on-line data increases, its management becomes a primary concern. Incorporated with that management concern are the issues of how to solve the ever growing need for capacity and the incessant demand for better performance.

Data access patterns in many environments have proven that a significant amount of access activity tends to reference a small percentage of the available data. This can lead to some rather peculiar circumstances. The well known phenomena of DASD skew comes to mind as an example of such a case, whereby access is required to different portions of data spanning different time patterns. How can one deal with these various phenomena?

This tutorial will deal with the issues surrounding the isolation, identification, and subsequent configuration of high performance data. A thorough understanding and definition of high performance data, and how it should be configured for capacity and performance reasons, can solve the major problems of most I/O environments.

It is also intended to address the data classification issues of high performance data and provide some general guidelines as to the various storage product classes that may be required to alleviate performance and capacity problems. One primary focus is in emphasizing concepts that are apparent with high performance data; for example, the concept of access density and its interpretation. Tools and techniques that emphasize the ease of analysis of high performance data and the on-going performance monitoring of it are also discussed.

Finally, the hierarchical structure of the storage system is examined. That leads to a discussion of the various costs and capacity type arguments that are of paramount concern to today's discriminating user, and provides a frame work whereby one can analyze the effects of increasing capacity on data centre costs.

INTRODUCTION

Much of the material within this paper was derived from industry wide concerns as to the disposition of high performance data. The issues centered around the configurational aspects of data, the current and future technologies employed, the capacities, the reliability criteria, the availability criteria and, of course, cost. In looking at high performance subsystems, it is then proper to consider technology offerings that serve the needs of high performance data both current and future.

- TODAY'S PROBLEMS
- TOMORROW'S TECHNOLOGY
- DEFINITION OF HIGH PERFORMANCE DATA (HPD)
- ACCESS DENSITY
- CAPACITY OR PERFORMANCE
- APPLICABILITY OF CACHE AND SSD TO HPD
- BUSINESS CASE STRATEGY

FIGURE 1 - OUTLINE

This paper (see Figure 1) will deal with the problems that are apparent within todays environment; it will then speculate on how the technology of tomorrow (either rumored or real) could impact those problems; it will define high performance data and proceed to isolate methods for analyzing high performance data, and finally deal with certain configurational aspects of it. The application of cache and solid state technologies along with their associated business case strategies are also examined.

PROBLEMS? . . . FIRST CONSIDER

- CONTINUING TRENDS (PROCESSING)
- TECHNOLOGY TRENDS (ARCHITECTURE)
- PRODUCTIVITY TRENDS (HUMAN)
- APPLICATION TRENDS (BUSINESS)

LET'S CONSIDER EACH IN TURN

FIGURE 2 - FOUR PERSPECTIVES ON TRENDS

TODAY'S PROBLEMS

In trying to define the problems (see Figure 2) apparent in todays environment, it is perhaps best to look at four perspectives on trends:

the continuing trend (information processing), the technology trends (architecture), productivity trends (human), and the application trend (business).

The information processing trend (see Figure 3) has been, and continues to be, the shift from batch to online services; that is not to say that batch is decreasing, instead, it is ever increasing. The true recognizable trend is that more and more of a company's business is moving to online services. This has some interesting ramifications. The first is that the workloads within the computing complex is increasing in a non-linear format. This near exponential growth requires more online capacity (storage) as more applications are implemented. The tasks associated with the backup of active data and the migration of inactive data becomes compounded, hence storage management principles and practices need to be revised and updated. As a matter of fact, many user lament the fact that today they are adding storage capacity in units of gigabytes instead of megabytes as was the case only a few years ago; this punctuates the need for more effective storage management policies. Also, the need for high availability and reliability of the various systems is of paramount concern.

The technology trends (see Figure 4) have enabled DASD capacity to increase by a factor of sixty, CPU speeds by a factor of thirty and DASD performance by a mere factor of four; this defines the biggest problem in I/O subsystems today. The ever diverging gap of CPU speeds and DASD performance is a constant source of embarrassment to major hardware vendors, and a nagging headache to the performance analyst. In fact, Singh et al [8] commented "that during the design phase of the 3090, analytical evaluations showed that additional improvements in the I/O subsystem performance would be of considerable importance for a processor in that performance range". They continue to comment that cached DASD subsystems would offer the much-needed improvement in DASD service times.

The productivity trend (see Figure 5) is based on the human need for fast (low), and consistent response times. Thadhani [2] and others studied the relationships of productivity and response time. It was concluded that subsecond response times provided the highest productivity gains. In most environments today, subsecond response time is a fact of life, and an expectation; the only exception being those application areas that involve a considerable amount of data entry and subsequent processing.

The application trend depicts the increasing use of fourth or even fifth generation languages for application implementation. The impact on the I/O subsytem is manifested by way of large databases and many physical I/Os per transaction; this makes DASD tuning a challenge for even the most experienced performance analyst. This trend is expected to continue in an even more accentuated manner, suggesting that at some point in the future significant changes in the I/O architectures will be required to meet the response times, the availability, and reliability criteria.

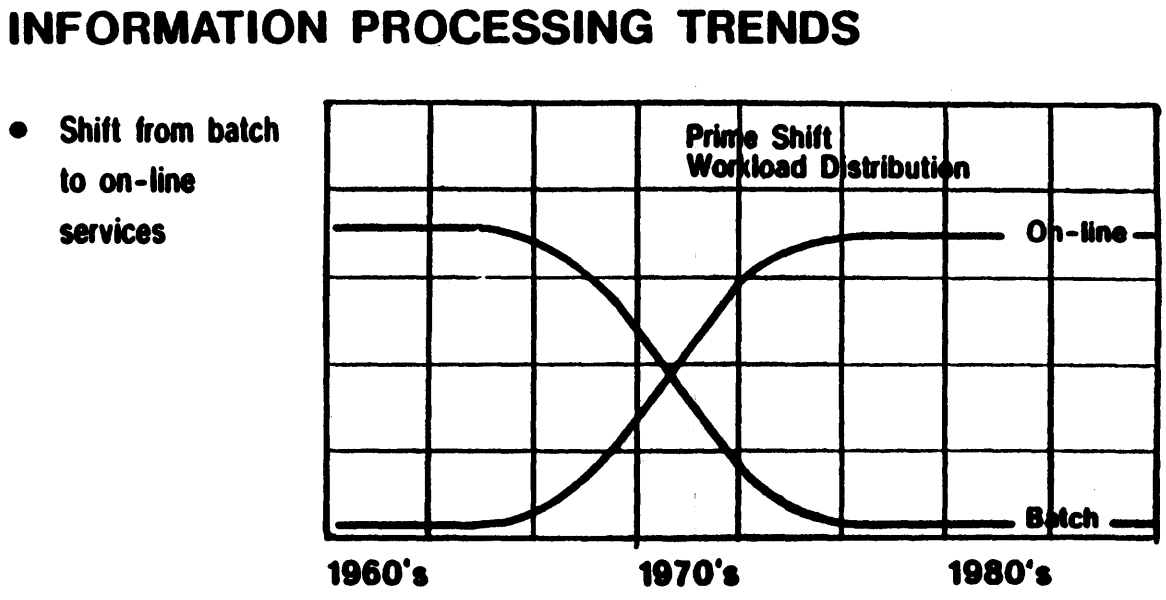

FIGURE 3 - INCREASING PRIORITY ON ON-LINE SERVICES

TECHNOLOGY TRENDS

CPU speed, 30X faster

DASD performance, 4X faster

FIGURE 4 - COMPARING THE TECHNOLOGIES: CPU & DASD.

PRODUCTIVITY AS A FUNCTION OF RESPONSE TIME

- **Productivity Factors**
  - **Fast response**
  - **Consistent response**

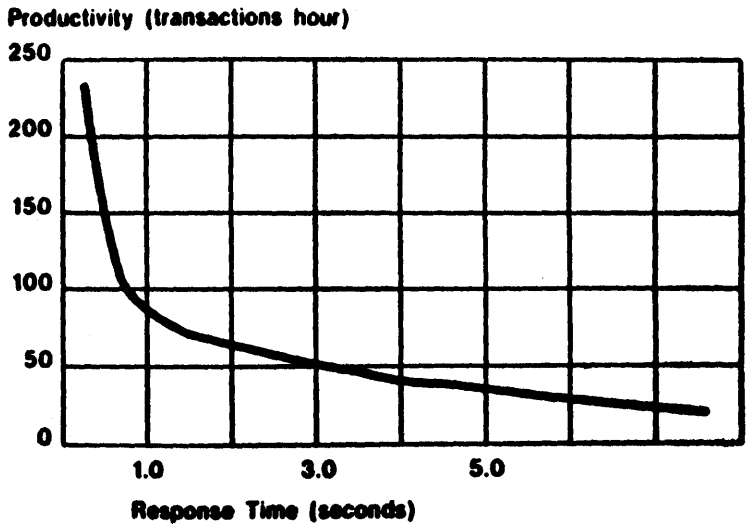

FIGURE 5 - THE PRODUCTIVITY TREND: SUBSECOND RESPONSE TIME.

Such changes may include device transparency and increased I/O parrallelism.

The trends therefore highlight the need for: increased availability and reliability, increased storage capacity, better storage management, increased I/O capacity, and better I/O service time.

It is not surprising then that approximately seventy-five percent of all reported performance problems are due to I/O contention. This is precisely why the technologies of I/O subsystems need to be evaluated on a continuing basis.

TOMORROW'S TECHNOLOGY ?

- BIGGER/FASTER PROCESSORS
- MORE CHANNELS/ FASTER CHANNELS
- EXPANDED STORAGE
- HIGHER CAPACITY DISKS (3X, 4X)

FIGURE 6 - TOMORROW'S TECHNOLOGY ??

FUTURE PROCESSORS

It is evident (see Figure 6) that future processors will be much bigger and faster; this will only widen the gap between processor speed and DASD access times, thus making an already bad situation worse. It is intuitively obvious that the usage of those processors will require more sprawling I/O subsystems. The key fundamental metric is data bandwidth; this increases as a function of processor speed. It is also a fact that future processors will offer more channels that may be even faster than existing ones; this provides the ability to address the I/O bandwidth requirement, but it also implies the procurement of newer technologies that will attach to it. One can speculate on such technologies as the triple or quad density disk drives and the availability of 4.5 and/or 6 megabyte transfer rates.

FASTER CHANNELS

Even if higher transfer rates were to become a reality with existing technology, it only still addresses one component of the I/O service time - that being transfer time. For example, (see Figure 7) consider a 4K transfer on a 3 megabyte channel taking approximately 1.3 milliseconds and then the same block on a 6 megabyte channel halving that time to 0.65 milliseconds. The saving of 0.65 milliseconds per I/O for a processor doing 400 I/Os per second will be approximately 260 milliseconds per second. Now consider one quarter of 400 I/Os (100 I/Os) with a current service time of 16 milliseconds which is later reduced by a mere 3 milliseconds to 13 milliseconds, thereby yielding a savings of 300 milliseconds per second. It is obvious that treating even a subset of the total I/O rate to a lower service time can outperform transferring the whole set of I/Os at an increased transfer rate. The above scenario can be computed for a 4.5 megabyte transfer rate, and is left as an exercise for the reader.

DO YOU WANT FASTER CHANNELS?

3 MB/SEC 4K BLOCK = 1.30 MS

4.5 MB/SEC 4K BLOCK = 0.87 MS

6 MB/SEC 4K BLOCK = 0.65 MS

- 400 I/O PER SEC @ 6 MB/SEC SAVES 260 MS/SEC

- CONSIDER: 100 I/O PER SEC WITH SERVICE TIME OF 16 MS REDUCED TO 13 MS
  ==> SAVINGS OF 300 MS

NOTE: SEEK AND LATENCY ARE NOT IMPACTED
THEY REMAIN A FUNCTION OF THE TECHNOLOGY

REDUCING THE TRANSFER TIME EMPHASISES THE NEGATIVE EFFECTS OF SEEK AND LATENCY

FIGURE 7 - CHANNEL TRANSFER RATE ANALYSIS

In the case of DASD I/O (see Figure 8), seek and latency are not influenced; and they remain a function of the technology. The percentage improvement of the I/O in going from 3 mb/sec to 4.5 mb/sec was 12.2; from 4.5 mb/sec to 6 mb/sec, it was 6.25; and from 3 mb/sec to 6 mb/sec, it was 17.7. Duhl [12] discusses many of the issues surrounding faster channels and their applicability to future subsystems. Thus, faster channels alone is not a solution to improving I/O subsystem performance; one must impact the negative effects of seek and latency.

TYPICAL 4K I/O

	3 MB CHANNEL		4.5 MB CHANNEL		6 MB CHANNEL	
SEEK	3.0	17.9%	3.0	20.4%	3.0	21.7%
LATENCY	8.3	49.4%	8.3	56.4%	8.3	59.7%

EXPANDED STORAGE

The current uses of expanded storage on the 3090 processors is an effective means of reducing page and swap traffic. While other uses exist for expanded storage (data base buffers, VIO, and linear data sets), cost, volatility and sharing still remain as outstanding concerns. There are other ways to provide better cost performance for any given system; some of these issues are addressed in detail by Mungal [11].

HIGHER CAPACITY DISK

Higher capacity disk (rumoured 3X & 4X - 3 and 4 times the current "D" capacity respectively) holds great promise for the realization of a much lower than current cost per megabyte, and associated environmentals. However, even that promise degrades to superficiality when one scrutinizes the access density characteristic of them. Access density is discussed later in this paper.

CHARACTERIZING HIGH PERFORMANCE DATA

HIGH PERFORMANCE DATA IS CHARACTERIZED BY:

- HIGH I/O RATES
- LOW SERVICE TIME REQUIREMENT
- HIGH AVAILABILITY REQUIREMENT

FIGURE 9 - CHARACTERIZING HIGH PERFORMANCE DATA

High performance data (see Figure 9) is characterized by high I/O rates, a low service time requirement, and high availability requirement. In fact, the high availability criteria led to the development of the dual frame architecture featured in current DASD controllers. There are many questions (see Figure 10) to be answered in further qualifying high performance data. The first category of questions qualify the "what is" high performance data, i.e., what subsystems utilize it, what are the characteristics of it in terms of read to write ratio, I/O rates and so on.

CHARACTERIZING/QUALIFYING HIGH PERFORMANCE DATA

- WHAT COMPRISES YOUR HIGH PERFORMANCE DATA (HPD) ?
- WHAT SUBSYSTEMS REQUIRE ACCESS TO HPD ?
- WHAT ARE THE CHARACTERISTICS OF IT ? I.E. R:W RATIOS, I/O RATES ETC
- WHAT WILL YOU DO IF THE DEMAND FOR IT INCREASES ?
- WHERE DOES IT CURRENTLY RESIDE ?
- WHERE SHOULD IT BE PLACED IN THE FUTURE ?
- HOW MUCH EFFORT IS REQUIRED TO MONITOR ITS PERFORMANCE AND RESPONSE / SERVICE TIMES ?
- HOW MUCH DOES IT COST ?
- HOW MUCH OF MY BUSINESS DEPENDS ON IT ?
- HOW MUCH AVAILABILITY IS ACCEPTABLE ?

FIGURE 10 - FURTHER CHARACTERIZING/QUALIFYING HIGH PERFORMANCE DATA

The second category of questions qualify the "where" high performance data should reside, i.e.,on the processor (1 or more), disk, solid state or some combination thereof.

Improper placement/configuration of high performance data will translate to increased cost to the user in terms of dollars, performance, availability, and even reliability

The last category of questions is concerned with qualifying "how much" effort and capital is invested on an ongoing basis in high performance data. This category of questions defines the reliability and availability criteria since they are a direct function of cost; it also deals with the cost per megabyte issue.

ACCESS DENSITY

The concept of access density is a well understood one. It is defined as accesses per second per gigabyte; and as yet, serves as the only correlation between access activity to a volume (I/O rate) and volume capacity (gigabytes). In fact, access density has declined steadily over the years with a promise for even further decline if higher capacity devices become a reality. Arresting this steady decline can only be addressed by accommodating more actuators per volume in future dasd devices.

Figure 11 shows the access density for "D" type DASD boxes; note the rapid decrease of access density as i) the string length is varied from 1 to 4 boxes, and ii) the I/O rates is varied from 20 to 100 I/O's per second. In fact, one may well argue that I/O rates in excess of 60 I/O's per second to a string of D's requires cache, and hence, this data may be so interpreted.

Recent GUIDE surveys indicated that the average allocation percentage across strings in many large environments was only 45%. Figure 12 shows the behaviour of access density when only 45% of the string is allocated/used; again a range of I/O rates is considered. This suggests that users traded capacity to achieve performance as manifested by the greatly increased access density (compared with Figure 11).

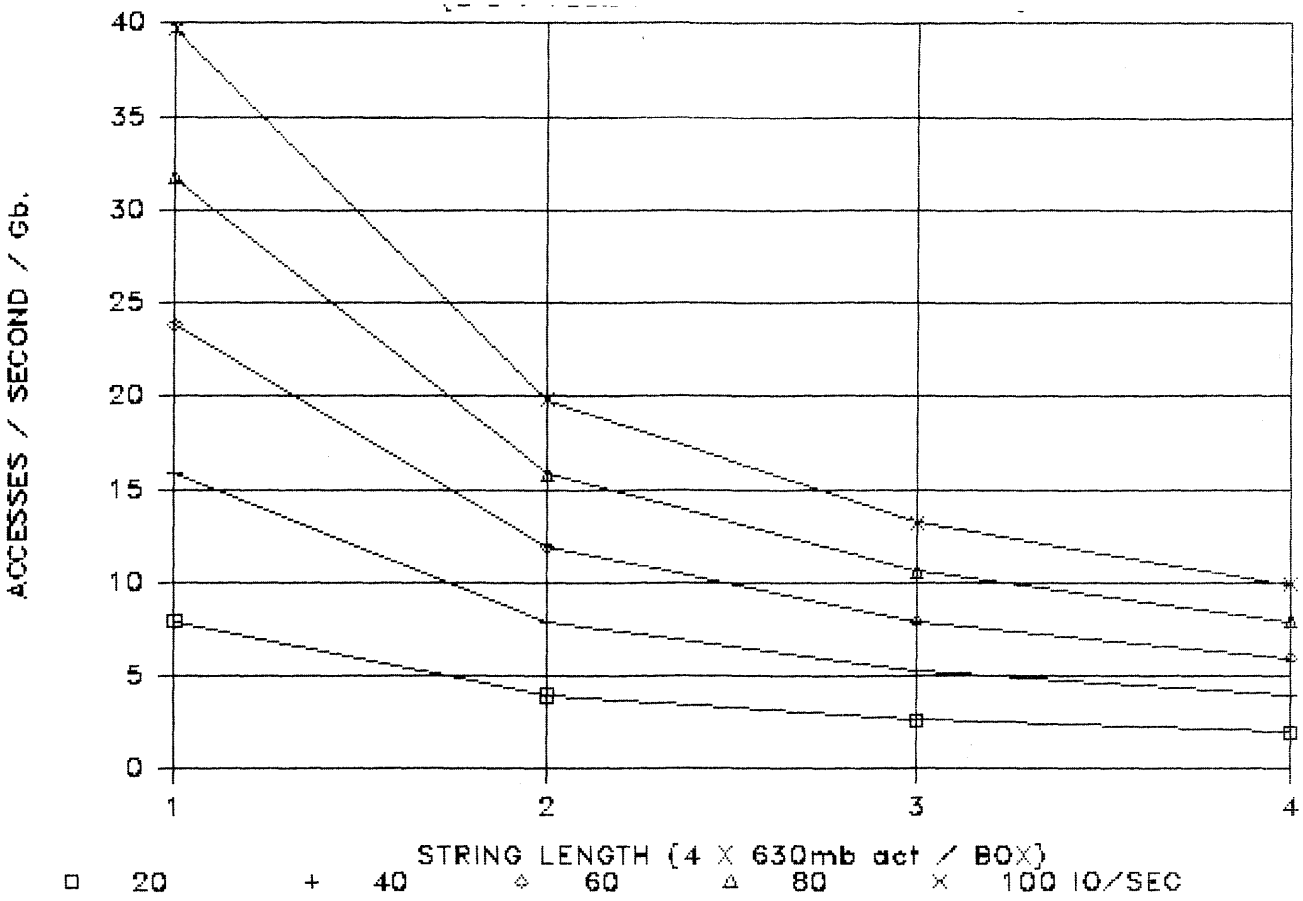

FIGURE 11 - ACCESS DENSITY VS STRING LENGTH (100% ALLOCATED): A COMPARISON OF 5 I/O RATES.

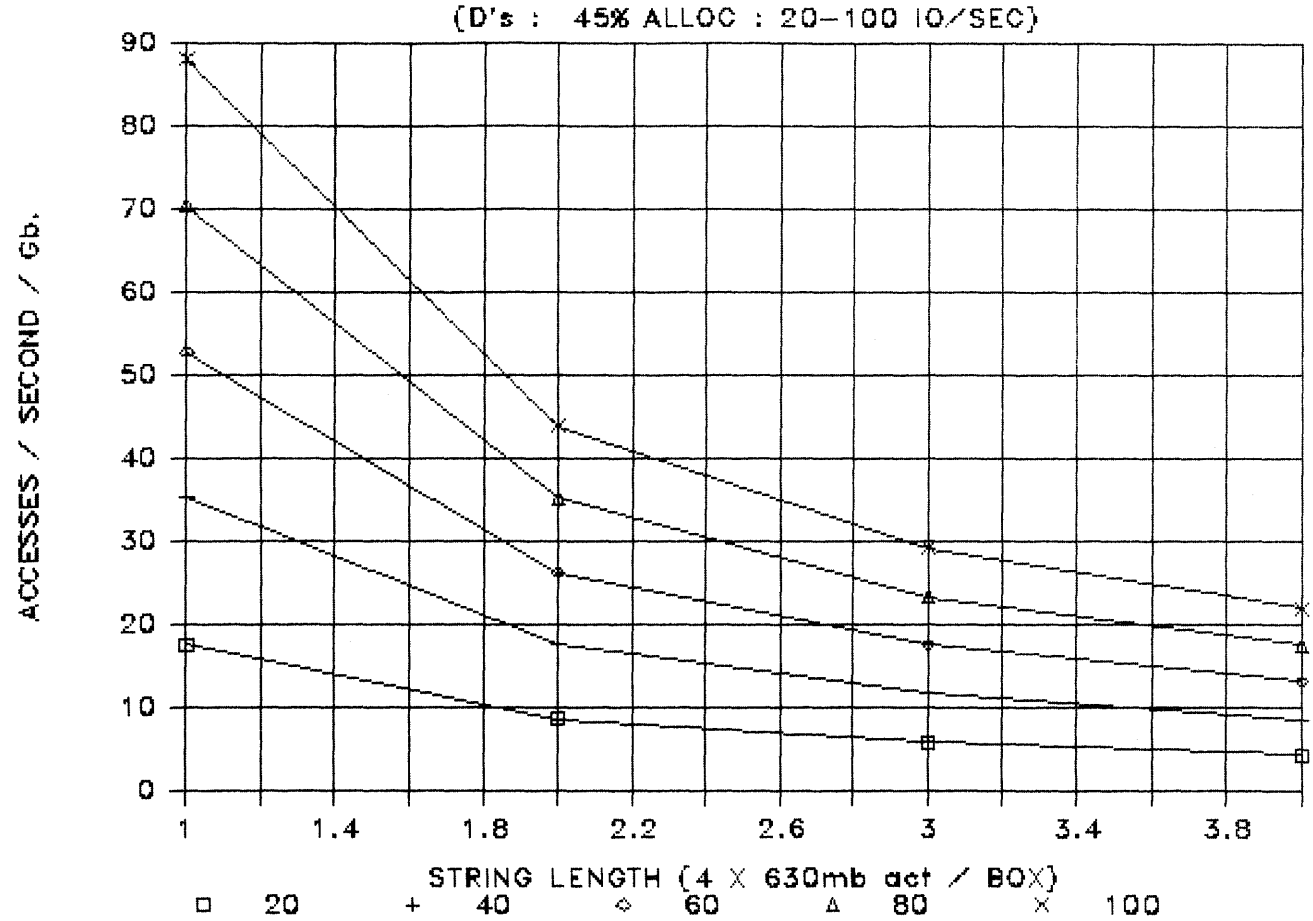

FIGURE 12 - ACCESS DENSITY VS STRING LENGTH (45% ALLOCATED): A COMPARISON OF 5 I/O RATES.

Figure 13 shows similar data to Figure 12, except that it demonstrates the behaviour of access density as the percentage allocation is increased (string becomes loaded), and the string length (1 to 4 boxes) is varied. Given that access density varies with any/all of I/O rates, string length, and percent allocation, suggests that the job of capacity planning and/or tuning is somewhat simplified; since it is usually easy to hold at least one of them constant (e.g. string length).

Figure 14 depicts the relationship of access density with I/O rate, when the latter is subjected to a shallow exponential growth. This sort of analysis is useful for determining the "strength" of the subsystem, and it's ability to respond to wide fluctuations in I/O load; this strength is typified by the solid state disk.

Figure 15 shows the behaviour of access density and gigabytes per string; the I/O rates vary from 40 to 160 I/O's per second. Even with the higher I/O rates (> 80), it becomes evident that beyond a certain string capacity, one must be prepared to employ cache as an effective means of achieving acceptable access densities. For example, 20 gigabytes of data (2 full strings of E's) can be made to perform acceptably if sufficiently high I/O rates can be sustained; this is the principal domain of caching.

In general, similar analysis for any/all DASD device types is easy to accomplish. The message from such analyses is only to suggest that prior knowledge of criteria such as I/O rates, quantity of data to be accessed, and device type can go a long way in assisting the configuration/tuning efforts; cost emerges from this as being optimized.

CAPACITY OR PERFORMANCE

McNutt [1] used data from a survey of fifty-eight large installations (see Figure 16) spanning more than nine thousand DASD devices. This shows that a high percentage of the devices are less than ten to fifteen percent utilized; this subset qualifies for double capacity pairing . Only a small amount of the devices exhibit high busyness; this subset of devices is the classic candidate for residence on single capacity actuators, cache and/or solid state disk. This is an example of a methodology that would allow the identification of high performance data. An interesting by-product of such a methodology is the isolation of other data.i.e. data/string homogeneity. Another methodology would be that of employing access density as previously discussed.

CONFIGURATIONAL CONSIDERATIONS (SINGLE AND DOUBLE CAPACITY)

The strategy of placing data on double capacity devices looks at the device busyness which in turn is related to the number of concurrently open data sets per volume. On these devices, the potential exists for significantly more data sets , thereby increasing the odds for

contention which in turn would result in degraded I/O times.

RATIONALE FOR ACQUIRING "D" TYPE DASD

- HIGHER ACCESS DENSITY THAN "E" TYPE DASD
- UNCACHED: VERY GOOD PERFORMANCE/CAPACITY
- CACHED: EXCELLENT PERFORMANCE
  INCREASED ALLOCATED CAPACITY
  INCREASED ACCESS DENSITY

FIGURE 17 - APPLICABILITY OF "D" TYPE DASD

Many customers (see Figure 17) share the concern of whether or not single capacity devices are still applicable to their environment. In fact, many high busy volumes are perfectly suited to single capacity devices; these devices provide a good blend of capacity and performance. They also have a higher access density than their double capacity counterparts. By caching single capacity devices, one can boost both capacity and performance , which in turn results in even better access density.

How much intermix of single and double capacity should be tolerated at the string level? The answer to this question lies within an examination of the access density required for the data that is to be configured. This can be determined from Resource Management Facility data (RMF).

Figure 18 depicts the performance considerations for single capacity disks according to string length. It suggests the service times for certain I/O rates for any given number of actuators (up to 16).

PERFORMANCE CONSIDERATIONS

SIO/SEC/ ACTUATOR	A	B	C	D
5	14.2	15.7	16.3	16.9

15	18.2	20.9	24.4	29.2

A = AD4 *** MODELED DATA
B = AD4 + BD4
C = AD4 + BD4 + BD4
D = AD4 + BD4 + BD4 + BD4

(4K BLOCKS; M/G/m)

FIGURE 18 - SUBSYSTEM RESPONSE TIMES AND STRING LENGTH

Having dealt with the issues surrounding single and double devices, the discussion shifts to true high performance data.

HIGH PERFORMANCE SUBSYSTEMS

High performance data (see Figure 19) belongs on high performance subsystems. When configured as such, the benefits provided will at least include the following: low service times, better I/O load, better I/O capacity, less tuning effort, consistency of service times (and the associated response times) and lower data centre costs. This leads to an examination of the benefits associated with caching.

HIGH PERFORMANCE DATA BELONG
ON A HIGH PERFORMANCE SUBSYSTEM

WHY ??

- SERVICE TIMES
- I/O LOADING ENHANCED
- BETTER USE OF EXISTING CAPACITY
- LESS TUNING EFFORT
- CONSISTENCY (TUNING; RESPONSE/SERVICE TIMES)
- FINANCIALLY ATTRACTIVE

FIGURE 19 - BENEFITS OF CONFIGURING HPD SUBSYSTEMS

CACHING

Before one can proceed with caching ,it would be useful to digress on cache analysis as a method of determining the cacheable data within any environment. Mungal [6] deals with this in detail. Other references include Gray [9] and Friedman [10]. Cache analysis is not dealt with at this time.

In applying cache to any environment (see Figure 20), one can adopt either or both of the following methodologies: dedicated caching and selective caching.

- DEDICATED CACHING
- SELECTIVE CACHING

ANALYSIS WILL DETERMINE WHICH ONE OR WHICH BLEND IS MOST APPLICABLE

FIGURE 20 - CACHING METHODOLOGIES

DEDICATED CACHING

Dedicated caching requires a more detailed data analysis of the environment. Such analysis will identify all of the cacheable volumes and will suggest which ones are best suited to a sufficiently large cache; this subsystem contains only cached data, since all volumes are defined as cacheable. This cache methodology has the advantages of being very stable, in that I/O tuning is minimized since the data is static by default.

Dedicated caching also lends itself to data homogeneity since most, if not all, of those volumes in the subsystem will exhibit similar read to write ratios, hit ratios and I/O rates. It is financially very attractive since it has the ability to provide the highest access density, thereby minimizing effective cost per megabyte.

The only major disadvantages with dedicated caching is that only a finite amount of data within any environment qualifies and data homogeneity is sometimes difficult to attain and even more difficult to maintain.

SELECTIVE CACHING

Selective caching identifies the hot data within a given subsystem; only that data is defined as cacheable to a sufficiently large cache and the subsystem is monitored from time to time. It is already obvious, from witnessing various customer environments that selective caching is the preferred means of deploying cache controllers to handle the needs of high performance data. The cache size is suitable to the amount of data, the I/O rates, and locality of reference patterns for the cacheable volumes within the subsystem, hence the economic benefits are maximized.

The obvious benefit of selective caching is that it allows a unique starting point for cache on a per string basis, thereby providing the very flexible growth capabilities in terms of the cache size, I/O rates and device capacities. Selective caching provides a very attractive cost/performance ratio.

Dataset level caching allows a significantly better level of granularity for dealing with dasd skew. This is a major enhancement to the overall process of selective caching.

Figure 21 shows the relationship between increasing I/O rates and response times for both cache and uncached subsystems. It is evident that cache subsystems provide the user with the ability to increase the I/O load at the same or lower response time that an uncached system, thereby gaining I/O capacity; or decrease the response time for the same load as an uncached subsystem, thereby achieving better response time. Those benefits are important to the capacity planner since they reflect the ability of the cache controller to behave as multiple uncached controllers.

Figure 22 examines a sample business case which serves to justify the cost of caching against any buyback in allocated capacity on either a volume or string level. In Figure 22, line A represents the capital cost of an uncached controller; line B represents an adjusted cost which reflects the level of allocation within that string (i.e., industry surveys indicate that strings are somewhere around forty five percent allocated);line C indicates the incremental cost of adding cache to this configuration, and thus has an increased cost per megabyte associated with it; line D represents the new cost per megabyte associated with being able to utilize more of the disk capacity once caching is activated; the difference between lines B and D is representative of the cost savings once a cache is deployed. The sample cost per megabyte for each curve (A thru D) is evidenced in Figure 23.

In summarizing the use of cache technology as it applies to todays high performance subsystems the following benefits are obvious: better device utilization of the cached actuators, lower service times, increased I/O capacity at the cached device and subsystem level, incremental savings in both floor space

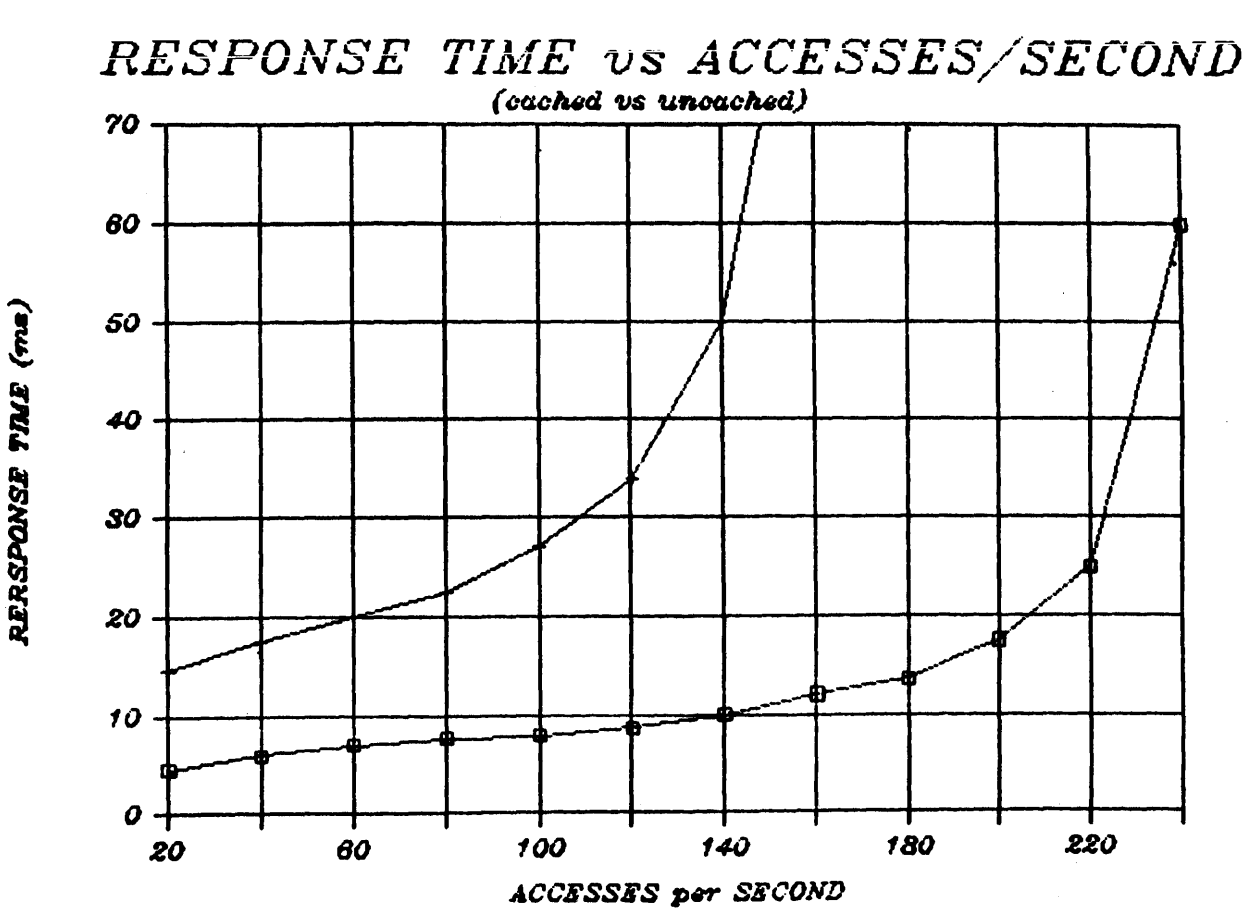

FIGURE 21 - RESPONSE TIME VS ACCESSES / SECOND:
COMPARING CACHED AND UNCACHED SUBSYSTEMS.

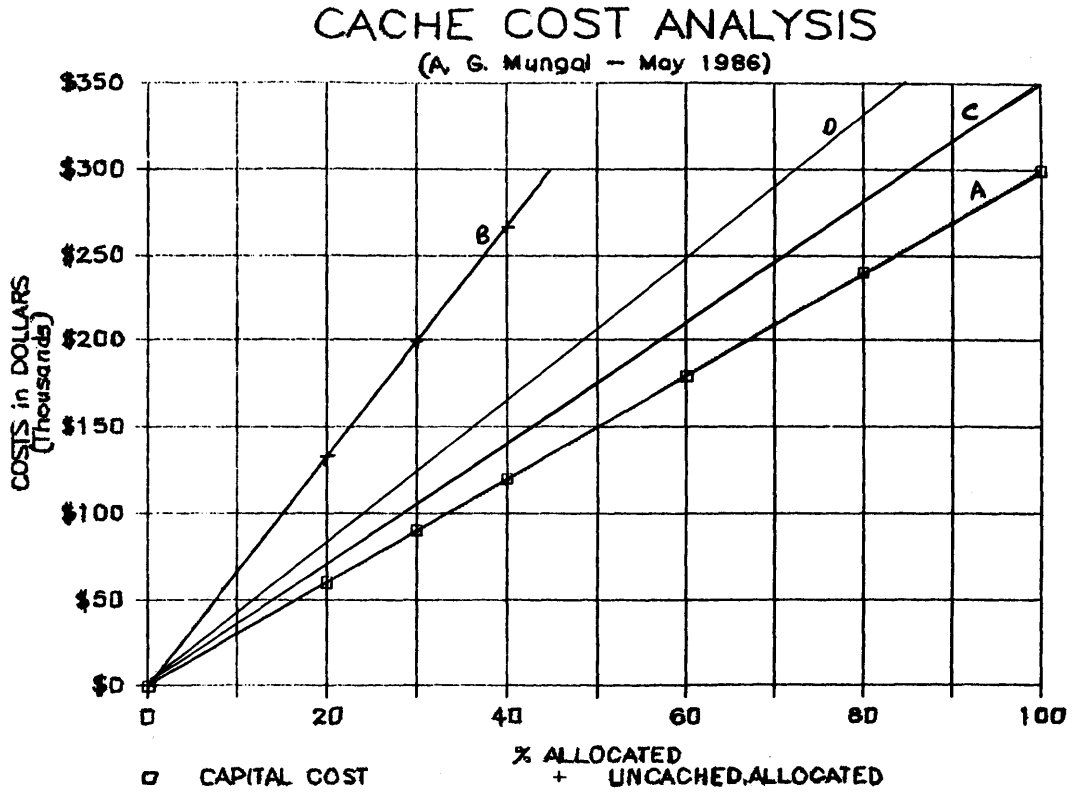

FIGURE 22 - A BUSINESS CASE JUSTIFICATION FOR CACHE: SAMPLE.

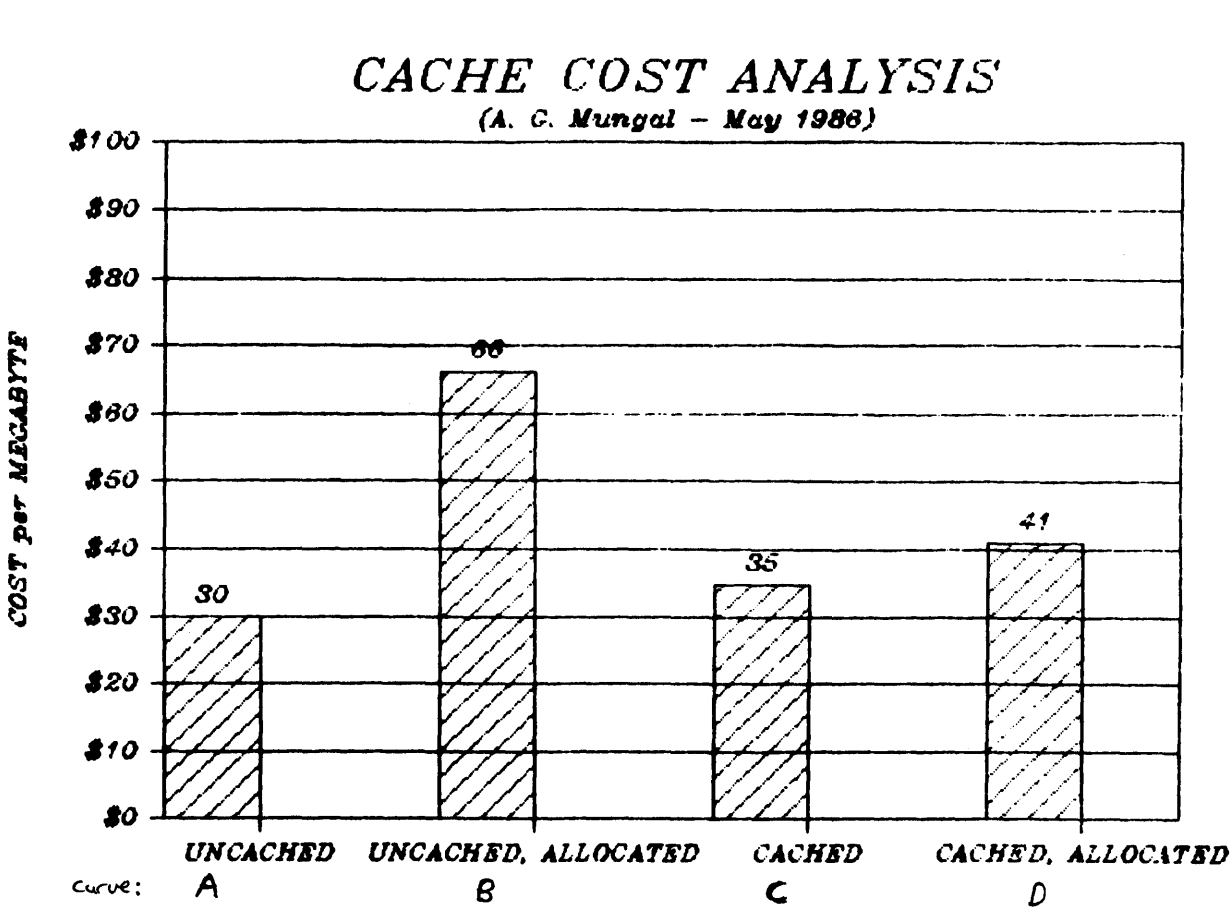

FIGURE 23 - COMPARING THE COST PER MEGABYTE.

and power; and also it provides the only real alternative to short strings.

APPLICABILITY OF SOLID STATE

Solid state subsystems share a subset of the high performance data configurable for caching. Data for solid state subsystems is characterized by high I/O rates, service time sensitive (low service time requirement), read to write ratio unsuitable for caching. The only concern for data on solid state subsystem lies in volatility; the issue of volatility is dealt with differently by various vendors of this technology.

The classic application area for the solid state disk has been, and continues to be, paging and swapping. This particular application area has been dealt with in other papers and is extremely well understood. Solid state subsystems, by virtue of their very low access times, the absence of seek and latency , have the ability to provide the best access density of all I/O systems being studied. It is this property that will allow for the most flexible and varied uses of this technology.

Even on processors configured with expanded storage, this technology can be used as a spill device. By employing solid state technology, one can insure that the access time disparity between expanded storage and the I/O subsystem is reduced. Mungal [11] suggests a method for utilizing solid state swap/page subsystems as a means of "effectively utilizing" main memory.

FUTURE CONSIDERATIONS

As high performance data continues to increase dragging the high reliability and availibility criteria, one must expect that devices employed in this arena will possess inherently high reliability and availability qualities. The issue of connectivity will also be of paramount importance in such subsystems. In coming to grasps with the requirements for low access times, one may expect that caches will become bigger, controllers smarter, and solid state subsystems to offer increased capacity and a myriad of pathing options. Disk subsystems may be expected to utilize smaller disks, provide buffering at the actuator level, and facilitate multi-porting (quad or octal).

Access density, which is the only true measure of I/O load and data set size, remains a useful measure for estimating the requirements of high performance subsystems. Utilizing access density as a means of evaluating the effectiveness of I/O subsystems, will provide the user with valuable information as to future configurations.

ACKNOWLEDGEMENT

I would like to thank my wife, Saroj for her painstaking efforts in the typing of this manuscript; also, for her patience and understanding during her many lonely hours while I prepared it.

AUTHOR/SPEAKER

Anthony Mungal is currently employed within Systems Engineering with Amdahl Canada Ltd. Prior to that he spent six years with Storage Technology (StorageTek Canada Inc.) in various positions within Systems Engineering, including product specialist, SE management and Consulting SE. His background is in systems programming with emphases on performance and tuning, capacity planning, storage management, programming, and I/O subsystems. He is a graduate of the University of Toronto (majors in mathematics and computer science) and an active member of the Association for Computing Machinery (ACM) and CMG Ontario.

PAGING, SWAPPING AND EXPANDED STORAGE

Jeffrey P. Buzen
J. William Mullen
Annie W. Shum

ABSTRACT

The introduction of expanded storage in IBM 3090 systems has been accompanied by a number of changes to the MVS algorithms that manage paging and swapping. This paper discusses the rationale for these changes and then explains their impact on certain measurement data reported by RMF. In addition, the paper illustrates several important aspects of page and swap performance through use of an analytic model.

INTRODUCTION

MVS has always supported a variety of devices for paging and swapping. When expanded storage became available, it could have simply been treated as a new type of paging or swapping device. The new device would, of course, rank higher than all others in terms of speed, and it would clearly require its own device driver.

Once these changes were made, MVS could have operated as usual. That is, system programmers could have allocated page and swap data sets directly to the new "expanded storage device", the existing page and swap algorithms could have accessed these data sets without modification, and the reports produced by RMF on page and swap activity could have included measurements of the additional traffic to the new page and swap data sets.

Although the VM/SP operating system has, in essence, adopted this approach, MVS has not. Instead, MVS has chosen to treat expanded storage as an entirely new type of resource, requiring special algorithms for management and new formats for performance reporting. In addition, the algorithms that control paging and swapping in MVS have been modified to take advantage of certain special properties of expanded storage.

There appear to be at least four reasons why MVS and VM have followed different paths:

1. VM already provided a page migration mechanism, whereas MVS did not.

2. Given that MVS had to be modified to support page migration, other algorithm changes needed to exploit the special properties of expanded storage were presumably easier to justify.

3. MVS had a greater need to provide selective control of expanded storage for individual workloads such as IMS, TSO and batch.

4. Given that all the above changes were being made, there was the additional opportunity to install changes needed to support DB2, VSAM linear and Data in Virtual (DIV).

The next few sections of this paper discuss these points in greater detail.

PAGE MIGRATION

Both MVS and VM are designed to favor higher speed paging devices over devices with lower speeds. In MVS, higher speed devices are used first, and lower speed devices are only used when no other space is available.

VM goes even further. If high speed paging devices become full, pages that have resided on these devices for a long time can be migrated (i.e., moved) to lower speed devices to make room for new pages being removed from central storage.

Note that migration is a costly process since it requires one read and one write operation for each page or block of pages that are migrated. Nevertheless, if there is a substantial difference in speed among the available paging devices, the cost of migration can be more than offset by having the most important (i.e., the least recently used) pages on the highest speed devices.

With the advent of expanded storage, the overhead of the migration process was substantially reduced (the estimated page transfer time between central and expanded storage is only 75-80 microseconds [2]). Also, the speed difference between expanded storage and conventional auxiliary storage could now be more than two orders of magnitude. These two factors made it essential to modify MVS to support page migration once expanded storage became available.

PRIMARY AND SECONDARY WORKING SETS

The designers of MVS have also introduced a number of other changes that can, in principle, substantially improve system performance by exploiting the special properties of expanded storage. One such change involves control of the swap-out/swap-in process. In systems without expanded storage, one of the critical steps in the swap out process is identifying the "working set" pages of the address space being swapped. These are the pages that the address space will need when it is swapped back into central storage and resumes execution.

To improve efficiency, working set pages are swapped out in contiguous groups to all available swap devices. When a swap-in is required, all working set pages are transferred back to central storage before the address space begins execution. In this way, address spaces can avoid generating costly demand page faults for pages that are part of their working sets.

Note, however, that demand page faults are not at all costly if the required page is in expanded storage. In fact, the CPU overhead to move a page from expanded to central storage is approximately the same for both page-in and swap-in operations. Hence, there is no real advantage to swapping the entire working set back into central storage before allowing an address space to resume execution.

MVS architects exploited this fact by introducing a distinction between primary and secondary working sets. The primary working set for a task contains only its LSQA pages and fixed pages. Secondary working sets are all pages owned by the task but not included in the primary working set.

At swap-out time, if the task is going to expanded storage (rules discussed later), the working set for the task is trimmed and the pages are transferred to expanded storage.

At swap-in time, only the primary working set for the task is swapped in. Thus, the task can resume execution more quickly, reducing response time.

After task swap in, the secondary working set pages remain in expanded storage and may subsequently be brought in via demand paging. In addition to improving response time, this algorithm also makes better use of central storage since only those pages actually used by the task are ever paged back in.

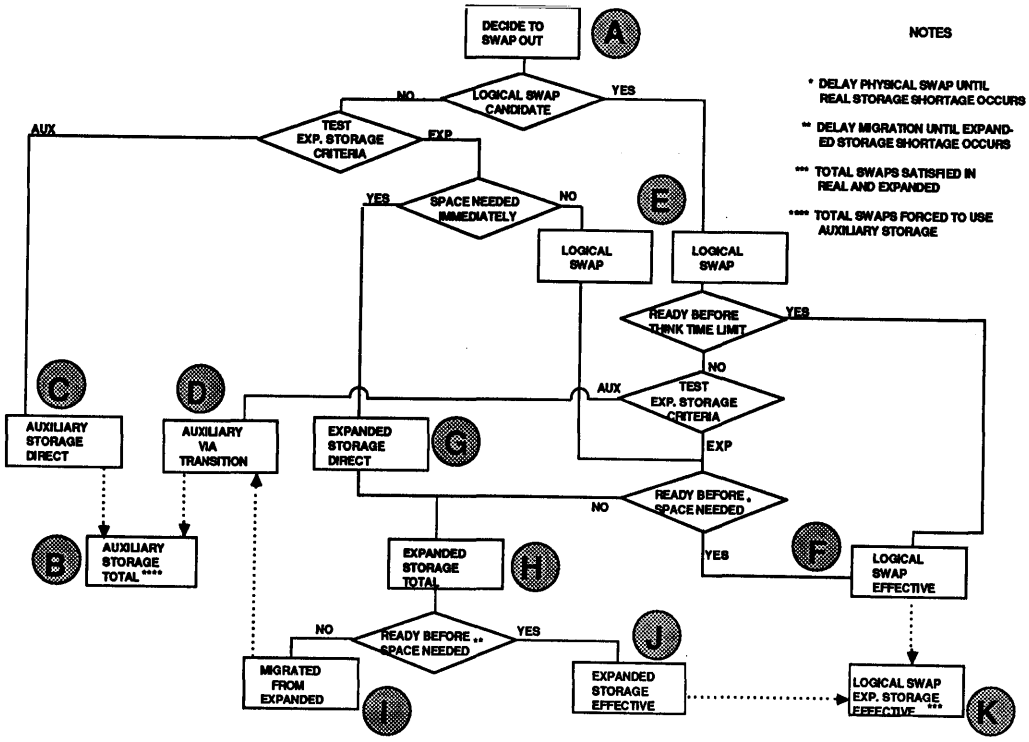

Figure 1

SWAP OUT ALGORITHM

A number of other changes have been made to the algorithms controlling logical and physical swapping in MVS. The flowchart in Figure 1 presents an overview of these algorithms. The flowchart begins at Box A when the decision is made to swap an address space out of central storage. The swap out decision could be the result of a variety of conditions including terminal input/output wait, long wait, detected wait, unilateral swap, exchange swap, etc.

Once the swap decision is made, the next step is to determine whether or not the address space is a logical swap candidate. For interactive tasks, this depends on whether the user's think time is less than the value of system think time.

Suppose that the address space is a logical swap candidate. In this case, the right branch (yes) below Box A is taken and the address space proceeds to Box E, Logical Swap. The address space is then allowed to remain in central storage until the "think time limit" expires. For interactive tasks, this limit is equal to the current value of the system think time. For batch tasks, this limit is a fixed constant (MVS currently uses 5 seconds).

If the address space becomes ready before the think time limit is reached, there is no need to carry out a physical swap. Instead, the address space proceeds to Box F (Logical Swap Effective) and is re-dispatched.

Thus far the existence of expanded storage has not affected any aspect of the basic algorithm. Suppose, now, that the address space does not become ready before the think time limit expires. In this case, a test of the expanded storage criteria is made to determine if the address space should be swapped to auxiliary or expanded storage. The nature of this test will be discussed later.

Suppose that the test indicates that the swap is to auxiliary storage. The address space will then proceed to Box D (Auxiliary via Transition) and be swapped out. The term "transition" refers to the fact that the address space has made a transition from a logical to a physical swap.

On the other hand, suppose that the test indicates that the swap is to expanded storage. In this case the original swap out algorithm is modified slightly. Note that expanded storage functions as an exceptionally fast swapping device; since the address space can be swapped out to expanded storage so rapidly, there is no need to initiate the swap out immediately unless central storage is needed by some other task. Hence, if central storage space is not needed, the address space is given a "second chance" and allowed to remain logically swapped even though the think time limit has expired. This "second chance" can be quite valuable since it allows systems to react immediately to fluctuations in the demand for real storage.

If, after its second chance, the address space becomes ready before the space it occupies in central storage is needed, there is an opportunity to proceed to Box F (Logical Swap Effective) as illustrated in Figure 1. On the other hand, the address space's page frames in central storage may be needed before the ready condition occurs, and there may, in fact, be a swap out to expanded storage via Box H, Expanded Storage Total.

At this point it is helpful to break the flow and return to the decision point below Box A. Now consider address spaces that are not logical swap candidates. Taking the left branch, the first test determines whether the address space should be swapped directly to auxiliary storage (Box C) or to expanded storage. Following the right hand branch at this point implies that the address space should be swapped to expanded storage. Once again, the original swap algorithm is now modified since there is no need to swap the address space out immediately unless the page frames it occupies in central storage are needed for other purposes. If the space is needed, the address space is swapped directly to expanded storage (Box G) and counted in the expanded storage total (Box H).

On the other hand, suppose the space in central storage is not needed immediately. In this case, the algorithm gives the address space a "second chance" and allows it to remain in central storage. However, the only means available for providing this second chance is to mark the address space as "logically swapped" (second copy of Box E). Thus, address spaces that are not logical swap candidates can, in fact, be logically swapped under this algorithm.

Once an address space undergoes this special logical swap, it is treated the same way as an address space given a second chance after exceeding its think time limit. That is, it either undergoes a swap to expanded storage (Box H) when its space is needed, or it completes a successful logical swap (Box F) if it becomes ready before its space is needed.

Figure 2

Now consider all address spaces that eventually become swapped to expanded storage (Box H). If they remain in expanded storage too long, the space they occupy may eventually be needed by other address spaces. In this case they are migrated to auxiliary storage (Box I). The dotted line connecting Box I to Box D indicates that migrated address spaces are also included in the total number reaching auxiliary storage via transition.

On the other hand, if an address space becomes ready before it is migrated, its primary working set is swapped back immediately to central storage (Box J). This box is labeled "Expanded Storage Effective" since it represents a desirable case where the swap-out/swap-in cycle is handled entirely by expanded storage.

Box K (Logical Swap/Exp. Storage Effective) represents the sum of Boxes F and J. In effect, it is a count of the total number of high performance swap cycles. In contrast, Box B (Auxiliary Storage Total) is the sum of Boxes C and D. It represents a count of all low performance swap cycles that used conventional auxiliary storage devices.

SWAP PLACEMENT ACTIVITY REPORT

The flowchart illustrated in Figure 1 bears a direct relationship to the RMF Swap Placement Activity Report shown in Figure 2. Each box in the flowchart corresponds to a column heading in the report, as indicated by the associated letters. The number of times that address spaces make transitions through the various boxes in the flowchart is represented both by raw counts and by percentages in this RMF report.

EXPANDED STORAGE CRITERIA

There are two decision points in this flowchart where the "Expanded Storage Criteria" are tested to determine if an address space should be swapped out to auxiliary or expanded storage. These tests are based on the IEAOPTxx parameter values in the Expanded Storage Criteria Table (ESCT). They also depend on the current values of the system high UIC, the migration age (MA), and the address space's think time.

In general, if there is space available in expanded storage, the address space will be swapped to expanded. If expanded storage is almost full, the address space may be swapped to auxiliary storage instead. See [1] for a further discussion of algorithms that operate on the ESCT.

MEASUREMENT OF PAGE/SWAP ACTIVITY

Paging and swapping activity in MVS is recorded by the SRM and subsequently retrieved by RMF for generation of the RMF type 71 record and the Paging Activity Reports. Introduction of the 3090 processors and expanded storage required a restructuring of the RMF type 71 record to provide usage statistics for expanded storage. Additional information relating to migration age and to page movement to expanded storage were added to the paging activity section of the record. Swapping activity for each of the 11 swap reason codes was removed from the body of the record and placed in the record's relocate sections. Each of the 11 relocate sections now contains swap placement information, including expanded storage usage, for the respective swap reason code.

The RMF Paging Activity Report was updated with Release 3.3 of RMF to reflect the new measurement values available in the RMF type 71 record. Two new values of interest to the performance analyst are the 'Rate of Page Movement to ES' and the 'Migration Rate'. Each of these values is reported as pages-per-second for the measurement interval. As a guideline, it has been suggested that the processor capacity used to transfer pages to and from expanded storage should not exceed a maximum of 5%. Using a value of 75-80 microseconds per page, this would imply that a 3090-400 processor should not have a transfer rate to and from expanded storage that exceeds 2500 pages per second ((1,000,000 * 4 processors * .05) / 80). This guideline must obviously be reconciled with other considerations such as the service objectives for the workloads being processed, and the impact that page movement has on these service objectives. In 303X and 308X systems without expanded storage, some performance analysts have traditionally recommended as a guideline that no more than 5% of processor utilization be devoted to demand paging operations. It is interesting to note that the same 5% value is now being recommended for 3090 systems with expanded storage.

A third value added to the Paging Activity Report is the minimum, maximum and average values of migration age for the measurement interval. These values are an indication of the contention for expanded storage frames. Average migration age also affects the probability of certain types of paging and swapping operations being directed to expanded or auxiliary storage, as explained previously.

The fourth value added to the Paging Activity Report is the number of installed and online expanded storage frames during the interval. If the online expanded storage frames reported for the interval is less than the installed expanded storage frames reported for the interval, the performance analyst should determine the cause.

The Swap Placement Report was replaced in RMF Release 3.3 with a new report identified as the Swap Placement Activity Report. The new report format, which is illustrated in Figure 2, was needed to report the various swap transition rates for each of the eligible swap reason codes and to provide the additional information on swapping activity to expanded storage. The Swap Placement Activity Report contains swapping information for only 7 of the 11 swap reasons since some of the swap conditions are not candidates for logical swapping or swap to expanded storage.

One statistic of interest to the performance analyst is 'LOG SWAP EFFECTIVE' (column F). This column contains the rate of logical swaps per second and the percentage of tasks logically swapped out that were subsequently swapped in from the logically swapped out state. A high percentage for this statistic indicates that contention for real storage is low.

A second important statistic is the'LOG SWAP/EXT STOR EFFECTIVE' (column K). A high percentage for this statistic indicates that contention for expanded storage is low and frames are plentiful. As this percentage decreases, the analyst will note a decrease in 'EXT STOR EFFECTIVE' (column J). The latter is most undesirable since it indicates that contention for expanded storage frames is growing and forcing the MVS/XA Real storage Manager (RSM) to remove pages from expanded storage (migration) and place them on auxiliary storage paging data sets.

Several statistics that are available to RMF for data capture and subsequent reporting are conspicuously missing from the Paging Activity Reports. The minimum, maximum and average system 'think time' for the measurement interval could be added to the Paging Activity Report to provide the analyst with a better view of the SRM decision making processes for the interval.

The RMF type 71 record contains a count of the pages written to expanded storage as well as a count of the pages migrated from expanded storage. These counts are converted to rates (pages/sec) and reported in the Paging Activity Report. It would be very desirable to add measurements of page-in rates from expanded storage to this report.

Information on individual task usage of expanded storage or specific types of task usage of expanded storage is currently available through the RMF type 79, subtype 1 (ASD) Monitcr II recording facility. This information could be accumulated in the RMF type 72 records for subsequent reporting in the RMF Workload Activity Report as minimum, maximum and average expanded storage frames utilized by performance group and domain during the interval. MVS/XA Release 2.2, available 3Q87, is supposed to provide additional information on expanded storage usage.

PAGE AND SWAP INTERACTIONS

Expanded storage adds one new dimension to the already complex process of characterizing paging and swapping behavior in MVS. Some of the major factors that affect this behavior will now be examined with the aid of a queueing network model. The model incorporates facilities for automatically evaluating paging and swapping behavior as various parameters are altered.

Consider first an MVS system without expanded storage. Suppose the external load on the system is held fixed while the size of central storage increases. As expected, paging and swapping are reduced in this case. Figure 3 illustrates this reduction for a typical model.

Even in this familiar case, note that two distinct factors are operating. First, demand paging is reduced since each active address space is able to acquire more page frames. This increase in resident set size implies that each address space will encounter less page stealing. Thus, the number of page faults caused by references to stolen pages is reduced. Figure 4 illustrates the nature of this interaction.

Swapping is also reduced in this case, but for a different reason. Essentially, increasing the size of central storage increases the system think time, allowing logically swapped address spaces to postpone the need for a physical swap. If the address space becomes ready soon enough, a physical swap is avoided. Figure 5 illustrates the nature of this process.

Note that other factors are also operating. For example, since the demand paging rate is reduced, each address space requires less time in central storage per transaction. Thus, the average multiprogramming level is reduced as illustrated in Figure 6. This in turn reduces the demand for real storage, allowing resident set sizes to increase further and logical swapping to be even more effective. The queueing model used in this example automatically accounts for these factors and incorporates them into the graphs that appear in Figures 3, 4 and 5.

A similar interaction between multiprogramming level, paging rate and swapping rate would arise if CPU or I/O device speeds were increased. This increase would, in general, reduce residency time. This would, in turn, reduce multiprogramming levels, making additional space available for active resident sets and for logical swapping. This would then reduce paging and swapping rates. The automatic analysis of these interactions is of real value in capacity planning applications.

Now consider a different set of interactions that occur when storage size is held fixed while the transaction arrival rate for interactive applications increases. As Figure 7 illustrates, both paging and swapping rates increase in this case.

Paging increases because, as the arrival rate increases, there is more queueing for the CPU and the I/O devices in the system. Thus, each transaction requires more time in central storage (i.e., residency time per transaction increases). This in turn increases the average multiprogramming level. Since there are more active address spaces at each instant, MVS will have to increase page stealing to reduce resident set sizes. This will cause more demand page-in's for stolen pages as Figure 7 illustrates.

Swapping will also increase in this case since the increase in transaction arrival rate is typically accompanied by an increase in the number of interactive users. With more logically swapped out users competing for space in central storage, MVS will reduce system think time and force physical swaps to occur sooner. This interaction is also accounted for in the queueing model used to generate Figure 7.

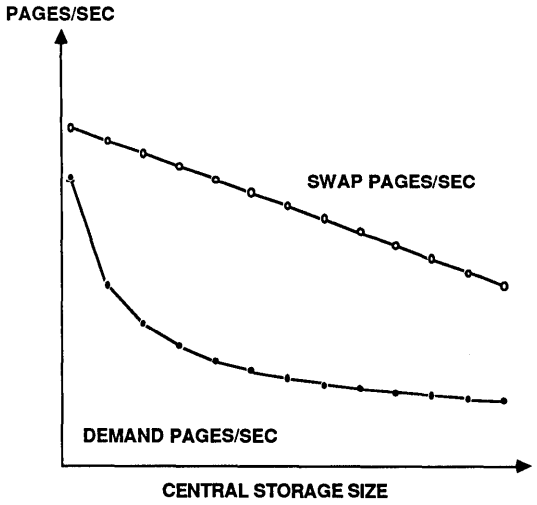

Figure 3

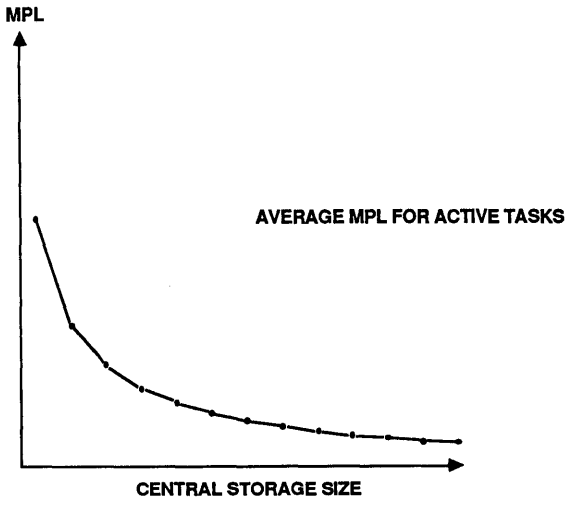

Figure 6

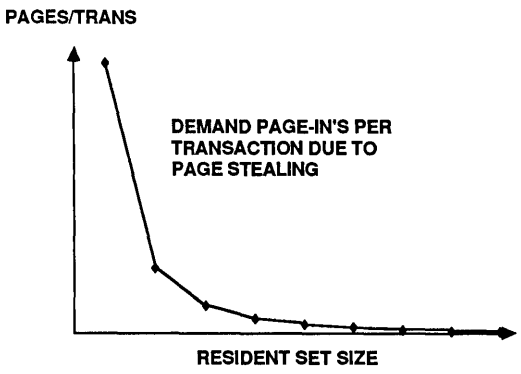

Figure 4

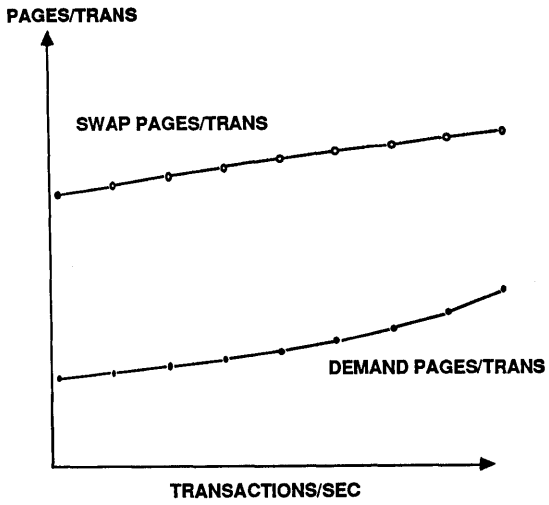

Figure 7

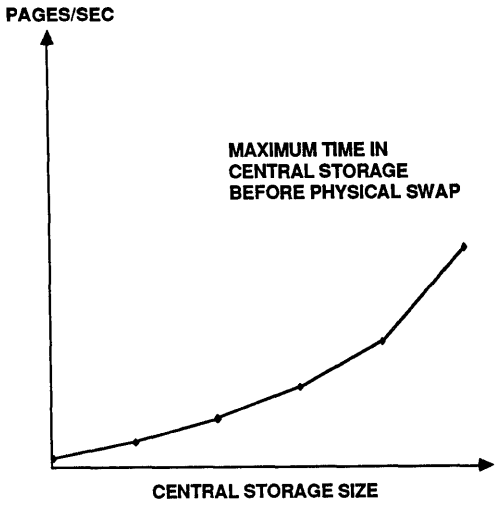

Figure 5

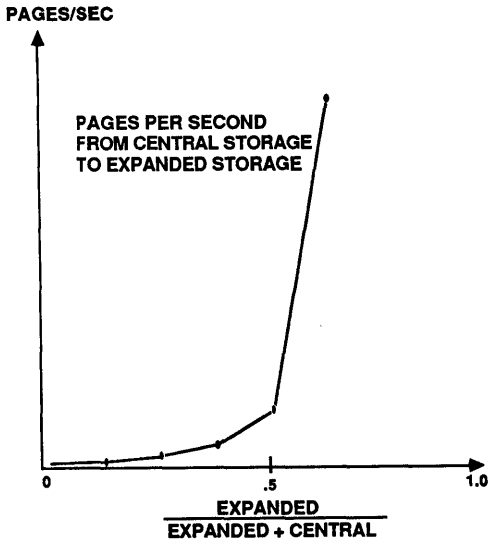

Figure 8

IMPLICATIONS OF EXPANDED STORAGE

Now consider the effect of expanded storage on the interactions illustrated in Figures 3-7. Note first that systems with expanded storage can be analyzed at two levels:

Level 1 - Consider only the total amount of processor storage (central storage plus expanded storage), and focus only on page and swap traffic between processor storage and conventional auxiliary storage devices.

Level 2 - Provide additional analysis of page and swap traffic between central storage and expanded storage, and also analyze the page migration process.

In a Level 1 analysis, the overhead required to transfer pages between central and expanded storage is ignored. Thus, the major concern is page and swap traffic to auxiliary storage.

As has been noted earlier and illustrated in Figure 1, pages may be sent to auxiliary storage directly from central storage, or they may be sent indirectly from expanded storage because of migration.

Essentially, migration occurs if a page is being removed from central storage at a time when expanded storage is "nearly full." Note, however, that direct transfers from central to auxiliary storage also occur if a page is being removed from central storage at a time when expanded storage is "nearly full." The only difference is that, in the direct case, the page itself is transferred to auxiliary storage; in the case of migration, a different page is transferred.

Since, in either case, page transfers to auxiliary storage only occur when both central and expanded storage are nearly full, a simple Level 1 analysis need only be concerned with the total amount of central plus expanded storage (i.e., the total amount of processor storage). If the term "central storage" is replaced by the term "processor storage" in the discussion of Figures 3-7, then all the observations and conclusions will apply equally well to a simple Level 1 analysis of a system with expanded storage.

The queueing model used to generate Figures 3-7 does, however, have to be enhanced to carry out a Level 2 analysis. One required extension is predicting the amount of page traffic between central and expanded storage. In general, if the total amount of processor storage is held constant, this page traffic will increase as the relative proportion of expanded storage increases. Figure 8 illustrates this effect. [Note, of course, that a system can never contain 100% expanded storage. MVS/XA needs a substantial amount of real storage to operate effectively.]

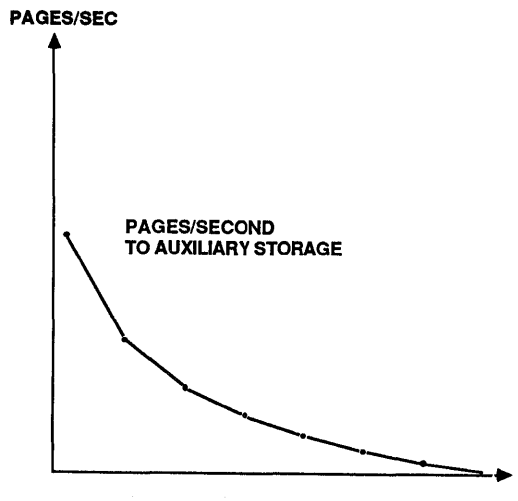

Figure 9

Figures 9-12 illustrate another interesting interaction involving real and expanded storage. The figures represent a case where the size of real storage is held constant while the size of expanded storage is steadily increased.

As illustrated in Figure 9, increasing the size of expanded storage causes a decrease in the number of demand pages per second that go to auxiliary storage. This result is entirely expected.

One might also expect that the reduction in demand pages per second to auxiliary storage would be accompanied by a corresponding increase in the rate of demand pages per second to expanded storage. Figure 10 shows this relationship.

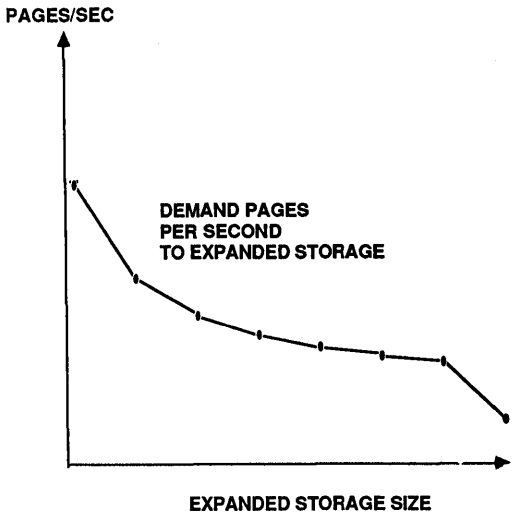

Figure 10

Surprisingly, the rate of demand pages per second to expanded storage does not increase: instead, it shows a distinct decrease, with a sharp acceleration at the point where all demand paging is handled by expanded storage.

To understand this phenomenon, note first that expanded storage is obviously much faster than conventional auxiliary storage. As the amount of expanded storage increases, it is able to handle a higher and higher percentage of total demand paging. Thus, the response time per transaction will steadily decrease.

As response time decreases, the amount of time each transaction occupies real storage will, of course, decrease. Thus, the average multiprogramming level (i.e., the average number of active transactions in real storage) will also decrease. This effect is illustrated in Figure 11.

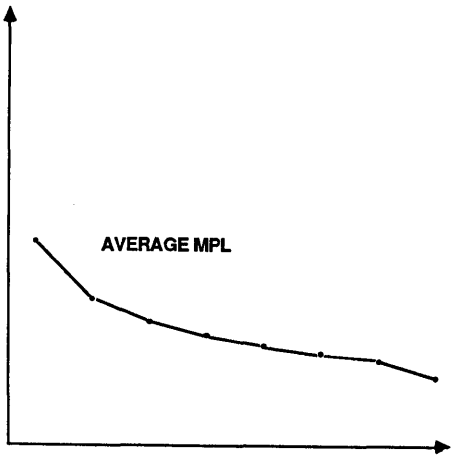

Figure 11

Finally, decreasing the average multiprogramming level increases the amount of real storage available to each active transaction (since there are fewer active transactions at any given instant). Thus, the average resident set size per transaction will increase. Figure 12 illustrates this increase.

Figure 12

Since resident set size increases, there is less page stealing. Thus, the total number of demand page-in's per transactions decreases. This is the key to explaining the decreasing paging rate in Figure 10.

The total demand paging rate is obtained by adding together the auxiliary storage paging rate in Figure 9 and the expanded storage paging rate in Figure 10. Figure 13 presents this total rate.

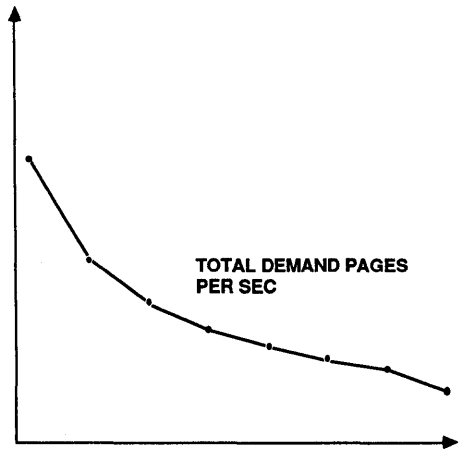

Figure 13

As expected, the total rate declines as expanded storage size increases. This, of course, follows from Figure 12 since resident set size increases steadily. Moreover, the decreasing rate in Figure 13 is more than enough to offset the increasing proportion of demand paging that is being handled by expanded storage. Hence, Figure 10 has a very reasonable explanation even though it may first appear to be counter-intuitive.

As the example demonstrates, the use of powerful analytic models can be invaluable in analyzing the complex interactions that occur in high performance computer systems. The ability to carry out these analyses in an accurate and fully automatic manner can be of substantial benefit to anyone working in the area of capacity planning or performance management.

SUMMARY

A number of changes have been made in MVS to accommodate expanded storage. These changes have been discussed, and their impact on the RMF Swap Placement Activity Report has been reviewed in detail. Also, an analytic queueing model has been used to illustrate important aspects of paging and swapping behavior that arise in systems with, and without, expanded storage.

PERFORMANCE EVALUATION OF FUTURE SYSTEM DESIGNS

J.M. Quernemoen, M.A. Fahland, B.G. LaPlante and T.L. Nelson
UNISYS Corporation

ABSTRACT

This paper presents a method of evaluating the performance of future computer systems. Although the design and development of a computer is a process that generally is not visible to customers, much of the methodology is relevant to the performance evaluation of existing systems. Presented is an established means of determining computer performance of systems that exist only as design concepts.

The paper covers three topics:

1) Workload Selection, Characterization and Measurement
2) Automated Discrete Event and Analytic Modeling Tools
3) A Hierarchical Approach to Modeling Future Systems from the Machine Cycle to End-user Response Time

1 INTRODUCTION

Performance prediction has become an integral and necessary part of the computer design process. The performance evaluation of increasingly complex systems and their components, as they evolve from design concepts into prototypes and products, provides a dynamic means to foresee and prevent performance-related design shortcomings. To successfully predict the performance of future systems, one must use meaningful performance metrics, and the correct tools and methodology.

Measuring and predicting performance have much in common. They both provide an evaluation of how well a system operates and why it performs as it does. They both evaluate the system with the same set of performance metrics and with the same sets of workloads, both of which are used to specify performance requirements before design begins, to estimate performance during the design, and to verify performance after the product is built.

These workloads must be representative of real applications in order to be meaningful. They must also be repeatable. To satisfy these requirements appropriate workloads or sets of workloads are developed into standard system benchmarks which are used as the basis for system performance measurement and prediction.

Performance measurement is accomplished by running benchmarks on existing systems. Performance prediction consists of running a model of the system driven by the workload characteristics of these benchmarks. Therefore, part of the modeling process is to decide what characteristics of the workloads are required as input to the model and to measure those characteristics on an existing system. Section 2 discusses workload selection, characterization, and measurement.

Finally come tasks of developing a complete and concise model definition, choosing the proper modeling technique, and building and running the model. Section 3 describes automated modeling tools that were developed to facilitate and expedite these tasks.

For each component of the system being modeled, one must evaluate the level of detail required to adequately represent the performance-related aspects of that component. Certain components may need to be simulated at the nanosecond level, others at the millisecond level. Mixing these levels in a single model poses serious modeling problems, yet ignoring important details could result in undetected performance problems. To avoid mixing widely different levels of detail in a single model, we use a methodology that uses results from detailed models as input to higher level models. This hierarchical modeling methodology is described in Section 4.

2 WORKLOAD SELECTION, CHARACTERIZATION, AND MEASUREMENT

Workloads representative of those that are expected to run on the new system are used throughout the system design process. They are first used in specifying the performance requirements for the new system. Then the workload characteristics are determined, and used as input for models. Finally, the workloads are run on the new system to verify that the performance goals have been met. This section discusses how we select, characterize, and measure workloads.

2.1 SELECTION CRITERIA

Workloads are selected to do one or more of the following:

- o Represent actual customer environments
- o Stress some aspect(s) of the system architecture
- o Gauge the performance of system software

The first of these is the most important. To sell a system, you must be able to tell the customer how it will perform in his environment. Workloads may be selected to represent banking, airlines, business, or scientific environments, depending on how the system will be marketed. These workloads come from existing customers, or are based on measurements made at customer sites.

When there is a known potential bottleneck in the system, or when doing trade-off studies on a particular component, a workload may be selected which stresses that part of the system. For example, in evaluating the main storage system, we would use a workload with high memory bandpass requirements.

Lastly, workloads must be available to assess the performance of system software, including the operating system, compilers, linkers, and applications such as communications, database management, and transaction processing. For instance, standard workloads are used to evaluate every compiler release, based on the efficiency of both the compilers and the oode generated.

Of course, today's workloads do not always represent what we expect to be running in the not-too-distant future. Workload characteristics are changing due to the following factors: off-loading of certain tasks onto personal computers or specialized processors; increasing memory size, thus allowing higher concurrency levels, larger programs, and all kinds of caching; and increasing peripheral performance, thereby raising memory bandpass requirements. Thus, the design of tomorrow's systems is based on today's workload characteristics with some over-design and extrapolation for the expected characteristics of tomorrow's workloads.

2.2 WORKLOAD CHARACTERIZATION

In order to use models to predict how well a system or its components will operate under a given workload, the performance-related characteristics of the workload must be understood. Three areas commonly profiled are IP characteristics, I/O characteristics, and memory characteristics. The detail of the characterization is directly related to the detail of the model.

The IP profile of a workload includes the sequence of instructions executed, the frequency of various instructions or classes of instructions (such as load, store, jump, arithmetic, string, and memory-to-memory), and the number and type of operands. This information provides the basis for predicting IP and memory organization performance.

I/O profiles include the frequency of mass storage I/Os, pathlengths between I/Os, transfer sizes, read/write ratios, and load distributions across physical devices. This information is used to determine the design requirements for a system's I/O complex: bandpass and throughput, number of channels, number of I/O processors (IOPs) and performance requirements of the IOPs, disks and disk controllers.

Memory profiles include the frequency of memory references, the distribution of reference type (read, write, lock, etc.), and locality of references. These characteristics of a workload are used in evaluating performance of memory hierarchies, memory interleaving, and paging algorithms.

2.3 WORKLOAD MEASUREMENT

Workload characteristics required as input by performance models are generally derived from measurements performed on existing systems. This section covers three ways of measuring workloads.

2.3.1 SOFTWARE MONITORING. The Unisys Software Instrumentation Package (SIP) provides system-level performance measurements for 1100 Series products. SIP is a built-in software monitor which can be turned on and off at the system console. SIP writes the data collected to an output file at the end of regular time intervals. The length of the interval is selected by the operator in granules of seconds. While SIP collects many types of information, much of it is geared toward system tuning and capacity planning. Our description of SIP's capabilities will be limited to the I/O statistics it collects.

SIP collects data on I/O activity by channel, control unit, and device. Data collected include software queueing times, hardware service times, data transfer times, input and output request counts, and number of words transferred.

A feature of SIP called IOTRACE provides a record of each I/O activity occurring while it is active. IOTRACE can run independently or with other SIP data collection. In the latter case, the IOTRACE data can be synchronized with the other SIP data. The trace information for each I/O operation includes:

- o Request initiation time
- o Requestor (program or operating system entity)
- o File/device identifier
- o File/device starting address
- o Request type (e.g., read or write)
- o Transfer size
- o Timing: software queueing time, seek time, hardware response time

This data, together with synchronous hardware monitoring of the system's IP utilization and instruction count, provides a relatively system independent picture of the candidate workload's I/O profile. Specifically, one can reduce this information to obtain:

- o I/O arrival rate distribution
- o Duration of selected I/O arrival rate ranges
- o Distribution of load on channels, control units, and devices
- o Mass storage utilization
- o Distribution of transfer sizes

This information, which can be obtained for any time interval within the sample period, is used as input to subsystem models, I/O complex models, and system models.

2.3.2 HARDWARE MONITORING. Although software instrumentation provides system-level performance metrics, it has two distinct shortcomings. First, it is unable to measure lower level metrics such as IP cache hit rates and instruction mixes. Secondly, it can add significantly to system overhead.

Hardware monitoring is used to obtain detailed measurements of such things as cache performance, instruction mixes, memory references, software pathlengths, and processor activity breakdown. Since hardware monitors are generally passive devices, they do not alter the operation of the system under test.

Hardware monitoring typically involves connecting probes to monitor locations identified by the manufacturer. Depending upon the type of measurement, a few signals or several dozen may be required. The signals are brought to the monitor equipment where they are used individually or in combination to control counters, timers, data storage, and real-time displays.

Four basic monitoring techniques are counting, timing, mapping, and storing. Most monitoring equipment provides a means of doing some combination of these. Comparators are often used in conjunction with all types of measurements to restrict the measurement to specific intervals.

Use of counters is the most common mode of hardware measurement. In counter mode, one or more signals are combined by some programmable logic in the monitor, and the resulting signal is used to increment a counter. Periodically, the counter values are written to disk or tape, and the counters are reset. Examples of performance data collected using counters are shown in Table 2.1.

When more counters are needed than are available in a monitor, a mapping technique is used. For example, to count the number of occurrences of each instruction type on a computer with an 8-bit function code would require 256 counters. Instead of using normal hardware counters, the binary value of the combined signals (0 to 255 in our example) is used as an offset into an area of memory. The value in the memory location at

Table 2.1. Examples of Counter measurements

Metric	Counters Required
Instruction Execution Rate	Instructions, Duration of Measurement
Cache Hit Rate	Cache References, Cache Hits
Instructions per I/O	Instruction Count, I/O Count
References per Instruction	Instructions, Memory References
Memory Reference Patterns	Memory References for each MSU or Bank
Pathlengths	Instructions

that offset is incremented. This technique is also used to determine frequently executed portions of code by monitoring memory address bits.

Hardware monitor timers are useful for measuring very short time durations such as memory access times, or the time from a request to an acknowledge. Typically, one signal is used to start the timer, another to stop it.

The store mode technique is used to gather details of consecutive events or instructions, such as instruction or memory address traces. In store mode, many signals are captured and stored on each event occurrence. Since mass storage is usually not fast enough to store data at a high rate, memory is generally used for holding these traces. When the available memory is full, it is written to disk or tape. The system being monitored usually must be suspended during the writing process, or events will be missed during the measurement.

2.3.3 HARDWARE SIMULATION. In addition to commercial hardware monitoring equipment, special purpose hardware is also used to collect highly-specialized types of data. One example of such hardware is the Unisys Buffer Information Collector (BIC).

BIC was designed in order to accurately predict the performance of future cache designs by simulating those designs in hardware. Cache simulation of large programs or benchmarks using software simulators was not feasible because of the large address traces required and the overhead of such simulations. Using BIC, cache performance for an entire benchmark can be evaluated in the time it takes to execute that benchmark.

BIC is a combination of hardware and micro-programmable components which simulate a wide variety of caches and provide several types of address traces. BIC operates by intercepting the memory address and function lines which connect an instruction processor and its local cache memory. The acknowledge from the cache is delayed by BIC until BIC's operations are complete. In normal simulation mode, the delay is minimal and has no impact on the program executing in the host.

BIC also contains a standard I/O channel interface which allows it to generate address traces as it is executing. The I/O channel is also used to download BIC microcode which is used to test the hardware, to verify that the cache algorithm is properly wired, and to aid in simulating caching algorithms not capable of being simulated in the hardware alone.

BIC has three modes of operation. Mode 1 is its standard simulation mode. The cache size and cache algorithms are selected via patch card jumpers. A hardware monitor connected to BIC records hits, misses, and reference counts for each of the caches being simulated. Mode 1 has been used to perform a large number of cache studies, including those shown in Table 2.2.

Table 2.2. Examples of BIC Mode 1 Measurements

Cache Organization
- Varying Cache Sizes
- Varying Block Sizes
- 16-word block with 8-word fetches

Caching Algorithms
- Store-in (Post-write)
- Store-thru (Write-thru)
- Prefetching
- Certain requests bypass the cache
- Various software locking algorithms

Aging Algorithms
- LRU
- FIFO
- Least Recently Used Pair

Multiple Caches
- Up to four caches
- Exec and User
- Instruction and Operand
- Buffer Invalidation

Modes 2 and 3 are used to collect address traces. Under preset conditions, the BIC hardware interrupts the BIC microprocessor, which then retrieves address and control signals and sends them out over the I/O channel. For example, by interrupting on only those references which would cause a reference to main store, BIC generates a complete trace of main store addresses and reference type (read, write, lock, etc.).

This address trace can then be used to evaluate second-level cache and memory designs. In addition, mode 2 provides a data compression technique, which can reduce the data and time required to evaluate paging and other higher-level memory management algorithms. BIC has also been used for special studies, such as simulating branch prediction buffers.

3 MODELING TOOLS

Computer performance modeling tools improve access to performance related data and automate the model building process. This section presents a selection of the tools we use: a database for managing the collection of performance data, a graphical model description language, and two automated model building packages.

3.1 PERFORMANCE DATABASES

Literally thousands of data collections have been made on the standard workloads we use for our performance predictions, as well as collections made at customer sites. To allow analysts to find what data has been collected and where the data resides, we have created a series of on-line databases (see Figure 3.1). They are implemented in MAPPER and are accessible nationwide via a proprietary development network.

The Collection Database describes each measurement in terms of what hardware and software were measured, and what data was collected. The Collection Database also has a 'Request for Measurement' function. If the information required does not exist, this function may be invoked to request that the data be collected. The request is recorded in the database, and its status is updated as it is scheduled and completed. When the measurement is complete, the measurement request record becomes the measurement description record and points to the measurement results.

The Collection Database also contains pointers to where the data is stored: in another database, in on-line files, or on magnetic tape. Much of the raw data from hardware monitor measurements is kept in on-line MAPPER databases. Having the data on-line allows the analyst to compute and compare the statistics needed for any number of cases. More voluminous data is not kept in the on-line MAPPER database; instead, standard reductions from hardware and software monitors are performed and kept in designated on-line files. All the raw data collected during a measurement is stored on magnetic tape.

Tools, designed to aid the analyst and modeler, have been integrated into the on-line databases using MAPPER's programming capability. The Instruction Trace Facility (ITF) is an application of the MAPPER programming capability. The ITF database contains detailed instruction trace information for each of the standard performance benchmarks, and instruction timings for each baseline machine and each machine currently under development. The tools associated with the ITF database include interactive runs which do the following:

- o Generate Instruction Mix Reports
- o Generate Instruction Sequence Reports
- o Analyze Operand Usage
- o Calculate base average instruction execution time for any combination of benchmark and machine in the database.
- o Generate customized instruction trace files to be used as input to discrete event models. The user defines the data needed and the appropriate format.

These database tools provide answers to "what if" questions as well. By supplying parameters such as timings, mixes, and instruction class definitions, the analyst can determine the effect of changes to hardware and software.

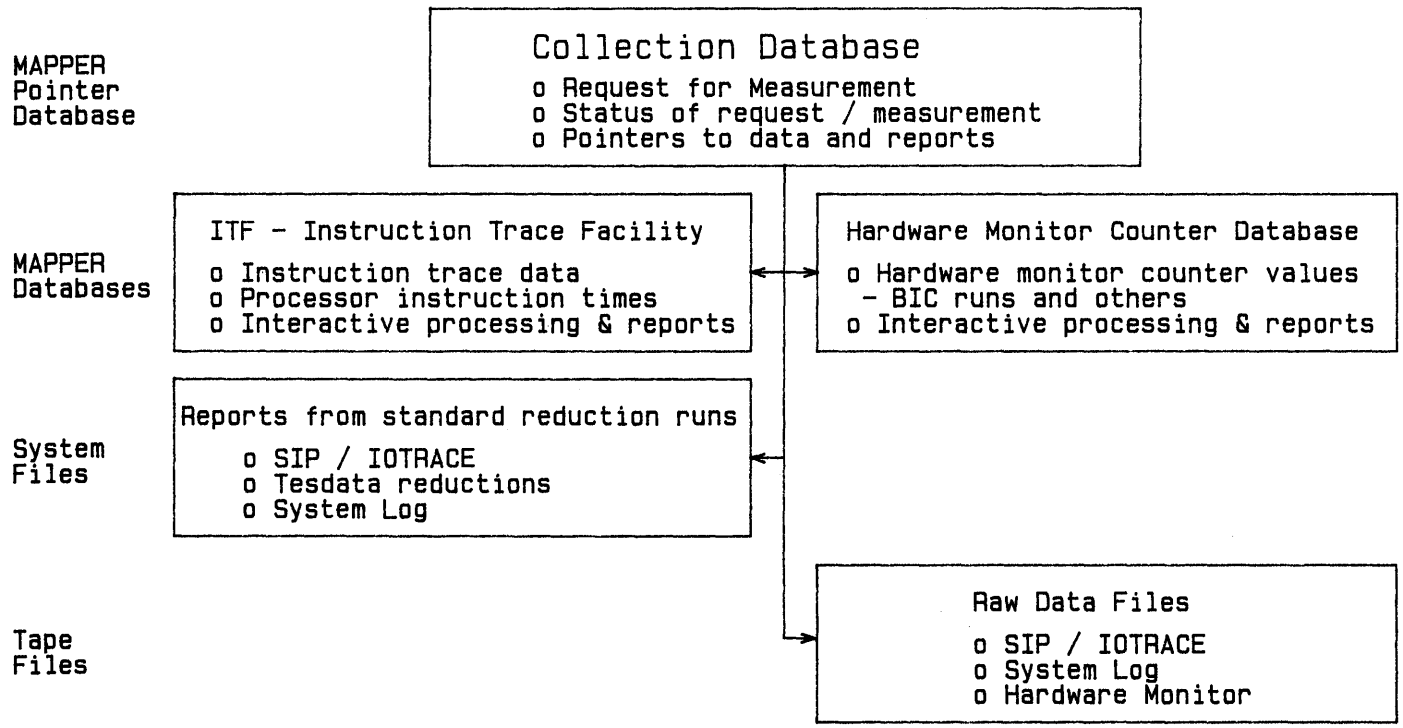

Figure 3.1. Performance Databases

3.2 AUTOMATED MODEL-BUILDING TOOLS

During the feasibility and design stages of the system design process, many alternatives need to be evaluated; fast modeling techniques are vital. In this section we discuss a graphical model description language developed to facilitate model definition and provide the basis for automatic model generation. We also discuss two automated model building packages, one for discrete event simulation models, the other for analytic queueing network models.

3.2.1 GRAPHICAL MODEL REPRESENTATION. One of the most difficult tasks in modeling complex systems is producing a complete model definition. Often the modeler and the design engineer don't speak the same technical language. To facilitate communications between engineer and modeler, and to provide an unambiguous model definition, we have developed a graphical model description language called QNETS.

QNETS diagrams are flowcharts with symbols representing concepts such as queues, delays, or forks. Each symbol belongs to one of five classes. Each class of symbol is identified by a particular shape, as illustrated in Figure 3.2.

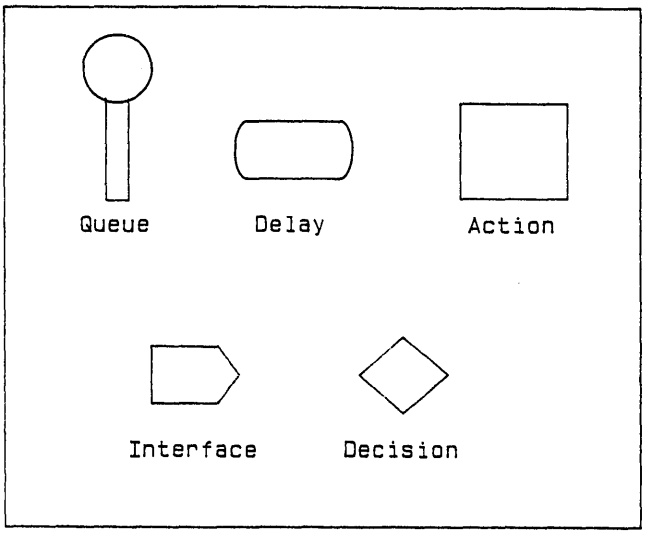

Figure 3.2. QNETS Symbol Classes

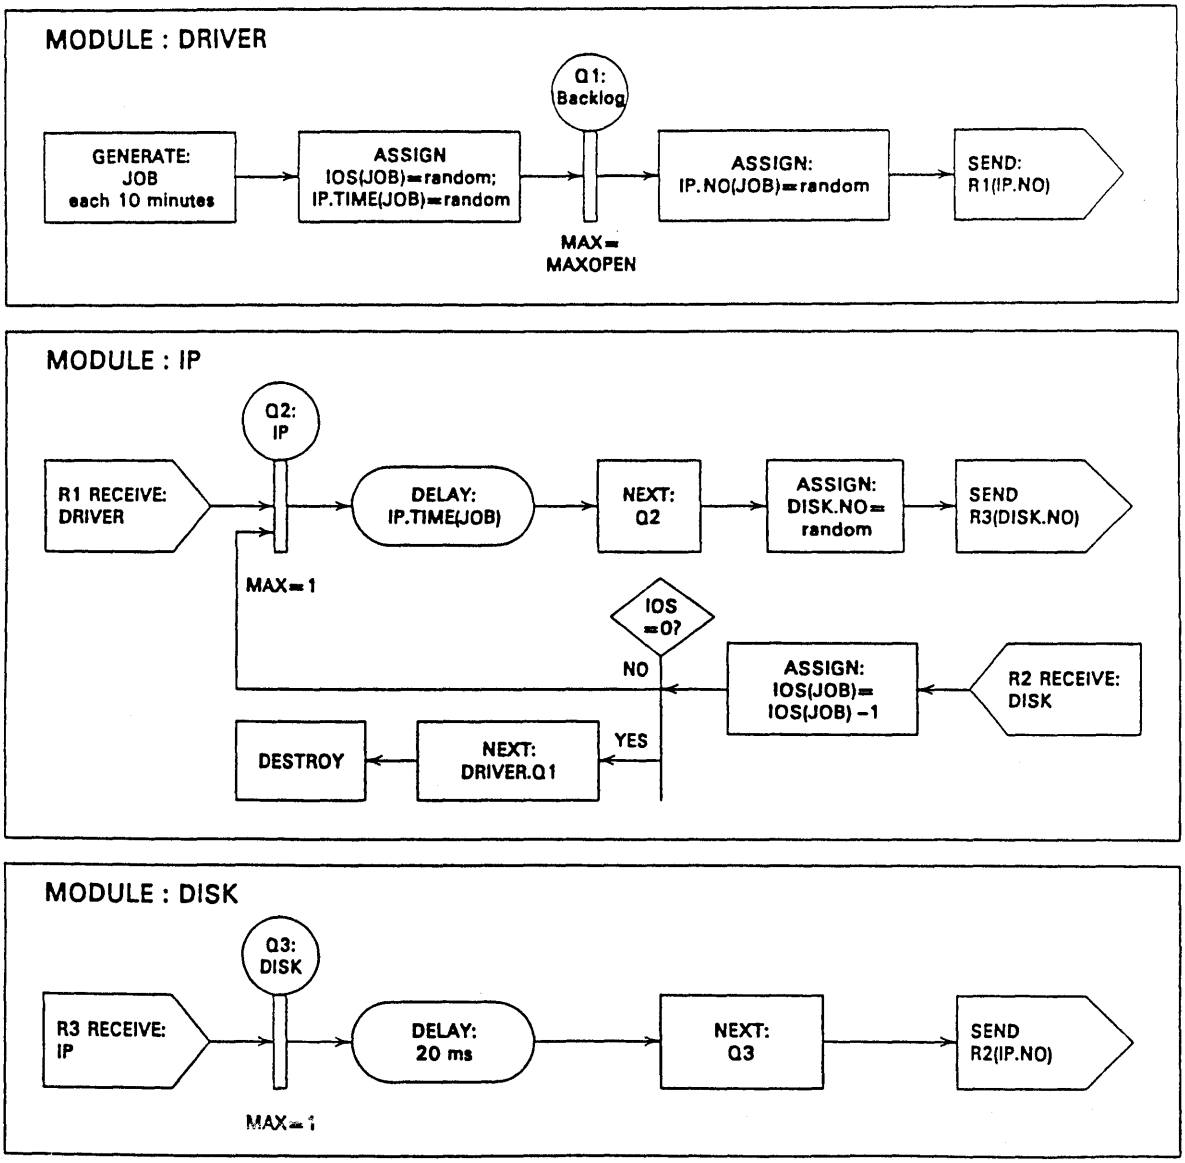

Figure 3.3. QNETS Diagram of a Batch Processing System

Logical divisions of a model, called modules, are described by independent QNETS diagrams. For instance, in a computer system separate modules are constructed for instruction processors, input/output processors, and memory units. Modules may be replicated any number of times and may be nested to any level. This encourages hierarchical, modular model definition and facilitates the use of previously defined modules in different models.

The basic concept of QNETS is the flow of tokens through a network. Tokens carry information from one point in a network to another. While tokens flow along arcs and through action, decision, and interface symbols in zero time, they are delayed at queueing and delay class symbols.

Figure 3.3 shows a simple QNETS diagram of a batch processing system. It contains three module types: DRIVER, IP, and DISK.

This model represents an open system, with batch jobs entering the system at the rate of one every ten minutes. The Generate symbol in the DRIVER module introduces a new token of type JOB every ten minutes. Note that this does not represent the standard open workload. The maximum number of batch jobs open is limited by the maximum concurrency at Q1. Each job, before terminating at the DESTROY symbol, allows a new job to begin (NEXT: DRIVER.Q1). If Q1 is never empty, this represents the classic closed workload.

Each job in the batch system above must first gain access to an IP for a specified time, then frees the IP ("NEXT Q2" symbol) and queues for a disk (selected according to a probability distribution). After releasing the disk, the token returns to the IP module and queues again for the IP. This process repeats until the job has completed its designated number of I/O operations. When all I/O operations are complete, the JOB token releases another JOB token from backlog ("NEXT Q1" symbol) and leaves the system (is DESTROYED).

The number of instances of each type of module is not specified in the QNETS diagram, but is an input parameter to the simulation. Thus the number of IPs and the size of the I/O complex can be varied easily. The SEND and RECEIVE symbols represent the logic for routing the tokens to the correct instance of the module.

3.2.2 **INTERACTIVE MODELING FACILITY.** The construction of a discrete event simulation model can be a long, error-prone task. To overcome this obstacle, we developed the Interactive Modeling Facility (IMF). IMF is a PC-based package which enables the modeler to enter the model definition interactively by constructing QNETS diagrams with a mouse and providing auxiliary information via pop-up menus. IMF ensures the completeness and basic consistency of the model definition, and prompts the user for more information when required. It then generates the complete model source code, including code allowing interactive trace and debug using the

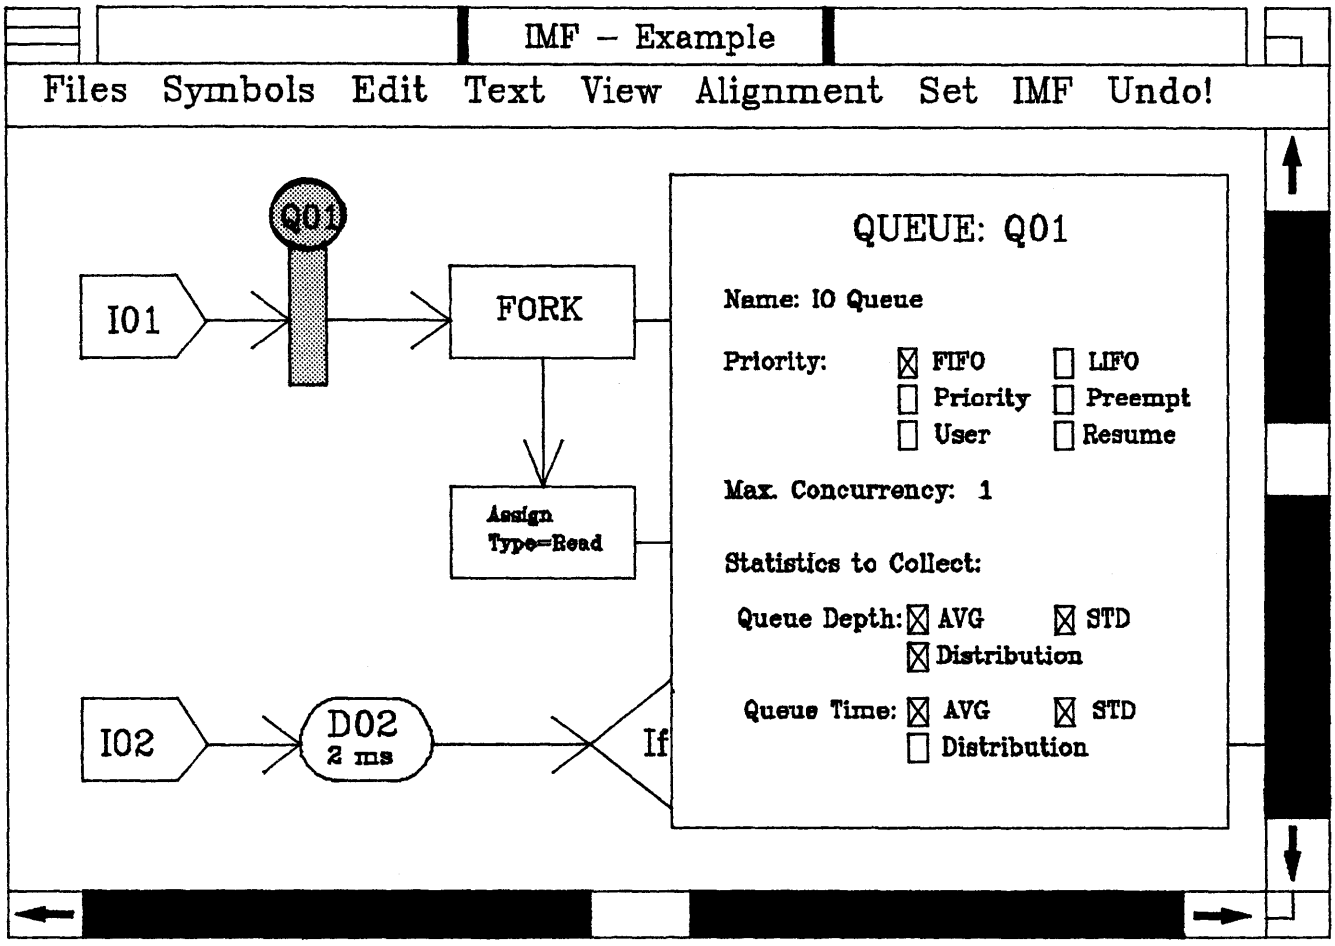

Figure 3.4. IMF Example

names the modeler selected for his modules, tokens, and variables. Models that may previously have taken weeks to develop and debug can, with IMF, be generated in a few hours.

The QNETS editor used to define the model also allows the model to be updated in a matter of minutes. This gives the analyst the ability to quickly study many alternatives for feasibility and design trade-off studies. Figure 3.4 illustrates the interactive model definition provided by IMF.

3.2.3 MVAP. The Mean Value Approximation Package (MVAP) is a general-purpose analytic queueing network package with enhancements for modeling computer systems. It features heuristic one-step mean value approximation solving algorithms, a discrete event simulator, and a simplified exact solver.

The advantages of modeling with MVAP include:

- o Fast and Efficient Solutions
- o Interactive Model Definition
- o Extensive Capabilities
  - Standard Queue Networks
  - Priority Servers
  - Preemptive Priority Servers
  - Priority and Preemptive Priority multi-servers
  - Limited Memory

MVAP is typically used for a .first look at many modeling problems, since we can build an MVAP model and obtain results in a matter of minutes. The results help show whether there is sufficient utilization and complexity to justify the effort of a simulation model, or if an analytical approach is adequate.

As queueing network packages cannot determine the distributions associated with the mean values they estimate, many applications cannot benefit from the use of these fast modeling techniques. In particular, design trade-off studies that require distributions for utilization, throughput, and response time require discrete simulation.

4 HIERARCHICAL APPROACH TO SYSTEM PERFORMANCE ANALYSIS

Our hierarchical approach consists of identifying sub-models by functionality and by the time granularity of related hardware components. At the bottom of the hierarchy are the sub-models having time units in the range from a few nanoseconds to single system clock cycle. At the top of the hierarchy are those with time units in the millisecond to second range. Each model at a given level builds on the results from sub-models at lower levels as the lower-level model results become available.

There are several reasons for using this hierarchical approach. First, it allows each component to be modeled at the appropriate level of detail. Design trade-off studies can be done at the component level and provide the performance data necessary for models further up the granularity dimension. Second, it allows simultaneous model definition and development of the sub-models. Third, high-level models can be constructed and executed using preliminary data even before detailed results from sub-models are available. As the sub-model designs take shape, successively more refined performance estimates become available as input to the higher levels.

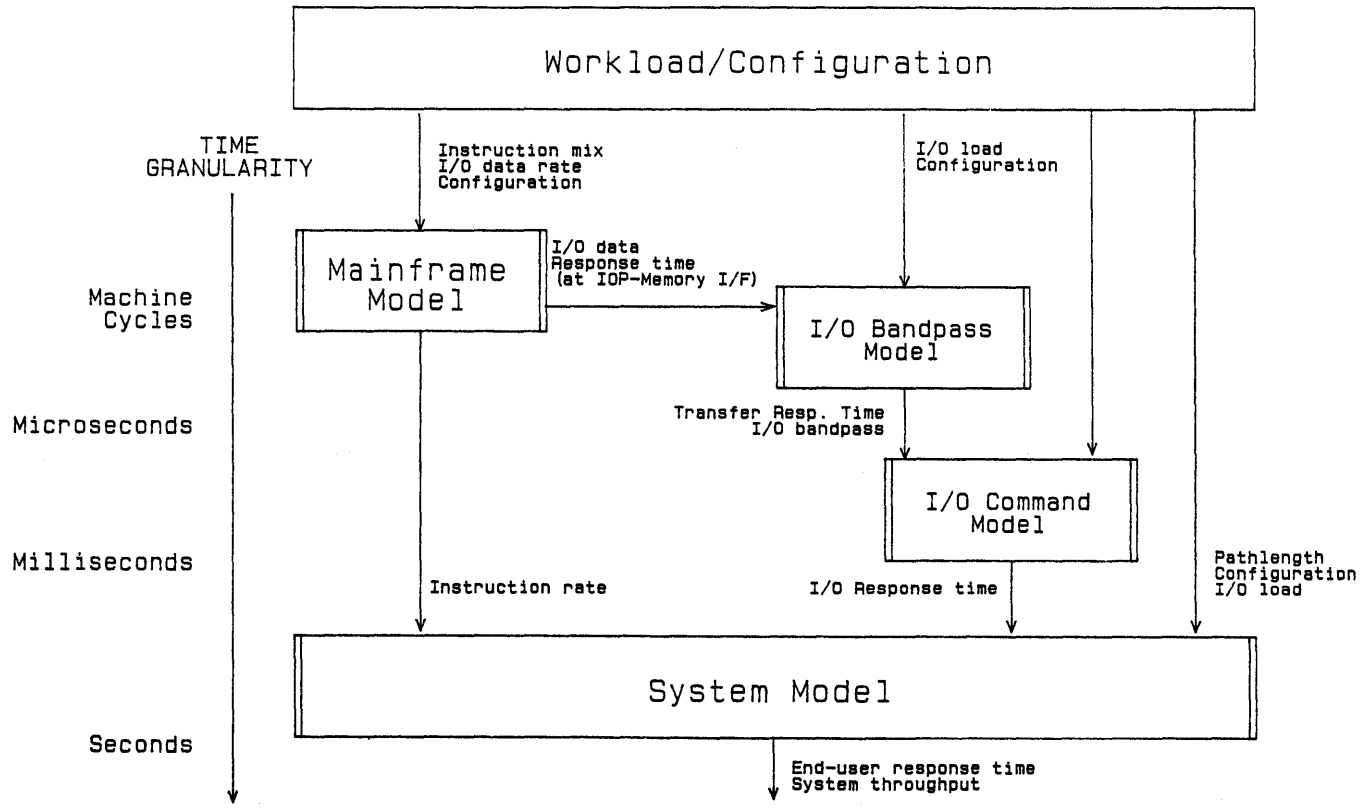

Figure 4.1. Hierarchical Modeling Example

A system-level model at the top of the hierarchy illustrates this well. When a system is at its first stage, design feasibility, we obtain educated guesses and assumptions about the performance of the instruction and I/O processors, storage organization, and mass storage projected to the time of system introduction. With this information, and workload pathlengths and I/O quantity and size, we can obtain preliminary system performance estimates: throughput and response time for given I/O and mainframe configurations. This process helps establish performance requirements at each of the sub-model levels. Conversely, as results are obtained from each of the sub-models, the system-level model uses them to obtain more refined system-level performance predictions.

Figure 4.1 presents a hierarchical modeling matrix based on a time granularity and functional characteristics dimensions. In this section we will first describe the preliminary modeling steps we use. Secondly, we will describe the sub-models in Figure 4.1.

4.1 PRELIMINARY MODELING STEPS

The hierarchy of sub-models is defined by discussing with the designers the questions and concerns they want to see addressed by the models and which areas are likely to change. Once sub-models are identified, three preliminary steps are performed: documenting model descriptions, determining driver requirements, and choosing the appropriate modeling tool.

4.1.1 DEVELOP MODEL QNETS DIAGRAMS. The first step in developing a performance model is for the analyst to work with the designers to develop the QNETS definition of the model. By interacting directly with the designers, design trade-off considerations are incorporated into the model from the start. It is the analyst's responsibility to ensure that enough detail is put into the model so that it can provide the data required by other models higher up the model hierarchy.

4.1.2 DETERMINE DRIVER REQUIREMENTS. As the model description is being developed, one must also determine the workload characterization required as input to the model. Input requirements depend on the type of system or component being modeled, and on the level of detail represented in the model.

For many types of models, the input consists of probability distributions which describe the workload in terms of the type and frequency of events influencing the performance of the system being modeled. When modeling results are highly sensitive to workload probability distributions, the distributions must have a high degree of accuracy to ensure representative results. The distribution of I/O data transfer sizes is an example of an input probability distribution. If the system being modeled is sensitive to sequences of long data transfers, then specifying the average and standard deviation of the transfer size may not be sufficient. A more detailed probability distribution, taking into consideration bursts of activity, may be required. On the other hand, if a model shows little sensitivity to the workload probability distributions, then more tractable distributions and simpler representations can be used in the model.

4.1.3 DISCRETE EVENT SIMULATION OR ANALYTIC IMPLEMENTATION? Several factors must be weighed when choosing between analytic queueing techniques and discrete-event simulation for a particular model. These factors include: the detail required of the input, the complexity of the model, and the types of output statistics required.

Analytic queueing models require the assumption of exponential inter-arrival and service-time distributions. If these assumptions are too restrictive, then discrete-event simulation is necessary.

There are several modeling constructs that do not have exact analytic solutions, and for which analytic approximations may give inaccurate results. These include forking (parallel activities), complex queue disciplines and service-time distributions, and holding multiple resources simultaneously. Models that require detail of such activities must use discrete techniques.

The output of most analytic models is limited to mean values of service times, utilizations, and response times. If designers are concerned about distributions around the mean values, then again, simulation is the choice.

With all that simulation has going for it, it unfortunately tends to be very expensive in terms of personnel and computer resources. For this reason alone, analytic methods are reviewed and used wherever possible.

4.2 HIERARCHY OF MODELS

4.2.1 MAINFRAME MODELS. A mainframe model consists of representations of the instruction processors, portions of the I/O complex, the storage organization, and the interfaces between them (see Fig 4.2). It does not explicitly represent peripherals and communication equipment; rather it represents the load they exert on the main storage complex. The complexity of a module varies according to how much is already known about the component it represents and whether or not design trade-off simulations are foreseen for that component.

Typically, the instruction processor is simulated at the memory reference level. It is often driven with an instruction trace (obtained using a hardware monitor) specifying the types and sequence of memory references. In detailed processor models, these traces can be used directly to model the execution and performance of the processor executing this mix. Alternatively, the instruction sequences can be analyzed to produce shorter, statistically valid instruction streams characterized by instruction class (such as load, store, jump, arithmetic, string), number and type of operands, and instruction execution time. The complexity and run time of the model is reduced by not simulating each individual instruction, yet maintaining important details such as inter-request time and request type distributions.

The processor local cache memory is simulated by a probability distribution resulting in the correct proportion of cache hits and misses for requests generated by the processor module. The distribution is obtained from hardware cache simulations using BIC (see 2.3.3).

The I/O in mainframe models is generally represented by a simple I/O request generator which issues a realistic series of memory references to the main storage unit. However, more detailed representation, including the simulation of buffers, buses, and/or I/O processors may be appropriate in some mainframe simulations. I/O memory requests are generated at rates taken from the I/O profile statistics for each given workload. Sensitivity studies are conducted to determine how significant increases in the I/O memory request rate affects mainframe performance.

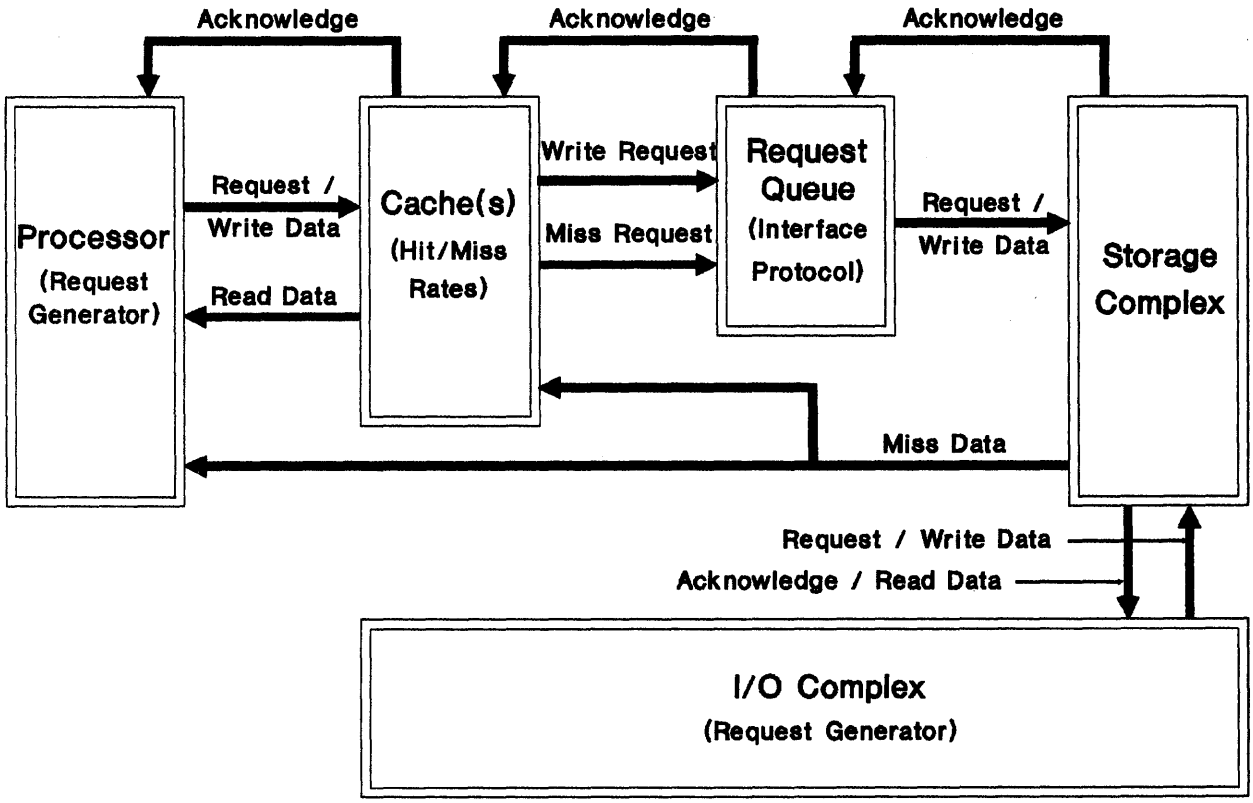

Figure 4.2. Conceptual Mainframe Model

The memory interface is modeled as one or more queues of memory read and write requests generated from the processor/cache modules and the I/O modules. These queues are usually released by the simulated acknowledges or data returned from the memory module. In bus-structured systems, the bus is generally modeled as a separate module.

Complexity of representation of the storage organization varies, depending on whether or not the storage complex contains caches, how sophisticated its queueing mechanisms are, etc. In a simple system, where the main storage unit merely services incoming requests without any of the complexities, the memory may be represented by a queue and a couple of simple delays for access and service time. On the other hand, if the storage complex consists of a hierarchy of real memories, the representation may be extremely complex.

The unit of time for mainframe models ranges from one clock phase to one clock cycle. The primary output of a mainframe model is the instruction execution rate, measured in millions of instructions per second (MIPS). Other statistics include average queue depths, average wait times, and server utilizations. Mainframe models are usually discrete time simulation models; thus, we can obtain standard deviations and distributions of the same parameters.

4.2.2 I/O DATA TRANSFER MODELS. I/O data transfer models are used to study maximum, minimum, and average channel transfer rates. In order to determine aggregate transfer rates, simulations of the data path from subsystem control unit to memory are performed at a level of detail encompassing the transfer of single words along the data path.

The purpose of these simulations is two-fold. The first is to identify which components are bottlenecks of the data transfer path; primary areas of interest are buffer, microprocessor, and bus utilizations. The second purpose is to provide average transfer rates for use as input to I/O request throughput models. Results are given for each combination of channels transferring data concurrently. Delays associated with IOP access to the data path for control purposes are also obtained from these simulations.

I/O data transfer models exhibit a large number of possible states. Along one dimension are differing combinations of active channels. Along another are the combinations of read and write operations. A key modeling consideration is the ease in running the numerous combinations required.

4.2.3 I/O COMMAND THROUGHPUT AND SUBSYSTEM MODELS. I/O processors (IOPs) perform all tasks related to the initiation and termination of I/O requests. They are microprogram-controlled general purpose processors designed to off-load I/O tasks from the instruction processors. IOP models are used to perform design trade-off studies and to determine what types of channels and subsystem configurations these processors can support.

IOP models build on the results of I/O data transfer models by simulating channel program execution around the data transfer operation. Depending on the design, the IOP may or may not combine the control and data transfer functions under a single controlling function. In the latter case, the IOP is not involved directly with data transfer, but it contends with transfer operations for memory and bus accesses. Queueing delays obtained from the data transfer model are

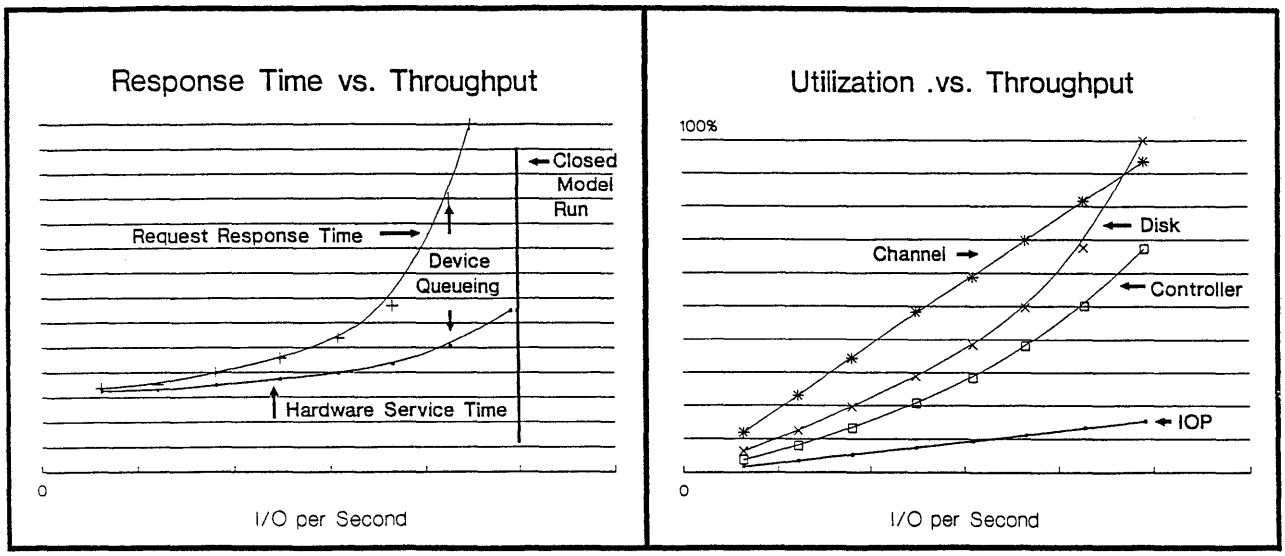

Figure 4.3. Sample I/O Throughput Results

incorporated to represent contention that the IOP experiences when fetching channel control words from memory or transferring control parameters to subsystem controllers.

I/O systems support multiple channel interfaces, each capable of supporting three general types of mass storage subsystems: cache disk, solid-state storage devices (SSD) and disk-only subsystems. By varying timing parameters and cache hit rates (0% for disk-only, 100% for SSD, and somewhere in-between for cache disk), all three subsystems can be represented by a single IMF module.

I/O throughput model results are primarily reported as performance curves in which throughput is plotted against response time (see Figure 4.3). Other results include IOP, channel, control unit, and device utilizations.

4.2.4 MEMORY-MANAGEMENT MODELS. The primary purpose of studying paged systems is to determine what the working set sizes and page fault rates will be for different management schemes. For these studies, a trace of each memory reference could be obtained and used to drive a simulator. As many have found before, that is a very expensive approach. Since we are not interested in individual references, but rather in working sets, we use a somewhat different approach. (We find that this method of tracing is at least 10 times faster than software trace methods and allows us to collect more data on a larger set of programs.) Using BIC in Mode 2 (see 2.3.3), we obtain traces of the activity of a small post-store cache. BIC accumulates the number of references to each block while it is resident in the cache. When flushed from the cache, a record containing the block address and reference count is written to tape. The cache is designed to force frequent block replacements in order to minimize accuracy loss. This is done by having the block size considerably smaller than the page size, specifying a maximum reference count between record flushes, and ensuring that the cache is small enough so that blocks are replaced every 5-10 references on the average. The BIC trace is then used as input to a simulation program designed to study the effects of various memory management algorithms on fault rates and working set sizes of a single program.

We are currently developing a stochastic representation of how well a program runs (number of page faults) for various algorithms, to be used as input to a system-level memory management model. The output of this model will be the system page-fault rate and swap rate, and the associated I/O load. This information on I/O due to memory management can then be input to the system level model.

4.2.5 SYSTEM MODELS. For modeling purposes, system-level workloads are characterized by probability distributions of the following:

Transaction arrival rate (transaction environment)
Number of active terminals and think time (interactive environment)
Number of jobs active (batch environment)
Pathlength per system interaction
Memory size requirements per system interaction
I/O profile (as described in Section 2)

System modeling allows us to build on the lower-level modeling previously described. Given the appropriate assumptions about the probability distributions, system modeling also lends itself well to the standard analytic queueing network modeling techniques. The components represented in the system model are instruction processing, the environment-generated I/O processing, the overhead associated with program loading and task switching, and communications overhead.

The instruction processor is treated as a simple queue which has a total service time equal to the product of the average instruction time and the pathlength; the service time per visit is a function of the total service time, the pathlength between I/O requests, and time slice allotment. The average instruction execution time is that found by the mainframe model; this time is dependent on the benchmark and the configuration. The pathlength is obtained from hardware monitor analysis of the workload during benchmark execution.

In our performance analysis of banked Unisys 1100 Series systems, we have assumed there is sufficient memory to load the programs and to prevent excessive swapping. Thus, the overhead of program loading and

task switching has been lumped into the environment-specific processor and I/O load. In a paged environment, the overhead of page faults is added as well.

There are several methods of modeling I/O processing at the system level. The method selected is based on the information available about the system's interactions with the subsystems. The simplest method basically treats the IOP, channels, control units, and disks as a single server per disk. This allows us to define some variation of the standard central server model and appropriately model the system via analytic queueing network techniques.

Another method treats the IOP as a simple queue with a service time representing the time to perform the command related functions. The I/O subsystems are represented in a somewhat simplified manner, but do take into consideration the overlap in time of device, control unit, and channel usage. The results from these simplified versions allow us to determine optimum system configurations. Subchannel statistics from these models can be compared for accuracy with simulated representations of subsystems.

The results from the IOP command throughput models are used in system modeling studies as results become available. The performance curves for the IOP replace the representation of the I/O complex at the system level.

With communications processors, we also use the sub-model concept to simplify our system modeling. Communication processors, systems in their own right, are modeled by the communications design group to determine response time and throughput. We use these parameters in the system model.

The outputs of the system model are: response time, throughput, utilization, and queue depth. Their values help determine the number of IOPs and channels that should be designed into the system. The ramifications of this extend into physical layout, interfaces, etc.

As the product approaches delivery, the system model is used as an aid to determine whether the product will deliver expected performance. During the product performance validation process, the models are used in conjunction with actual product instrumentation to identify potential problem areas. As part of the validation effort, the models are calibrated to the actual product.

Frequently, the system model does not perish with the release of the product. Instead, the model or its results are turned over to marketing for use as a sizing tool for prospective customers. System models are also used by the designers to evaluate potential performance improvements, future enhancements, and in some cases, next generation products.

5 CONCLUSION

Getting technology and design to coincide with a market window is difficult, and every delay has a potential impact on the product's success. Thus, the ability to provide prompt and accurate evaluation of proposed designs is a paramount ingredient to the product's success. This is the basis for the evolution and development of the performance analysis tools and hierarchical modeling methodology described above.

The hierarchical methodology allows us to break the system into smaller parts; this not only reduces the complexity of the modeling, but also facilitates faster response to performance related design questions by distributing tasks by sub-model. When the inevitable design changes occur, it is also easier and less error-prone to modify a smaller model. As a result we can reduce the time required to respond to changes.

The automated modeling means described above simplifies and expedites the modeling process. By use of the hierarchical methodology and the automated modeling tools, we have reduced the time to respond to design questions from months to weeks and sometimes hours.

Of the above described means of collecting data that characterizes a workload, the hardware simulator (BIC) has proved invaluable in obtaining accurate, detailed workload characteristics. It has been especially useful in obtaining memory referencing patterns used in the study of storage organizations. The data obtained via this technique has been used directly by the designers themselves to answer their design questions; this further expedites the design process.

In order to make sure our methodology is working, and to add to the credibility of modeling, verification is a vital part of our methodology. Not only does verification provide feedback which is vital to the modeler, but also frequently helps the project and the customer by finding performance quirks before introduction. In the case of one of our recently introduced products, the system performance estimates made by these methods were found to be within 2% of the actual measurements, illustrating the success of our methodology.

3090-CLASS PROCESSOR ARCHITECTURES AND WORKLOAD PERFORMANCE LEVELS

Gary Keeney and Greg Simmons
National Advanced Systems

ABSTRACT

This tutorial presents the specifications and fundamental architectures of the IBM 3090 and 308X, Amdahl 5890 and NAS XL series of processors. The presentation includes a discussion of the primary characteristics of several workload types and how they would take advantage of the features of the different processor architectures.

1. INTRODUCTION

IBM announced the 3090 Processor with a range of performance improvements over the 308X series depending on the workload type and the operating system environment. In similiar fashion, Amdahl's 5890 and National Advanced Systems' (NAS) XL series of processors were introduced with workload dependent performance ranges. Although, these three processors provide IBM program and peripheral compatibility, each has its own unique design and internal architecture which offer performance advantages for various software characteristics of the evaluation workload.

Computer architecture concepts and particuliar specifications of these 3090-class processors and their impact on performance can be demonstrated in the framework of measurement methodologies. Performance achievement is dependent on several quantifiable essential workload characteristics. These characteristics when matched with a particuliar processor design can be used to predict the relative performance of each workload type.

2. PROCESSOR CYCLES

An instruction is processed in a number of steps with each step basically requiring one machine cycle: therefore, the speed of any processor is a function of both the machine cycle time and the number of cycles per instruction:

Rate = (1/cycle time) x (1/(cycles/instruction))

MVS Extended Architecture (XA) instructions can be classified as one of three types depending on their memory reference characteristics. Register to register (RR) instructions have no memory reference, storage to register (RX and RS) have one memory access, and storage to storage (SS) instructions have a mininum of two operand fetches and one reference for operand store of the result. The number of memory references is a major determining factor in the number of cycles required to complete instruction execution.

The Arithmetic and Logic unit (ALU) of a processor consists of an Instruction Unit (I) and an Execution Unit (E). The I unit fetches instructions into buffers where the E unit then performs the operation.

The sequence of the E unit is accomplished in stages:

* instruction decode (D)
* operand address generation (A)
* operand fetch (F)
* instruction execution (X)
* operand store (S)

Since the operation of the I unit is overlapped with E unit processing, E unit cycles are the primary factor in processor performance. Generally, I unit instruction fetch can occur during idle periods of E unit operand fetch so that cache contention is minimized.

The relationship between the instruction stages and processor cycles varies by processor design. Each processor offers some unique architectural enhancements in order to decrease the cycles required per instruction.

3. INFINITE CACHE RATE

An elementary method of processor performance rating is the Infinite Cache Rate (ICR). Since this method assumes an infinite cache size with no cache misses, the effect of main memory overhead is ignored.

ICR methodology is basically a function of three primary factors:

* cycle time
* cache bandwidth
* pipeline efficiency

with the latter two influencing the cycles per instruction ratio.

The cycle time is constant for each processor series with the exception of the 3090 E enhancement.

Cache bandwidth is the rate at which data can be read from or written to the cache buffer. The bandwidth depends upon the processor cycles required to fetch a standard operand data quantum of sixteen bytes. The cache bandwidth measurement is a product of:

* data path width
* bank interleaving
* access time

Efficiency of the pipeline depends on many design factors including:

* STO/TLB hit rate
* parallel operand fetch
* multiplicity of execution units
* operand conflict
* instruction modification
* branching

A large STO/TLB hit rate provides less Dynamic Address Translation (DAT) and decreases the fetch requirements for segment and page table entries. Parallel operand fetch decreases the cycles required for two operand instructions by providing the concurrent fetch of both operands. Multiple execution units allow the E stage overlap of two instructions. Operand conflict occurs when an instruction requires the results of the preceeding instruction as one of its arguements. This conflict along with instruction modification and branching all cause pipeline turbulence with a resulting decrease in the execution rate.

4. INTERNAL EXECUTION RATE

A more comprehensive method of measurement is Internal Execution Rate (IER) where given a realistic limited cache size the effects of memory overhead are considered. IER methodology is defined with an infinite amount of main memory so that the effects of paging and data I/O are ignored. Three additional performance factors are introduced with IER:

* cache hit rate
* cache architecture
* memory bandwidth

Cache hit rate depends on both the size of the cache and the aggregate working set size of the evaluation workload.

These processors have different cache architectures. Store-in design provides for the memory store of modified cache data upon cache line reuse. Store-through design does memory store immediately with cache modification so that corresponding memory and cache data always match: however, store-in architecture provides less overhead due to possible multiple data modifications prior to cache line reuse.

As with cache, memory bandwidth is a function of the data path width, bank interleaving and access time. One unique design introduces a memory pipelining technique and a two-level memory hierarchy. Its effect is to increase the effective memory bandwidth and reduce the cycles per instruction ratio particularly for memory intensive workloads.

5. INTERNAL THROUGHPUT RATE

The most inclusive measurement of the performance of a workload is the Internal Throughput Rate (ITR) where the real world effects of a limited main memory with paging and data I/O are included.

ITR requires consideration of two additional design criteria:

* Expanded Storage (ES)
* external I/O processor

ES impact is a function of the memory hit rate (i.e. demand paging) and the ES bandwidth. The influence of external I/O processor design depends on the extent to which I/O path selection and queueing are offloaded from the ALU.

6. WORKLOAD CHARACTERISTICS

The task in matching workload characteristics against processor specifications is to eliminate those elements that have a marginal effect on performance. There are two areas of processor design where performance is greatly influenced by workload criteria:

* pipeline efficiency
* memory overhead

The efficiency of pipeline execution is chiefly impacted by operand conflict and the locality of operand references. Data found in the same cache line as previous references reduces the probability of pipeline wait on a cache miss. The ordering of program data and the sequence of operations on that data have a significant impact on pipeline throughput.

Memory overhead may be reduced with increased cache and memory hit rates. Workload variables determine the number and distribution of memory accesses. These rates are mostly dependent on the instruction type mixture and the aggregate working set size of the workload.

Given values for these essential parameters for an evaluation workload, the relative processor performance may be predicted. Examples will be presented to illustrate the fit of workload characteristics to processor architecture.

COUPLED SYSTEMS FOR PERFORMANCE

Dr. Edward I. Cohen•
International Business Machines Corporation (*)
P.O. Box 390, Poughkeepsie, NY 12602
(914)-435-7898

ABSTRACT

A key approach to meeting the requirement for ever increasing performance capacity is the coupling of processors. Tightly coupled multiprocessors provide a wide range of performance levels within a single system image. Many design considerations are important factors in obtaining efficient execution in a large capacity multiprocessing system. These design factors include both hardware and software and in many cases are sensitive to total system capacity as well as the degree of multiprocessing. Providing a balanced system configuration is also key in obtaining the full performance potential of a large processing complex. Many multiprocessor performance characteristics have close analogies in the area of looslely coupled system complexes, and many of the same questions arise in both contexts. Current system structures and requirements lead to a view of future trends and directions in the area of coupled systems.

PERFORMANCE DEFINITIONS

BALANCED SYSTEMS AND THE 3090E

MP PERFORMANCE ANALYSIS

HARDWARE/SOFTWARE MP INTERACTIONS

LARGE SYSTEMS EFFECTS

LOOSELY COUPLED SYSTEMS

FUTURE TRENDS

<1> CMG 87 EIC 12/87

This presentation begins with some basic standard definitions of system performance, including both responsiveness and throughput. A key concept in obtaining the maximum capacity of a system is maintaining a balanced system configuration. The major components of a balanced system are highlighted with special emphasis on storage and I/O. An analytical approach to MP performance is described, and aspects of both hardware and software MP effects are considered. The most effective way to analyze the dynamics of a large MP system is to view it as a "system" and to understand the interactions of all hardware and software components. Actual examples of this kind of system analysis and design will be presented. Loosely coupled system complexes have their own unique multisystem characteristics and problems. However, in many cases these are very similar to problems encountered within a single MP system. The discussion of these items leads naturally to a comparison of tightly coupled MP and loosely coupled MP from a performance perspective. In conclusion significant trends and directions in the area of large systems are identified and discussed.

HOW TO DEFINE PERFORMANCE

RESPONSE TIME FOR ON LINE TRANSACTIONS

ELAPSED TIME FOR BATCH JOBS

EXTERNAL THROUGHPUT RATE (ETR)

- TRANSACTIONS PER ELAPSED SECOND
- SYSTEM CAPACITY IS MAXIMUM ETR

INTERNAL THROUGHPUT RATE (ITR)

- TRANSACTIONS PER CPU BUSY SECOND (AVG.)
- MEASURE EFFICIENCY OF HARDWARE/SOFTWARE COMBINATION
- COMMON MEASURE OF UNCONSTRAINED SYSTEM THROUGHPUT

INSTRUCTION EXECUTION RATE (IER OR MIPS)

- MEASURE OF CPU "HORSEPOWER"
- INSTRUCTIONS EXECUTED PER CPU BUSY SECOND (AVG.)
- SUM INSTRUCTIONS OVER ALL CPs

<2> CMG 87 EIC 12/87

The most critical aspect of system performance for the user and therefore for the system as a whole is responsiveness. This is measured as transaction response time for on-line applications and as elapsed time for batch applications and programs. Fast response time is so critical in the on-line environment that without it other measures of system performance are not very meaningful.

A basic measure of system processing capacity is External Throughput Rate (ETR). It measures the throughput of the system without regard to CPU utilization and when at maximum level is a good indicator of total system capacity. ETR can be constrained by a bottleneck anywhere in the system complex, and therefore it is not a good measure of the processing power of the central processing complex.

Internal Throughput Rate (ITR) measures throughput of the system but considers only the time during which the CPU is actually busy. Therefore, ITR is a standard measure of the efficiency of the central processing complex and its associated software. Accurate ITR values are best obtained in an environment which is free of constraints (storage, channels, control units, DASD arms, etc.). In this way it can provide as clear a picture of processor potential as is possible. Of course the degree of resource constraint existing in a system will affect the actual throughput which is achievable.

Instruction Execution Rate (IER or MIPS) of a processor is simply the rate at which it executes instructions during those periods when it is busy. IER is a basic measure of CPU horsepower which is available to the software. As such, it is an accurate measure of the central processor itself. All other things being equal, the IER ratio of two processors is a good estimate of their relative capacity. However, differences in the efficiency of software and differences in the level of resource constraint can frequently impact the level of performance obtainable. For both ITR and IER, transactions and instructions are summed over all CPs, while busy time is calculated as the average over all CPs.

PROCESSOR IER

IER DETERMINED BY CYCLE TIME & CYCLES PER INSTRUCTION

- CYCLE TIME IS CONSTANT
- CYCLES PER INSTRUCTION (CPI) VARIES GREATLY
  - INSTRUCTION SET
  - INSTRUCTION IMPLEMENTATION
  - INSTRUCTION MIX GENERATED BY "WORKLOAD"
  - NUMBER OF CPs IN TIGHTLY COUPLED MP

EXAMPLE PROCESSOR USES 25 NANOSECOND CYCLE TIME

- ENG/SCI WORKLOAD WITH 2 CYCLES/INSTR ==> 20 MIPS
- MIXED WORKLOAD WITH 3 CYCLES/INSTR ==> 13 MIPS
- DATABASE WORKLOAD WITH 4 CYCLES/INSTR ==> 10 MIPS

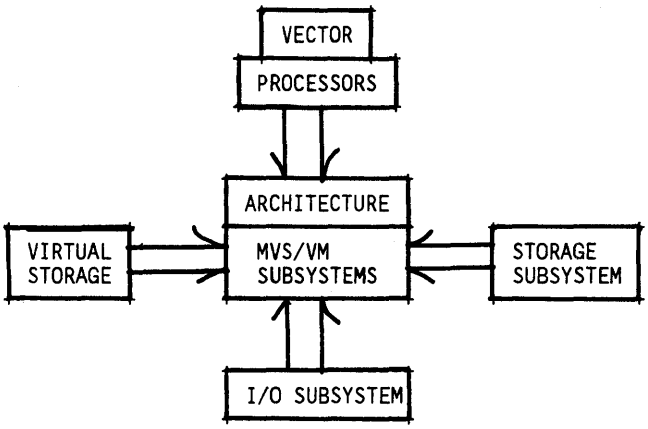
<3> CMG 87 EIC 12/87

The IER of a processor is determined by two factors, the cycle time of the machine and the average number of cycles it takes to execute an instruction. The cycle time is constant for each processor model and is driven by a highly accurate central oscillator. The cycle time achievable in a processor depends on the speed of the technology used, the machine organization, and the distances which internal signals must travel.

The average cycles needed to execute an instruction is highly variable and depends on a great many things, including the specific instruction set architecture used, the method of instruction implementation (degree of microcoded operations), and the number of CPs in a tightly coupled MP. Probably the key factor in determining cycles per instruction (CPI) is the specific instruction mix generated by the workload. In this case workload should be interpreted in the broadest sense to include operating system, subsystems, program products, and application programs. In addition many seemingly unrelated parameters can also impact IER, such as I/O rate, amount of data transferred, and storage usage.

A clear example of this sensitivity is seen when comparing workloads such as data base and engineering/scientific. The CPI in the former case may be about double the latter and as a result the IER in this example would also vary by a factor of two. The key point is that CPI and IER are not fixed numbers uniquely describing a processor. They are really dependent variables which can be affected by a wide range of factors. Because of this, comparative processor measurements must be done in the most controlled and repeatable environment possible to obtain meaningful and accurate results.

BALANCED SYSTEMS CONCEPT



PROCESSORS NEED BALANCED SYSTEM CONFIGURATIONS

3090E FAMILY PROVIDES RICH SET OF CONFIGURATION OPTIONS TO MEET WIDE RANGE OF WORKLOAD REQUIREMENTS

<4> CMG 87 EIC 12/87

In order to be able to utilize the potential power of a large processor a "balanced system configuration" is required. This will provide sufficient resources of each type to meet the needs of the total set of applications which will run on the processor. The key components of a balanced system configuration are the resources necessary to process work, including CPU horsepower (provided by CPs and vector processors), storage for data and programs, I/O capacity including channels, control units, and devices, and also virtual storage. A shortage of any of these resources in relation to the amount needed by the workload will constrain the entire system causing it to operate at less than full capacity, to elongate response times, or both. Each unique application workload requires a specific mix of resources. For example, one workload may require a lot of processor storage and little I/O, while another is I/O bound. A family of processors such as the 3090E must provide for a wide range of requirements by offering a rich set of possible configurations.

3090E CONFIGURATION OPTIONS

6 PROCESSOR CONFIGURATIONS (150E --> 600E)

0 TO 6 VECTOR FACILITIES

32 MB TO 256 MB CENTRAL STORAGE

0 MB TO 1024 MB EXPANDED STORAGE

16 TO 128 CHANNELS

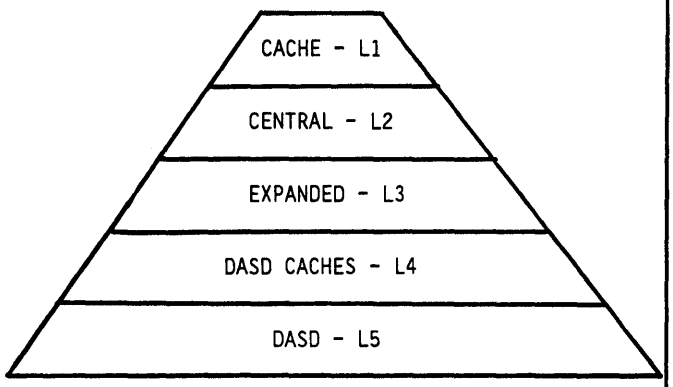
MODEL	VECTOR		CENTRAL		EXPAND		CHANNEL		TOTAL
150E	2	*	2	*	3	*	2	=	24
180E	2	*	2	*	5	*	3	=	60
200E	3	*	2	*	6	*	4	=	144
300E	4	*	2	*	6	*	4	=	192
400E	5	*	2	*	6	*	4	=	240
600E	7	*	2	*	6	*	4	=	336
TOTAL									996

<5> CMG 87 EIC 12/87

The 3090E family of processors offers configuration options covering a wide range of capacity levels and providing multiple options for each level of processing power. There are six models, starting with two uniprocessors up to the largest single image processor available, the 3090-600E. Each model can be configured with from zero to N vector processors where N is the number of CPs. Multiple options and combinations of central storage, expanded storage, and channels are available with each model. The total number of combinations available across the model line is 996 configurations. For each model a maximum configuration of each resource is available which can handle the most stressful load attainable in any production environment. For example, the maximum number of channels offered on a particular model has been determined by studying production workloads and identifying the most stressful workload environment. In this way a 3090E configuration is available which can satisfy almost any conceivable workload requirement.

The strategy behind the design of the storage subsystem of a large processor is called a "Storage Hierarchy." Its goal is to provide multiple storage levels so that the average cost per bit across all storage is very close to the cost of the least expensive level and the average access time to data, as seen by the processor, is close to the fastest level. The hierarchy has many levels, for example L1 (CP cache) to L5 (DASD). In this example both access speed and cost decrease as one moves down the hierarchy. Size increases dramatically from top to bottom along the hierarchy, and this leads to the desired average price per bit.

STORAGE HIERARCHY



SPEED DECREASES GOING DOWN HIERARCHY (L1 -> L5)

COST DECREASES GOING DOWN HIERARCHY

SIZE INCREASES GOING DOWN HIERARCHY

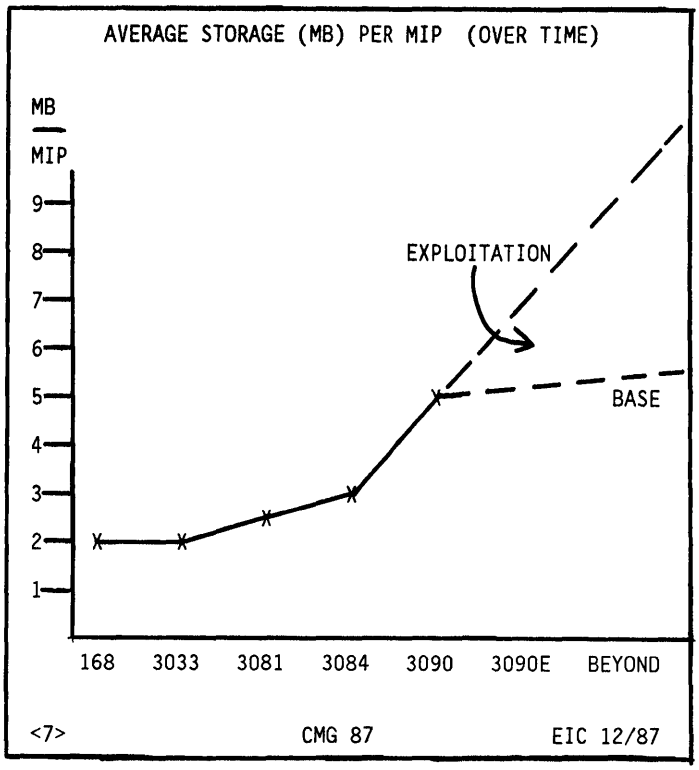
INTERLEVEL MOVES MANAGED BY HARDWARE OR SOFTWARE

GOAL IS "AVERAGE SPEED OF L1" & "AVERAGE COST OF L5"

<6> CMG 87 EIC 12/87

Data movement between levels is normally managed by hardware, microcode, or software. For example, movement between processor cache and central storage is managed by CP hardware using an LRU philosophy. Movement between central and expanded storage is managed transparently by the operating system. Finally, movement between DASD and DASD caches is managed by microcode in the cached DASD controller. While each of these storage managers may be implemented somewhat differently the basic goals and algorithms (LRU) are the same. The concept of a storage hierarchy is key to providing a fast storage subsystem at a reasonable cost and will continue to be the guiding strategy in large system designs.

Historical trends in the usage of storage can be studied by graphing average storage (MB) per MIP over time, where time can be represented by the chronological sequence of IBM high end processors (168, 3033, etc.). Using typical storage configurations provided with those processors we see that during the 168 and 3033 time frame configurations were about 2 MB per MIP. That rose slightly with the 3081 and 3084 processor lines to about 3 MB per MIP and then jumped to about 5 MB per MIP for 3090s. This trend shows that storage configurations were constrained by technology limits and costs until the 3090 provided large storage configurations of central + expanded storage.



The storage available with 3090 and 3090E processors allows one to achieve full system capacity and can relieve the problems of paging/swapping performance and tuning. The interesting question is what will happen in the future? If future use of storage is similar to today's usage one would expect to see a fairly flat curve which would lead to configurations growing only at about the rate of MIPS growth. However, with the attractive and impressive gains being made in storage technology and price, the direction is to exploit larger storage configurations for new functions. A key area of storage usage will be in large database buffer pools. This can reduce database I/Os dramatically, provide improved response times and system ITRs, and allow for somewhat smaller database I/O configurations. Functions such as this which can successfully exploit large storage will move the MB per MIP trend higher. The 3090E systems can provide over one gigabyte of processor storage and are positioned to take advantage of new uses of storage such as large buffers.

The MP/UP throughput ratio depends on the software and hardware factors determining the MP/UP CP MIPS ratio and the change in path lengths between the MP and UP case. In general one expects to get less than N times a UP from an N-way MP system. The same formula can be used to calculate the ratio of any two systems (for example quadratic to dyadic) by using the ratio of 4-way to 2-way in each factor in the equation. By studying the formula one can see that both hardware and software are potential sources of extra processing time on highly parallel and dynamic MP systems.

TIGHTLY COUPLED MP PERFORMANCE

$$Pn = N * (1 - Hn) * (1 - Sn)$$

WHERE

Pn = N-WAY MP/UP ITR RATIO

N = NUMBER OF CPs

Hn = N-WAY MP HARDWARE FACTOR

Sn = N-WAY MP SOFTWARE FACTOR

EXAMPLE: N=2, Hn=5%, Sn=5%

N=4, Hn=10%, Sn=10%

P(DYADIC/UP) = 2 * (.95) * (.95) = 1.805

P(QUAD/DYADIC) = 4/2 * (.90/.95) * (.90/.95) = 1.795

<8> CMG 87 EIC 12/87

While the cycle time remains constant the cycles per instruction (CPI) tends to increase with the number of CPs in the MP system. This is the result of many functions which must be executed differently on an MP, both in hardware and software. A shift in instruction mix is generally observed when comparing an MP to a UP, and this is the result of MP and large system management algorithms executed by software. For example, SIGP instructions are only executed on MPs, and they take a long time to execute compared to more typical average instructions. In addition other instructions and functions may be executed on both UP and MP systems, but their frequency may be higher on MP and the time it takes to execute them may be higher. For example, since supervisory functions in the software are executed more frequently on an MP, privileged ops such as LPSW and LCTL, which are relatively slow, may be executed more frequently per MIP on an MP. Also, an instruction such as Compare & Swap (CS) requires more cycles as CPs are added because N-1 of them have to be synchronized with the issuer of the instruction.

Another area in which MP is affected is in cache performance. Each CP needs to coordinate with all other CPs when locating a valid copy of a particular cache line, since another CP may have a changed copy in its cache which has not been reflected in storage. In this case the CP needs to crosscheck with the other caches. Also, from time to time an active piece of data may be shifted from one CP cache to another before the first has finished using it and this can create data contention.

A final area of focus is access to storage and contention for the access paths and staging facilities. Since an MP generates a higher requirement on storage, the level of contention for common, shared facilities is necessarily higher with the higher levels of MIPS available in the MP. These characteristics have been recognized and studied since the early years of MP design, and sufficient capacity and redundancy is now designed into MP systems to handle peak loading requirements.

The path lengths executed by software increase both with the increase in CPs and as a result of higher levels of

total system MIPS. Certain software functions are used more heavily on a large MP system than on a smaller UP such as dispatching, wait state processing, and locking. In addition more instructions are needed to manage the more dynamic environment found in an MP system. It has been recognized that many functions which at first seem to exhibit MP growth characteristics really are being driven higher by the need to manage a larger system image and its associated larger sets of resources and work units. These "Large System Effects" have been identified and removed on a regular basis in new software releases and will continue to be studied. These effects react solely to the level of capacity independent of the number of CPs configured. Since MPs have always been the largest image available these effects are always observed first on the MP. Large system effects impact both IER and path lengths since they typically do not execute as efficiently as average instructions. Overall, these MP and large system characteristics are well understood, and each new release of software and each new processor model incorporates the latest improvements in these areas.

MP HARDWARE, SOFTWARE, AND SYSTEM FACTORS

CYCLES PER INSTRUCTION INCREASES WITH NUMBER OF CPs

- INSTRUCTION MIX CHANGES
- CACHE INTERACTIONS
- STORAGE CONTENTION

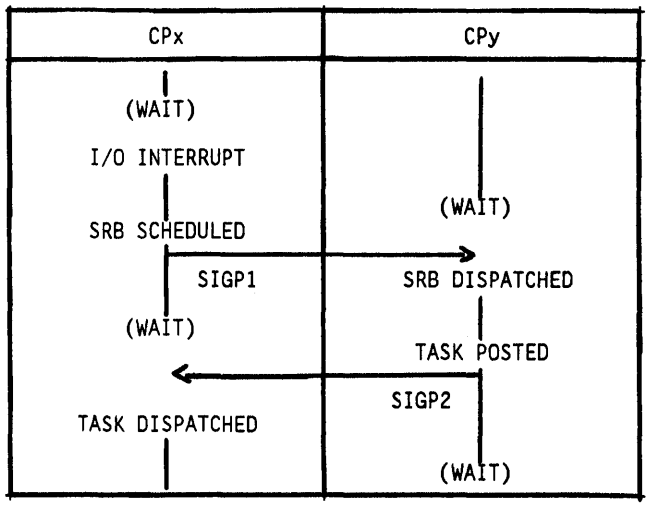
INSTRUCTIONS PER TRAN. INCREASE WITH NUMBER OF CPs

- WAIT STATE PROCESSING
- LOCKING AND RESOURCE UTILIZATION
- MANAGING MULTIPLE PROCESSORS

INSTRUCTIONS PER TRAN. INCREASE WITH TOTAL SYSTEM MIPS

- "LARGE SYSTEM EFFECTS" IN SOFTWARE
- DEPENDS ON WORKLOAD AND CONFIGURATION SIZE
- MOST NOTICEABLE ON LARGEST SUNGLE IMAGE MPs
- IMPACTS BOTH IER AND INSTRUCTION PATH LENGTHS

WAIT STATE PROCESSING



SIGP IMPACTS PATH LENGTH AND IER

FREQUENT CONTEXT SWITCHES IMPACT CACHE LOCALITY

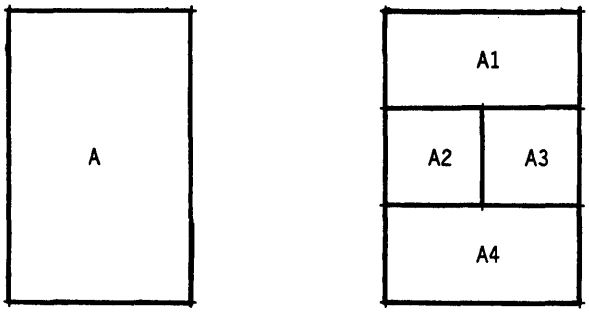
PROBABILITY OF ONE OR MORE WAITING CPs FOR 600E

- 88% AT 70% CPU UTILIZATION
- 74% AT 80% CPU UTILIZATION
- 47% AT 90% CPU UTILIZATION

The management of waiting processors has steadily gained importance as the number of CPs has grown. For example, on a 6-way MP the probability of finding one or more processors in the wait state is 47% even at 90% CPU utilization. The processing of I/O interrupts and the interaction with waiting processors illustrates the increased dynamic nature of N-way MP. After the I/O interrupt is accepted, an SRB is scheduled to run in the address space waiting for the I/O to complete. At this time any waiting processor will be signalled (using a SIGP) to dispatch and execute the SRB while the initial processor goes on with what it had been doing. This uses the philosophy that there is nothing of lower priority than sitting in the wait state. Similarly, when the SRB posts the task as ready to run (since its I/O has completed) the posting function will SIGP any waiting processor to dispatch and execute the task. This process exploits the parallelism available on an MP and optimizes responsiveness. However, it also execute a lot of extra instructions which tend to execute slowly. Wait state processing was thought to be of little importance because interrupting wait state is not like interrupting a busy task. However, its increasing frequency on large MPs indicates that a more efficient mechanism may offer improved performance.

RESOURCE SERIALIZATION AND LOCKING

TIGHTLY COUPLED SYSTEMS REQUIRE MORE PRECISE LOCKING



ATOMIC SERIALIZING INSTRUCTION (CS)

- ALWAYS USED TO OBTAIN LOCKS (MP AND UP)
- REQUIRES MORE CYCLES ON MP TO SYNCHRONIZE N-1 CPs

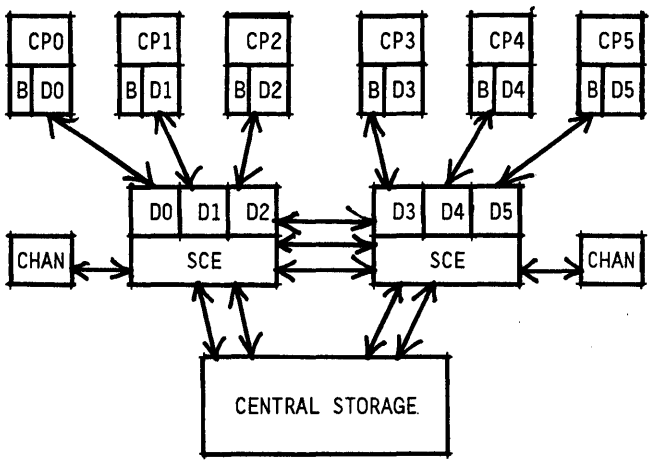
LOCK CONTENTION AFFECTS BOTH IER AND ITR

<11> CMG 87 EIC 12/87

Resource serialization and locking is a basic requirement for any software system which needs to support parallel execution of independent tasks and functions. Serialization using an atomic updating instruction such as Compare & Swap (CS) is used for locking and also to update any shared, common, or global field which may be accessed in parallel. For example, many system level counters maintained within MVS are incremented and decremented using CS. In all of these cases the CS instruction is executed and the lock or counter is serialized even if execution is on a UP. In this case the performance difference in MP is in the timing of the instruction itself, and this is reflective of the extra time it takes to synchronize N-1 other processors.

As software has evolved to be able to support more MIPS and higher levels of MP it has been necessary to enhance the granularity or precision of the locked entities in order to reduce contention. For example, if a large set of data resources (labeled A) are all controlled by a single lock then multiple functions needing access to subsets of A will contend with each other since they each must serialize all of A as a single entity. In this case the enhancement is to subdivide A into parts (A1-A4) which correspond to the subsets frequently accessed together by each of the functions using A. In this way multiple functions (up to four of them) can share the resources which only one could use previously. This approach has been used in many software products through the years to improve MP performance. However, care must be taken in this approach since if A is broken up unwisely, some functions will now need to obtain serialization on multiple resources from the set A1-A4. In this case any reduction in contention may be compromised and multiple lock obtains and releases may be required (using CS). In general, resource and lock contention affects both IER and ITR, and it can also occur on a UP system which uses suspend locks to serialize one task with another in a multiprogramming environment.

STORAGE SUBSYSTEM OVERVIEW



KEY STORAGE COMPONENTS

- SCE AND SCE TO SCE BUSSES
- HIGH SPEED STORE-IN BUFFERS (PROCESSOR CACHES)
- CACHE TO CACHE BUSSES
- CENTRAL STORAGE ACCESS BUSSES AND REGISTERS

<12> CMG 87 EIC 12/87

An overview of the storage subsystem shows that the System Control Element (SCE) is the key component. It controls all accesses to storage and is central in the resolution of all cache faults. For high speed transfers and wide bandwidth there are three busses between SCEs in an MP system. The channel processing engine is also ported to the SCE (as are all the CPs) since it needs to store and fetch data from storage for each I/O. Each SCE is designed to handle the stress load of a fully configured system consisting of requests from three CPs, from the other SCE, and from the channel engine. Each CP has its own high speed cache buffer and associated cache directory. In addition the SCE maintains a duplicate copy of the cache directories in order to resolve crosschecking on cache faults.

The caches in the 3090 and 3090E processors are store-in, which means that a change to a data element in cache does not have to be reflected back to central storage at the time of the update. In this design a changed data element may be valid only in the copy in a cache and the copy in central storage may be obsolete. The SCE manages all of these events so that data integrity is maintained at all times. Although a store-in cache design is more complex than a store-through design it is advantageous since it dramatically lowers the data flow to central storage. When the SCE recognizes the case in which a cache line requested by a processor is in another processor's cache it obtains that line for the requestor via a cache to cache transfer rather than from storage. In the case of a changed line of data this reduces the delay time significantly since a cache to cache transfer is much faster than cache to storage to cache. Even in the case of an unchanged line the cache to cache path is frequently used since it reduces the load on the storage access paths. Overall, this structure is a sophisticated and time proven

design which provides the required function and performance.

STORAGE IMPACT ON PROCESSOR IER

CACHE MISS

- DIRECTORY LOOK UP
- FETCH CACHE LINE FROM CENTRAL STORAGE
- OBTAIN DATA VIA CACHE TO CACHE PATH

CYCLES PER INSTRUCTION (CPI)

- CPI WITH INFINITE CACHE ASSUMPTION
- FINITE CACHE STORAGE ADDS TO CPI
- DEPENDS ON CACHE MISS RATE AND AVERAGE CYCLES NEEDED TO RESOLVE MISS

CYCLES TO RESOLVE MISS

- CACHE TO CACHE TRANSFER
- CONTENTION FOR CENTRAL STORAGE ACCESS PATHS

MP STORAGE DESIGN INCLUDES CONTENTION

- DESIGN POINTS ARE 3-WAY AND 6-WAY MPs
- CONTENTION LESS ON UP, DYADIC, AND QUAD
- CONTENTION ALSO DEPENDS ON CPU UTILIZATION

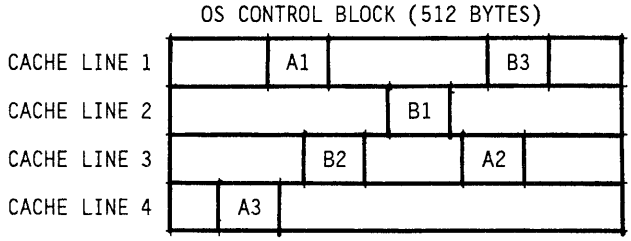
<13> CMG 87 EIC 12/87

The cycles per instruction (CPI) performance of a processor can be studied in two stages. The first stage assumes that all data references are satisfied from cache (100% cache hit is equivalent to having an infinite cache). In this stage the analysis centers around the processor logic normally divided into I-units and E-units. Infinite cache performance is very important since actual cache results typically show that 95+% of all storage references are satisfied from the processor's cache directly. Cache misses are much less frequent and can be analyzed separately. The second stage studies the finite cache impact to CPI which includes the rate of cache faults and the time required for resolution. In this second stage the impact of the storage subsystem is key and both cache and storage delays need to be considered.

When a cache fault is detected the first step is to search for the requested line in other caches. This is done by the SCE using its copies of the cache directories. The first case is when no other cache contains the data. This is a simple miss, a storage fetch is initiated, and the time to resolve the cache fault depends on the contention encountered on the access path to central storage. In the second case, if another cache contains the data and it is changed in that cache, then that is the only valid copy and a transfer of the changed line over the cache to cache path is invoked. In the third case, if another cache holds the line with no change then a copy of the line can be obtained via cache to cache or from storage depending on the type of request. In this case the holder of the line might also retain a copy.

The current storage design point is the 3-way and 6-way MPs because they produce the most stressful requirements on the storage subsystem. Any practical system must be designed with contention detection and resolution in mind since it is a normal occurrence in these situations. Sufficient capacity is designed into these areas to handle maximum loads with reasonable amounts of contention for resources. Of course the level of contention is less when the CPU utilization is lower or when less than the full complement of CPs is active or installed (UP, dyadic, quad).

ANALYSIS OF CACHE PERFORMANCE



SOFTWARE DRIVES CACHE PERFORMANCE

INCREASED CACHE SIZE CAN INCREASE XIs

CPU UTILIZATION AFFECTS CACHE PERFORMANCE

SOPHISTICATED LABORATORY INSTRUMENTATION REQUIRED

- STUDY CACHE MISS AND XI HOTSPOTS
- IDENTIFY EXACT INSTRUCTION AND STORAGE REFERENCE

SOFTWARE REDESIGN GOALS

- LOCALIZE A1-A2-A3 AND B1-B2-B3
- REDUCE DIRECT CACHE MISSES BY A FACTOR OF THREE
- REDUCE CACHE MISSES CAUSED BY CACHE FLUSHING
- REDUCE XIs BETWEEN FUNCTION A AND FUNCTION B

<14> CMG 87 EIC 12/87

Software design, particularly data formats, is the driving force behind cache performance both for cache miss rates and the level of intercache contention. Studies have shown that operating systems have cache hotspots which are specific instructions in frequent software functions which suffer an unusually high rate of cache faults. This is also true for cache interference (cache cross interrogate), but these two sets of hotspots may be disjoint.

In the example control block, two functions A and B are shown which exhibit hotspots on references to fields A1, A2, A3 and B1, B2, B3 respectively. The first problem is that each function requires three of the four cache lines in this control block and will generate many more cache faults than absolutely necessary. Also, an indirect result is the flushing of the cache. This type of control block frequently exists within a queue of identical

blocks, many or all of which need to be accessed. In this case a large fraction of the cache may be replaced by these same three lines multiplied by the number of control blocks on the queue. These functions also can cause a lot of cache interference since they are trying to share the same cache lines (although they are actually using different data fields).

A common solution is to rearrange the control block in the next available release of the software so that function A's data is in one cache line and function B's data is in a different cache line. In this way the cache faults in each function will be reduced by two-thirds, there will be less chance of cache flushing, and contention will be significantly reduced.

LARGE SYSTEM SOFTWARE EFFECTS

SOFTWARE SYSTEM/SUBSYSTEMS INTERNAL DESIGN

- BASIC STRUCTURE IS LINKED QUEUE OF DATA BLOCKS
- KEY ACTIVITY IS SEARCHING QUEUE
- SEARCH PATHLENGTH INCREASES WITH TOTAL SYSTEM MIPS

PROCESSOR POWER	X	2*X
QUEUE LENGTH	A	2*A
INSTRUCTIONS/ELEMENT	B	B
SEARCHES/SECOND	C	2*C
TOTAL INSTRUCTIONS	A*B*C	4*(A*B*C)

HIGHER MIPS LEVELS EXPOSE NEW LARGE SYSTEM EFFECTS

LARGE SYSTEM AND MP SOFTWARE EFFECTS OCCUR TOGETHER

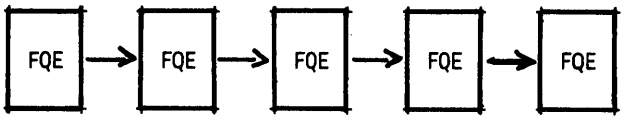
LARGE SYSTEM EFFECTS REMOVED IN NEW SOFTWARE RELEASES

<15> CMG 87 EIC 12/87

In all software systems and subsystems the basic control structure is a linked queue of identical blocks, and the key action against these queues is searching. In almost all cases the search requires more instructions on a more powerful system because the queue tends to be longer in a larger system with more active elements (devices, channels, storage, tasks, etc.). This growth in path length is independent of whether the growth in MIPS is achieved by adding processors or by replacing one processor with a similar but faster model (UP to UP, dyadic to dyadic, etc.).

When the speed doubles, the function is executed twice as often, and each time it must search twice as many elements. This results in a four fold increase in instructions and a two fold increase in time because the instructions will be executed twice as fast. MP effects frequently occur with and because of these large system effects. For example, if the longer search requires serialization, the increased time spent in a serialized state will cause more contention (lock spin). Also, while searching the longer queue more cache flushing can occur. Often the frequency of execution on an MP will accentuate the large system effect. As new levels of MIPS and parallelism are reached, new large system and MP effects are identified and resolved as quickly as possible.

MVS/370 SQA GETMAIN/FREEMAIN



ORDERED BY ADDRESS

RANDOM ORDERING BY SIZE

GETMAIN

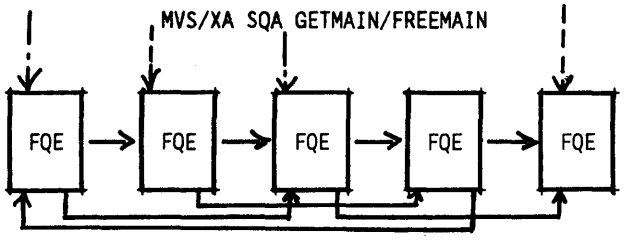
- SEARCH ENDS IF EXACT FIT FOUND
- ELSE ENTIRE QUEUE SEARCHED FOR BEST FIT

FREEMAIN

- QUEUE SEARCHED FOR INSERT POINT (BY ADDRESS)
- RECOMBINE FQEs IF POSSIBLE
- HALF OF QUEUE SEARCHED ON AVERAGE

<16> CMG 87 EIC 12/87

MVS/370 SQA Getmain/Freemain remains the classic example of the intermingling of large system and MP effects in software. In this case the queue of Free Queue Elements (FQEs) represents unassigned areas of SQA storage. The queue is ordered only by ascending address, and therefore the size order of the free elements is totally random. Getmain searches the queue until an exact size match is found; if no match is found it searches until the end of the queue and assigns a piece of the block which is closest in size but larger than the request. Most getmain requests search the entire queue. Freemain searches until the correct insert point is found based on address, and in general somewhat more than half the queue needs to be searched. As MIPS increase, the SQA area increases, the area becomes more fragmented with many small blocks, and the queue grows to enormous length. In addition the search uses a global MVS/370 spin lock to serialize access to the queue. All of MVS/370 storage management must contend with this elongated search algorithm for use of the lock. This case shows a large system effect which is compounded by and feeds a secondary MP effect.



ORDERED BY ADDRESS AND FQE SIZE

INDEX TABLES FOR BOTH ADDRESS AND SIZE

GETMAIN

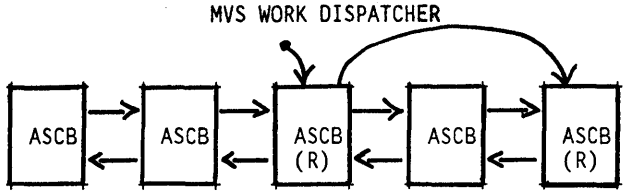
- FIND INDEX FOR SIZE REQUESTED
- SEARCH QUEUE SEGMENT STARTING AT INDEX POINT
- BEST FIT IS FIRST BLOCK LARGE ENOUGH

FREEMAIN

- FIND INDEX FOR ADDRESS RANGE
- SEARCH AND RECOMBINE AS IN MVS/370

<17> CMG 87 EIC 12/87

In MVS/XA the SQA FQE search is reduced by adding additional structure to the queue design. A second set of pointers were added which could be used to search the queue in size order instead of address order. Also, index tables were added for both size and address order which can be used to direct the search to a small subset of the queue. Getmain finds the index for the requested size and searches the queue from that point in ascending size order until the first block large enough is found. Freemain works as before except that the index leads quickly to the correct segment of the queue. These enhancements would be enough to resolve the associated MP lock out, but the locking structure was also enhanced and this function now has its own unique lock. These changes solved both the large system and MP aspects of this problem and led to improved MP/UP IER and ITR ratios even though the hardware involved was not changed at all.



QUEUE OF ALL SWAPPED IN USERS (ASCBs)

QUEUE SEARCHED FOR HIGHEST PRIORITY READY WORK

QUEUE GROWS WITH TOTAL MIPS

ALGORITHM ALSO EXHIBITS MP GROWTH

- HIGHER DISPATCH RATE ON MP
- ALL OTHER QUEUE SEARCHES SERIALIZED BY SPIN LOCK

MAJOR CAUSE OF "LOW UTILIZATION EFFECTS"

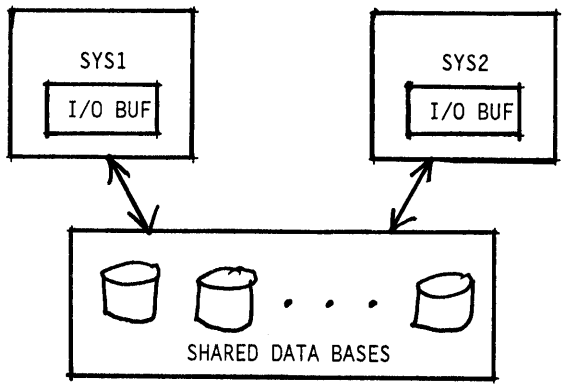
FIXED BY "TRUE READY QUEUE" DISPATCHER IN MVS/SP 2.1.7

<18> CMG 87 EIC 12/87

Another large system and MP problem was recently resolved in release 2.1.7 of MVS. The MVS dispatcher does frequent searches of a queue of all swapped-in address spaces (ASCBs) looking for the highest priority ready work. This queue grows with MIPS and tends to have very few ready ASCBs since most address spaces are in wait state. This algorithm also impacted MP/UP ratios because the dispatch function is invoked more frequently on an MP system. Also, other functions which use the queue needed to serialize it which also was reflected in the MP/UP ratio. This algorithm is the major cause of the "Low Utilization Effect" which uses extra CPU time to manage a system which does not have enough work to keep it very busy (time spent looking for work and processing wait state entries/exits). The "True Ready Queue" dispatcher enhancement fixed this problem by introducing a new set of pointers linking only the ready ASCBs so there should never be a long search for ready work. Again, this affected MPs more since their dispatch rate per transaction is higher and their queues are longer.

These examples show the difficulty in separating MP unique effects from other related effects. In general this requires high precision laboratory instrumentation of a running system to obtain accurate enough detailed information to pinpoint cause and effect relationships correctly.

LOOSELY COUPLED SYSTEMS



BUFFER COHERENCY PROBLEM

- DATA BASES ------> CENTRAL STORAGE
- I/O BUFFERS ------> PROCESSOR CACHES
- BUFFER CASTOUT ------> CACHE TO CACHE XIs

LOOSELY COUPLED PROBLEMS SIMILAR TO MP

<19> CMG 87 EIC 12/87

Frequently, loosely coupled problems are analogous to problems in a tightly coupled MP. For example while MVS has to schedule work between CPs in single image MP system, JES has to do the same thing across multiple systems in a complex. Problems caused by the requirement to share data are also very similar. In single image MP this problem becomes the sharing of data between processor caches with a common central storage. In loosely coupled complexes this problem is reflected as multiple systems trying to share data from a common centralized data base. In this case the general problem of buffer coherency appears as a common problem of any data sharing design.

In trying to compare and contrast the performance of single image and partitioned loosely coupled it is true that single image mode will have lower average CP MIPS and increased path lengths in comparison to a single partition. However, instruction path lengths will also grow in the loosely coupled case due to the overheads of sharing data (using functions such as IRLM and GRS). JES2 and JES3 requires extra instructions when trying to manage and schedule a workload across multiple systems. Also, there may be extra overhead due to increased paging in the partitioned case because of the need to support two copies of the operating system and its subsystems. Finally, a system such as MVS can more efficiently schedule and balance work across tightly coupled CPs than JES can across multiple system images. So, the conclusion is not clearly in favor of one over the other. While the IER and even the ITR may be lower on single image, the processing capacity (max ETR) may be higher.

LOOSELY COUPLED PERFORMANCE

CP MIPS IS LOWER ON SINGLE IMAGE MP

INSTRUCTIONS PER TRAN IS HIGHER ON SINGLE IMAGE MP

INSTRUCTIONS PER TRAN GROWS ON LOOSELY COUPLED

- SHARED DATA FUNCTIONS (IRLM, GRS)
- WORKLOAD BALANCING FUNCTIONS (JES2, JES3)
- INCREASED PAGING FOR STORAGE OF TWO COPIES OF MVS

SINGLE IMAGE MVS CAN MANAGE MP WORKLOADS BETTER THAN MULTISYSTEM JES2/JES3

CONCLUSION ---- NOT CLEARCUT

- IER LOWER ON SINGLE IMAGE
- EVEN ITR MAY BE LOWER ON SINGLE IMAGE

BUT

- PROCESSING CAPACITY (ETR) MAY BE HIGHER

<20> CMG 87 EIC 12/87

In conclusion, future trends have already been established and will continue. Both modes of coupling processors will continue to evolve, and the typical large installation will need to be a loosely coupled complex of large tightly coupled MPs. In the area of performance, single image performance will continue to improve as knowledge gained from working with current 6-way processors is incorporated into new product releases. Loosely coupled function and performance will continue to be enhanced. In the area of balanced systems, multiple configuration options will continue to be needed to meet the diverse needs of a broad spectrum of workloads. I/O capacity will keep pace with the growth in processing capability. Storage will become even more important in providing performance gains as large storage configurations and exploitation become more widespread.

FUTURE TRENDS

COUPLED SYSTEMS

- FUTURE NEEDS TIGHTLY COUPLED MP AND MULTISYSTEM
- COMPLEX OF LOOSELY COUPLED LARGE MPs

PERFORMANCE OF COUPLING

- MP PERFORMANCE STILL KEY FOCUS FOR HIGH END SYSTEMS
- LOOSELY COUPLED FUNCTION & PERFORMANCE ENHANCEMENTS

BALANCED SYSTEMS

- MANY OPTIONS FOR MATCHING CONFIGURATION TO WORKLOAD
- EXPLOITATION OF LARGE STORAGE CONFIGURATIONS
- INCREASED I/O CAPACITY TO MEET MIPS GROWTH

CMG'87 New Books Section, Paper Reference # 21
New Books Session, Tuesday, 8 December 1987

Introduction

A significantly revised edition of a book entitled **A Computer and Communication Network Performance Analysis Primer** which first appear in 1985 has been issued. The latest edition involves over 25% new material, as well as significant revisions to over 50% of the old material, resulting in a substantially new book that has benefitted from a wide variety of constructive criticism in the marketplace.

The new edition concentrates much more on the commercial marketplace (read IBM), and on networking issues, than the first edition. The exposition was felt to be overly terse with respect to a number of case studies, and this issue has been addressed. The goal has been to make the concepts accessible to the widest possible audience: the breadth and depth have been increased. The intent is that the new edition should prove to be a very valuable reference book for professionals as well as an excellent introductory text for neophytes. Time will tell.

The book is organized in a teach by example method, starting from specific case studies and moving toward general principles. Typically an actual situation is described, to motivate the material; the next step is to quantify what performance means for this situation, what are the inputs and what are the outputs; next, a formula is presented (with a reference in the open technical literature to where it came from) that relates inputs, outputs, and performance measures, with no time spent on derivation of the formula (a very limited number of derivations are presented for the few results that are felt to be critical); finally, a variety of numbers are substituted into the formula, to gain insight into what parameter changes are most significant on performance and what are not, in order to gain qualitative insight into performance tradeoffs by means of quantitative numerical sensitivity studies.

Over two hundred exercises, over one hundred and fifty figures, over one hundred fifty references to the open technical literature, spread over thirteen chapters spread and six hundred pages (plus an answer book for the exercises for instructional use) make this book a valuable addition to the library of any analyst.

The exercises are an integral part of this material: working the exercises stresses the understanding of the concepts in new directions, and reinforces what is important and what is not.

Two problems are encountered in this material: first, the actual applications (taken from real world computer communication systems) may boggle the purist in complexity, while being much much too simplified for the practitioner. Second, the large number of equations and formulae suggest to the practioner that this treatise is too mathematical; in fact, there is virtually no mathematics here, only substitution of numbers into formulae, requiring addition and subtraction and multiplication and addition, all of which may alienate the purist.

Section A. Mean Value Analysis

A significant amount of new material has been included in this section. The discussion begins with static or deterministic scheduling, such as in a batch environment, with all the work present at an initial time, and the goal is to minimize the time required to execute all the work. A uniform representation of these problems, based on specifying the steps required for each job, the resources required for each step, and the time per step, fixes all the ideas. This representation, based on a standard table or tableaux of steps, resources, and duration, is used throughout the entire text; the earlier edition was criticized, and rightfully so, for not being consistent in this regard.

This analysis is extended by allowing more and more jobs to be present at an initial time. It then becomes meaningful to deal with the ratio of the total number of jobs executed in a given time, or a rate or throughput. No stochastic processes, no queueing theory, nothing but workflow concepts, fix all these ideas. Over one half of the book is devoted to this topic: how to apply it, where it is strong and weak, and example after example to reinforce these points. Other books typically give this roughly ten pages, dismissing it as intellectually trivial. Here we argue that this material is the most important part of computer communication system performance analysis, and should be emphasized in the extreme, not dismissed in passing.

For those that want more, we pose this analysis as a linear programming problem, with the possibility for bounding performance using widely available numerical LP packages. The advantage of this approach is that it is hierarchical: as more constraints are included, as the model becomes more complex and realistic, this phenomena can be quantified and included, and the performance bounds become correspondingly tighter. Nonetheless, the bounds are useful at any stage of analysis, with the caveat that the more simplistic the model, the looser the bounds.

Major new examples developed here include online lottery transaction processing (with a performance goal of processing over 2,000 transactions/second with an end to end response time (measured from the time the wager is entered at a terminal until the terminal finishes printing a ticket for that wager), and a voice storage system analysis for a telephone common carrier.

A great deal of emphasis is placed on parallel processing: what performance is achievable for a given workload and schedule (how can algorithms and data structures help?). This is unique for an introductory text.

The section on data analysis or model validation is well known to statisticians, but is rarely found in books on computer communications performance analysis. This is surprising, because the crux of this type of analysis is to use computers and graphics to generate plots and pictures that suggest what models are most appropriate for the data, and how good a model fits actual data.

The entire section on mean value analysis forms a self contained one semester course on performance analysis.

Section B.Jackson Queueing Networks

Jackson queueing networks are motivated as a limiting case of mean value analysis: by making stronger assumptions about a model, correspondingly stronger statements can be made about performance tradeoffs.

New examples to be found in this section include a database management system hierarchical performance analysis, and a voice/data network design for a major commercial bank. The network design encompasses state of the art methodologies, and is unique.

The mean value analysis is carried out in parallel with the Jackson network analysis, in order to emphasize that the Jackson network analysis is a refinement that quite closely approximates the mean value analysis.

Section C.Single Serially Reusable Resource Scheduling

In many computer communication networks, under load one resource becomes a bottleneck, and virtually all performance tradeoffs revolve around how work is scheduled on the bottleneck.

This section proceeds hierarchically, starting with an introduction to the area, priority scheduling impact on performance, and local area networks.

The introductory section includes a discussion of link level communication protocols, including a delay analysis for HDLC. This is unique to an introductory treatment.

In addition, the introductory section includes a discussion of numerically approximating delay distributions, not simply averages or higher order moments, using a class of flexible, fast and quite accurate algorithms. This is rarely found in any book.

The priority scheduling section includes a discussion of non preemptive and preemptive resume scheduling, including the impact of correlation of tasks (a job consists of a set up phase, a work phase, and a clean up phase, and each is run with its own priority in this order) and burstiness (using a compound Poisson arrival process with multiple arrivals at the same time epoch of different urgencies and type of work). These results cannot be found anywhere else.

The concluding sections of priority scheduling deal with link level flow control and voice/data multiplexing. This analysis cannot be found anywhere else.

The section on local area networks include the most up to date analysis yet on Ethernet-like networks, token passing networks (rings and busses), and hybrid networks that behave like Ethernet under light load and like token passing under heavy load. Excellent texts are now appearing on these topics. The analysis of Ethernet appears nowhere else.

Section D.Special Topics

The final area deals with detailed case studies, including recent advances in performance analysis of switching systems (circuit switching, packet switching, Batcher/Banyan, and hybrid), a multivendor layered protocol performance analysis (including SNA, DECNet, TCP/IP, and ISO), a refinement of the voice/data network design case study described in the Jackson network section, a case study in operating system versus computer networking performance tradeoffs, and reduced instruction set computer (RISC) performance tradeoffs (processor, cache, main storage, bus performance, compiler, and networking capabilities).

Because these topics are of interest to specialists, they can be used as part of a seminar, omitted entirely, or touched upon in a variety of settings. One of the advantages of a book is that everything need not be used in a single class, but can be spread over different classes and different audiences.

A CLOSE LOOK AT MVS SYSTEMS:

MECHANISMS, PERFORMANCE AND SECURITY

by

Ronald Paans, IBM The Netherlands[1]

The book "A Close Look at MVS Systems: Mechanisms, Performance and Security" provides a functional description of many hardware and software components of MVS systems, and reflects an investigation of the performance and security aspects of these systems[2]. During the presentation at CMG, an overview of the areas investigated and the major conclusions will be presented. Emphasis will be on performance and monitoring aspects, showing that the behaviour of hardware, MVS system software and applications can exhaustively be observed by researchers.

1. INTRODUCTION

A synopsis is presented of the book "A Close Look at MVS Systems: Mechanisms, Performance and Security" by Ronald Paans, ISBN 0-444-70008-0, 572 pages, published by Elseviers Science Publishing Company, Inc., New York. The aim of the book is to indicate rational and practical means of improving the *performance* and *security* of mainframes running under control of IBM's *Multiple Virtual Storage (MVS)* operating system. This modern control program is sophisticated, complex and widely used: many tens of thousands of MVS systems have been installed worldwide. During the years to come, MVS is likely to remain one of the important control programs for commercial and scientific applications running on mainframes with the IBM System/370 architecture as implemented in IBM 43XX, 308X, 3090 and their plug-compatibles.

The primary goal of any computer system is to perform the functions requested by its users reliably, correctly, securely, effectively and efficiently. *Quality* should be the prime aim in this context. Computing-centre staff responsible for capacity-planning, tuning, maintenance, trouble-shooting, security and data integrity need detailed information about all activities within a system and their relation to the users. Without appropriate information, any form of prediction remains mere guesswork, while improving performance and security is awkward and sometimes turns out to be impossible.

The success of data processing and office automation is closely related to the acceptance of systems by their users; the quality perceived is not only gauged by response times and availability figures, but also includes *user-friendliness* of systems and applications. A critical view of the interactions among systems, applications and users suggests that the intermediate software is designed by technicians to be used solely by technicians, thus excluding many users from understanding anything. Command syntax and data-set names have to follow incomprehensible rules, while messages are cryptic due to quirks of design and implementation, so often causing feelings of discomfort and confusion to the users interacting with applications. Some designers persist in defending inconveniences; they hide behind incomplete specifications, refuse to fix the code and retrofit manuals, thus legalizing incorrect software.

Before a system's *performance* can really be improved, that is lowering its response and turn-around times and raising its availability and accessibility, one must first exactly know how the system's mechanisms behave and interact with one another. A prediction of the consequent gain can be no more reliable and credible than the information and knowledge the experimenter has been provided with. In practice, this experimenter is confronted with a severe lack of information:

- the processing power available for applications is not explicitly known, nor has the useful capacity of the CPUs or the I/O subsystems been stated in quantitative terms,
- there are no methods to determine properly the resource capacity wasted due to improper design, implementation or tuning of system and application software,
- most computing centres do not have appropriate monitoring aids to analyse the system's activities and to distinguish unambiguously between avoidable overhead and relevant, productive work.

It follows that the combined ignorance of system activities and the absence of yardsticks prevents one from optimizing the quality of the services delivered. There is a yawning abyss between most of the values currently recorded by engineers and the performance and security as perceived by users and management. The book attempts to bridge this abyss, however precariously. One of its primary aims is to explain the method of operation of many components in MVS systems and to make some previously unobservable activities of these systems observable and quantifiable to engineers by suggesting new monitoring techniques. Observation and modelling allow engineers to understand the underlying mechanisms, to collect pertinent information on their behaviour and, combining knowledge and data, to improve the quality by re-design, re-implementation and tuning.

Since the author is an engineer rather than a mathematician, the emphasis is on applied rather than theoretical knowledge. Mean-value analysis has been applied to create the models described, but no new analytical methods have been developed. Written from a *systems programmer's* point of view, the book is directed at systems and application programmers, performance analysts, security officers and computing-centre management. Of course, it also contains information relevant to all interested in performance and security aspects of mainframe systems under control of MVS. Each Chapter discusses a single topic and has been written as a relatively self-contained paper preceded by an abstract and terminated by the conclusions on the topic highlighted. The list of Chapters reads:

1 Introduction

PART I. THE UNDERLYING HARDWARE AND CONTROL SOFTWARE BASES

2 The Hardware Base (architecture and logical design)
3 The Control Program Base

PART II. MANAGING AND CONTROLLING MVS SYSTEMS

4 Performance and Service
5 EDP Performance Management
6 A Topology for Secure Systems
7 Secure User SuperVisor Calls

---

[1] IBM, Dept. International Business Services (IBS SC), Zoetermeer, The Netherlands. This paper reflects the personal opinion of the author, which is not necessarily shared by IBM.

[2] The research described has been performed at Delft University of Technology, The Netherlands, in close co-operation with Prof. G.L. Reijns and Prof.dr. I.S. Herschberg.

PART III. PERFORMANCE ANALYSIS AND MODELLING OF MVS SYSTEMS

8 Characterization of TSO Users' Behaviour
9 The Performance of Application Software
10 TSO: Performance of an interactive Facility
11 SuperVisor Calls and their Services
12 Performance Aspects of Access Control
13 The Control Program's Nucleus

PART IV. ANALYSIS AND MODELLING OF MVS HARDWARE

14 Throughput of Instruction and Execution Units
15 Performance Improvements by Firmware
16 System and Application Disk I/O
17 Simulation of a Disk Cache for User I/O

PART V. MONITORING IN MVS SYSTEMS

18 Monitoring and Recording Techniques
19 Monitoring by Event Tracing
20 Tracing Instruction By Instruction
21 Recording the CPU's Instruction Execution Times
22 The Artificial User as a Performance Observer
23 System Design Desiderata to Support Monitoring Tools
24 Epilogue

APPENDICES

A Evaluation Nets
B Sample of a Service Level Agreement
C System/370 XA Instructions
D Data Collected by MVS System Trace

Some of the investigations described in the book will briefly be summarized below, supplemented with some of the major conclusions.

2. PERFORMANCE AND SERVICE

The user's chief concern with a computer system is that it performs the requested functions reliably, correctly, securely and efficiently in a human-friendly way (and, preferably, at reasonable cost). This statement is a *contradictio in terminis*. For instance, if in a systems the level of reliability and security is raised, the level of efficiency will decrease and the cost will rise due to higher verification overhead. A balance should be struck between these factors so that the transactions are processed at an acceptable price and at the required speed with the requested quality. This is, as matter of fact, not an easy job in our complex computing-centre environment.

All activities in a system, explicitly or implicitly requested by users have one common aspect: they use *resources* such as CPUs, memories, disks, tapes drives, other devices, people, software, documentation and procedures. When considering a *computing centre* as a production unit the resources are the input: the sum of their individual costs shows the operational costs of the centre. The output of a production unit is usually expressed in goods or services; in a computing centre the output consists principally of *services* delivered to its users. Some of these services are: executing a batch job, processing an interactive transaction, making available compilers and other software to users, and performing data-entry and data-enquiry activities. Each of the services is associated with one or more applications or facilities using software and hardware resources.

A computing centre with its users is a complex of people and systems, controlled by rules and procedures. All activities should directly or indirectly be devoted to producing 'useful work', which may be updating data bases, obtaining specified records from data bases, executing commercial or scientific programs, etc. The notion 'useful work' must be defined in the objectives for the computing centre. In this context, one has to distinguish between *effectiveness* and *efficiency*. A background for these terms has been given by Norton and Rau in their "Guide to EDP performance management" [1]. The key-note question for effectiveness is:

"Are the requirements of the users fulfilled by the services delivered?"

The key-note question for efficiency is:

"Are the total costs of data processing as low as possible?"

There is an essential difference between these two notions, which may be formulated tersely by:

Effectiveness = Doing the right things Efficiency = Doing things rightly

Obviously, *effectiveness* has its due place in a computing centre: doing the wrong things efficiently will not supply any gain to the organization but is only wasting manpower and other resources. When one considers the computing centre as a black box, it uses resources as input and delivers services as output. Both the input and output should be evaluated for effectiveness and efficiency, resulting in the formulation of four queries. Each query is characteristic for a particular point of view and presents a theme for research, viz.:

A1. The effectiveness of the services (the service requirements):
does each service delivered fulfill the requirements of the users ?

A2. The efficiency of the services (the load of each service):
what are the resource loads of each individual service and which part of these loads is squandering of resources ?

B1. The effectiveness of the resources (the resource requirements):
are the resources capable of processing the total workload including momentary peak loads ?

B2. The efficiency of the resources (the resource balancing):
are the resources utilized optimally during processing of the workload including the instances with peak loads ?

In the book, examples are discussed to elucidate this classification and to show the relation between the queries and day to day practice. Answering the four queries gives some insight in the computing centre's activities: for instance, it reveals whether one performs useless work. In some organizations, work without any earthly use is processed very efficiently. To avoid this kind of squandering manpower and other resources, one has to evaluate periodically the effectiveness and the efficiency of the resources as well as the services. The queries A1 and B1 are worked out in more detail showing the user's point of view while interacting with the centre's services. This discussion results in defining a set of performance indicators which make the user's satisfaction visible. Bounds for these indicator's values should be included in the centre's *Service Level Agreement (SLA)*. The latter document acts as a written warrant for a certain level of comfort during the human-computer interaction. In the author's opinion, the requirements of the users, dictated by the principal objectives of their organizations, are the *pivot* in the process of defining services and SLAs. As matter of fact, the user is the one who really works with the services and, after all, he supplies the money to run the entire computing centre. Especially in a service-bureau environment, neglecting the user's requirements will not only result in unsatisfied customers but also in loss of these customers, obviously implying loss of revenue. In this context, computing-centre management is encouraged to pay attention to the performance indicators usability, availability, accessibility, number of service interrupts, and timeliness, in order to prevent their shop from being closed.

3. EDP-PERFORMANCE MANAGEMENT

The performance of computer systems must not only be observed and recorded, but must also be managed and controlled in order to process the services in an effective and efficient way. The aims of *performance management* are (a) optimizing the quality of the services delivered to the users and (b) delivering these services with a minimal load on the hardware and software resources. In the book, performance management is broken down into eleven distinct tasks representing eleven performance functions:

1. definition of SLA,
2. verification of compliance with SLA targets,
3. capacity planning,
4. elimination of bottle-necks,
5. tuning networks,
6. maintenance of disk space,
7. tuning applications,
8. tuning services and service environments,
9. tuning the system's kernel,
10. trouble shooting and keeping the system alive,
11. solving user problems.

The tasks 1 to 3 are related to capacity planning and the quality of the services as specified in the SLA; this is chiefly long-term work. The tasks 4 to 9 embrace maintenance, tuning and elimination of bottle-necks, and deals with a planning on a weekly or monthly scale, while the tasks 10 and 11 consist of ad hoc operations in order to keep the system alive and to solve user problems. As shown for a hypothetical computing centre with a compartmentalized organization, each task requires appropriate tools and skilled personnel, and is assigned to a department with a first-line responsibility. In addition, a formal structure is defined for second- and third-line support. This scheme is supplemented by an overview of the tools required to perform each of these tasks.

The majority of personnel in a computing centre are greatly in favour of delivering high-quality services. However, they are often frustrated by a lack of manpower and funds, and hence fail to meet quality targets. Obviously, no organization will make unlimited manpower and funds available to performance evaluation and improvement, since that is only a one of the many aspects of data processing. But, in sad practice, many centres are guilty of false economies and do not actively support performance management which they regard as avoidable overhead. As a consequence, effective performance management in such a centre is doomed to failure: low quality of the services and complaining users are the predictable outcome.

4. CHARACTERIZATION OF TSO USERS' BEHAVIOUR

The input of interactive data-processing facilities are the transactions generated by users; the messages displayed at the users' terminals constitute the output of these facilities. In fact, a user may be characterized by his rates of generating transactions and of requesting messages. Using observational data collected during three years in a service-bureau environment, the significant sensitivity of the user to system responses is derived by correlation and regression analysis, expressing the transaction rate and the message rate of each user in function of the average response time. It is shown that an increase in response times leads to an *over-proportional decrease* in the users' transaction rate which may, under specified conditions, be translated into an increase in the costs of programming projects.

Regression analysis is applied to derive an equation for the effect of the average response time, *Tresp*, on the user's think time, *Tthink*, and so on his transaction rate, λi. Assuming a linear relationship between these two time-related variables, with a given user 'head-scratch' time, $Ti\emptyset$, and a constant *Ki* representing its slope, one has

$$Tthink = Ti\emptyset + Ki * Tresp$$

This equation represents a straight line in the (*Tresp*,*Tthink*)-plane. Regression analysis (least-square fits on the perpendicular distance between the straight line and each pair) has been applied to the observational data, showing for users interacting with IBM's Interactive System Productivity Facility (ISPF)

$$Tthink = 11.3 + 2.1 * Tresp$$

This equation states that the population is affected significantly by the response times: ***an increase of 1 s for Tresp results in an increase of 2.1 s of an ISPF-user's think time.*** The transaction rate of a user is

$$\lambda i = \frac{1}{Tthink + Tresp}$$

The elimination of *Tthink* results in

$$\lambda i = \frac{1}{Ti\emptyset + (Ki + 1) * Tresp}$$

or, with the values for $Ti\emptyset$ and *Ki* as found via regression analysis

$$\lambda i = \frac{1}{11.3 + 3.1 * Tresp}$$

Due to the limited range of observations, however, this equation should not be used beyond the range 0.50-3.00 s in *Tresp*. Thadhani [6,7] has derived a similar equation for internal host-response times in the range 0.25-3.00 s, though he found different values for the constants $Ti\emptyset$ and *Ki*. The observations for two object groups demonstrate that these constants characterize the users' behaviour and therefore depend strongly on the group observed, their experience and their environment (e.g., the facilities supporting them). This means that the 'constants' $Ti\emptyset$ and *Ki* have only a ***limited significance***: they are object-group dependent and should be computed anew for each specific user population.

5. THE PERFORMANCE OF APPLICATION SOFTWARE

A critical evaluation of application programs indicates that many of them work far from optimally. Current development strategies often fail to provide applications operating human-friendly, effectively and efficiently. Some underlying causes are failing management of the programs' development stage, higher-level languages not leading, by default, to efficient programs, and an unmanageable complexity of hardware and software combined. In addition, applications are often inefficiently installed and their parameters are adjusted far from optimal. These pessimistic statements about applications are elucidated by examples.

Properly defining data-processing functions and converting these functions into programs is widely granted to be difficult. Most people do not have an analytical mind, cannot grasp a sequence of data-processing activities, and fail in correctly, unambiguously defining data items and data manipulations required. Of course, the weak definition capabilities of human beings are not only reflected in applications, but also in service programs and operating systems. However, the latter evolve into effective software somewhere in the future because they are improved from time to time by new versions and releases. This evolution may be characterized as:

> The adversary process of trial and error often leads, after a number of versions, releases and modifications, to effective and efficient programs.

For instance, IBM's Structured Programming Facility (SPF) is better attuned to users than the conventional set of Time Sharing Option (TSO) commands which it replaces, and is undoubtedly more human-friendly. Nevertheless, SPF showed still many inconveniences in human-machine interaction; currently some of these inconveniences have been

removed by SPF's successor Interactive System Productivity Facility (ISPF), especially by version 2 of ISPF. Following this line, one may expect that a future version *n* with *n*>2 will contain yet fewer inconveniences and will be yet more human-friendly. The only disadvantage of such a growth process is that the current software is never optimal and the user has to be equipped with sufficient patience.

An ambiguous, incorrect and incomplete definition of functions is not the only weakness of current data processing: in the stage of code generation and implementation, many inconveniences are introduced too. While ineffectiveness is principally due to definition errors, inefficiency is caused by improper code generation, implementation and parameter setting. Currently, optimally functioning software still requires human inventiveness, experience and skills. As shown in the book, performance analysts consulting during the development stage, observing existing programs and recommending improvements may still greatly contribute to the efficient use of a computing centre's resources. Tools and manpower should be made available for these purposes.

6. TSO: PERFORMANCE OF AN INTERACTIVE FACILITY

While in early days of electronic data processing the workload principally consisted of batch jobs, the current trend is towards executing the major part of the workload in the foreground, thereby establishing direct interaction between the computer and its users. The success of data processing and office automation is closely related to the acceptance of systems by their users; the quality perceived is not only gauged by response times and availability figures, but also includes user-friendliness of systems and applications. A critical view of the interactions among systems, applications and users suggests that the intermediate software often is designed by technicians to be used solely by technicians, thus excluding many users from understanding anything. Attention is focussed on the performance of Time Sharing Option (TSO) discussing resource loads and user-friendliness of some of its components. The major objects under observation are editors, data management, foreground processing of data, and background processing controlled by foreground commands.

7. PERFORMANCE ASPECTS OF MVS ACCESS CONTROL

A quantification of the invocation rates of an access-control package is a prerequisite for an evaluation of the resource loads occasioned by such a package. During the investigation described, the workload of a computing centre with four MVS systems has been characterized, formulas have been derived describing the relation between workload and access-control activities, and the invocation rate of access control has been quantified. The method developed is principally based on counting SMF records and is easy to use.

While in the versions up to 1.4 of Resource Access Control Facility (RACF) a system's owner was able to control RACF's resource loads by implementing exit routines, these loads may now be controlled effectively by Global Access Checking (GAC) and generic profiles since RACF 1.5. The effectiveness of these new mechanisms has further been enhanced by the RACF versions 1.6 and 1.7. Contrasted with RACF 1.4 in native mode (without performance improving exit routines), the significant load-reducing impact of Global Access Checking and generic profiles will be demonstrated.

8. THE CONTROL PROGRAM'S NUCLEUS

The activities of an operating system are shown to be observable by recording timed events at the level of Dispatcher activities and interrupts. A dedicated monitor, termed SYSTRAC, has been built to copy descriptions of these events, the so-called Trace Table Entries (TTEs), from the MVS System Trace Table. Analysing the stream of related pairs of events, termed bigrams, reveals how an operating system behaves and which parts of the resources are used by the major routines of the operating system's nucleus. Such an analysis provides a breakdown of the factor *overhead* by assigning fractions of the resource loads to particular user-initiated activities. When properly separating what is due to the users' activities and what is purely for the operating system, the latter becomes quantifiable as a minor contribution. The major contribution to the resource loads is work done on behalf of users and therefore should not count as overhead. For instance, initiating I/O for catalog and directory access is often wrongly included in the overhead; one then forgets that both catalog and directory have to be scanned to find information requested, explicitly or implicitly, by a user. Similarly, many other operating-system activities also are indispensable to run and support user software. In the book, the behaviour of some major software components is highlighted, viz. I/O Supervisor, interrupt handlers and Dispatcher.

The first component discussed is *I/O Supervisor (IOS)* of MVS systems running in 370-mode (non-XA), which contains two major groups of routines:

1. I/O Supervisor Front End with its IOS Drivers such as the EXECUTE CHANNEL PROGRAM (EXCP) Driver, initiating I/O activities so as specified by I/O-requesting programs,
2. I/O Supervisor Back End acting as Second Level I/O Interrupt Handler which informs I/O-requesting programs about I/O completion.

In this scheme, the First Level I/O Interrupt Handler plays only the minor role of saving the status of the task interrupted and branching to I/O Supervisor Back End for further handling an interrupt. By timestamping the invocation of an I/O Supervisor Driver, the moment of issuing a START I/O (SIO) instruction, and the moment of returning control to the I/O requestor, the CPU loads by I/O Supervisor Front End are calculated. In addition, timestamping the penetration of an interrupt as well as recording the next event reveals the CPU loads by I/O Supervisor Back End.

The second component highlighted is the *Program Check Interrupt Handler*, processing interrupts due to program errors and page faults. The investigation deals only with page-fault-handling activities; page faults occur frequently in MVS systems and are inherent in managing virtual storage by demand paging and page stealing.

The third and last functional component discussed is the *Dispatcher* responsible for passing CPU control to tasks under control of a Service Request Block (SRB) or a Task Control Block (TCB). When lacking dispatchable work, control is passed to the Wait Task causing the CPU to revert to the wait state. The latter activity - dispatching the Wait Task - is one of the few system activities to be regarded as *pure overhead*. However, this does not affect a system's performance because any and all user tasks are then waiting for events to occur such as I/O completion or timer expiration.

Observations in a number of systems over a period of four years have revealed that the CPU loads per activation of many operating system's routines are functions not sensitive to the momentary workload. For instance, the time required after a page fault to build a channel program for a single page-in transfer is relatively stable and is independent of the page-fault rate. Conversely, new versions, releases and modifications of the system turn out to affect these CPU loads; these impacts occasionally are drastic. On the one hand, this is a disadvantage of the method of analysis adopted because one has to requantify the resource loads for every new version, release and modification level of the system. On the other hand, it is also an advantage, because now one can also quantify the impact of any modification and is thus capable of determining the amount of CPU time saved (or lost) by these modifications.

9. THROUGHPUT OF INSTRUCTION/EXECUTION UNIT

One of the first parameters to characterize the performance of a computer system was its MIPS (Million Instructions Per Second) rate. In modern machines with microcode, prefetch mechanisms, pipelines and cache memories this term has been rendered obsolete and is no longer specified by the mainframe manufacturers. Admit-

tedly, in modern hardware, a single MIPS rate is unsuitable for characterizing CPU-power, the reasons being, amongst other things,

- it depends on the instruction type and the length and relative position of the instruction operands: among others operand overlap and byte access instead of full data-path access have a major influence on the MIPS rate for some instructions,
- it depends on the engineering level of the machine and on the microcode: any level modification can change the CPU time required to execute any and all instructions, and influences the total MIPS rate,
- it depends on the hit rate of the CPU's cache memory: hence, it is strongly influenced by the program behaviour,
- it depends on the instruction sequence: unexpected branches may destroy the contents of prefetch buffers and the pipeline.

Both the use of instructions and their *Instruction Execution Times (IETs)* in function of operands and environments have been observed in computers with the System/370 architecture. In the book, observational results are presented demonstrating, among other things, that IETs are suitable for observing and analysing the behaviour of hardware components in a CPU, and may be used to quantify the impact of performance improving mechanisms such as pipelines and branch-prediction logic.

Tables are presented with detailed information about the behaviour of four groups of programs and about the timing characteristics of seven types of CPUs. These Tables may be used by researchers to model and to simulate CPUs, multi-processor systems and cache memories. In academical environments (but not only there), researchers are often confronted by a severe lack of technical information due to the absence of large systems for exploratory purposes and suitable monitors. Moreover, they are often handicapped by insufficient experience in creating test environments and running monitor programs in order to collect relevant information. Hence, they all too often take refuge in using obsolete data such as Nessett's location-counter distributions (recorded in 1966 [2]) or Shustek's instruction-execution rates (recorded in 1978 [5]). With the Tables presented, researchers working at their desk with analytical and simulation models have up-to-date information at their disposal. The book also shows them ways to construct monitors to obtain the information required, even if their hardware is dissimilar to that dealt with here.

Another aim of this investigation was to prove that just two locally developed software monitors - PPTRAC and IETMON - are sufficient to obtain all relevant information on program behaviour and CPU characteristics, incidentally implying the obsolescence of hardware monitors. All relevant data, even at the machine instruction and hardware level, has become available to *software* monitors in modern MVS systems.

10. PERFORMANCE IMPROVEMENTS BY FIRMWARE

Computer manufacturers from time to time raise the effective processing power of their products, which power may be expressed in terms of work per unit of time as perceived by those in charge of the system. Two ways for increasing that power are open: building faster systems and improving the performance of existing systems. History shows that most manufacturers use both methods alternately. Due to compatibility requirements, the creation of faster systems usually will not affect the system's basic architecture but is limited to speeding up the hardware, e.g. by progressive integration of circuits. The second alternative, performance improvement, is most likely to be realized by software modifications in the operating system (OS) and in applications in order to process a given load more efficiently. When evaluating the performance of a system, one usually starts by constructing an ordered list of the routines with the highest resource loads, say a top-five list. The ordering is by decreasing values of the multiplication
*<activation rate> * <resource load per activation>*.
The rationale of this ordering is corroborated by Kendall [3], who states that only 1.5% of the application programs in a computing centre account for at least 50% of the total CPU load. This is not only true for applications, but also for the OS routines involved. Hence, the top-five OS routines are naturally most eligible for improvement, either by rewriting their software or by (partly) converting them into firmware. In this context, firmware is understood to be microcode, possibly assisted by associated hardware. Once it has been decided to incorporate frequently used OS functions into firmware, new machine instructions arise. From a programmer's point of view, new firmware is equivalent to additional hardware: in essence, a *new machine* is created with a *new architecture*, containing the new instructions serving (partially) to replace former software in addition to the original instruction set.

To quote but one example of such an evolution, in 1977, simultaneously with the announcement of the IBM 3033 CPUs, a new release of MVS was introduced: MVS/System Extension (MVS/SE). It showed a considerable performance improvement in comparison to earlier (pre-SE) releases. Many parts of its software routines had been rewritten and a set of new firmware-implemented instructions had been created, many of them completely replacing former software routines. Data-processing magazines (though non-certified sources) claimed a throughput improvement of some 14% in comparison with pre-SE systems. In order to make this gain available to computing centres with System/370 CPUs already installed, the System/370 Extended Facility was introduced at the same time, which upgrades any System/370 158 or 168 CPU by creating *fourteen new instructions* activating the new firmware and by adding several new hardware features. This facility supported three ends: improved system integrity, enhanced performance, and closing gaps in the instruction set.

By hindsight, the book attempts to reconstruct the research performed by the designers of System/370 Extended Facility, and quantifies the CPU load of the fourteen functions both in the pre-SE software implementation and with the new firmware. As will be shown, especially with the modern IBM 308X hardware, the firmware approach significantly reduces the CPU load of OS routines often invoked: a saving of some 75% of a routine's CPU load can be achieved. The data presented has academical value only since the new versions of MVS cannot run without this additional firmware. However, the key-note trade-off *'firmware versus software'* for frequently used routines remains relevant to computer architects, both for present and for future systems. This major trade-off is therefore addressed, attempting to balance the pros and cons of the competing approaches in the light of flexibility versus effectiveness.

11. SYSTEM AND APPLICATION DISK I/O

The architecture of the System/370 disk-I/O subsystem for non-XA systems is a logical outcome of decisions made during the design of the System/360 architecture in the late fifties and early sixties. In those days, logic circuits were relatively expensive. Principally due to economic reasons, the architects concentrated the intelligence in the channels located near the Central Processor Unit (CPU) and main memory. In this context, a channel acts as an I/O processor executing channel programs constructed by programmers or by access methods. Such a channel program is a chain of Channel Command Words (CCWs) each representing an instruction for a channel or a device.

Disk I/O in an MVS system is initiated by both system and application software. Their I/O requests have one aspect in common: all are issued on behalf of users or their batch jobs. However, these users specify only a part of the stream of I/O requests *explicitly* by, e.g., issuing an EXecute Channel Program SuperVisor Call (EXCP SVC) for reading or writing data, or a LOCATE SVC for retrieving catalog data. For these explicit I/O requests, identifying the requesting user is easy to do. The remaining part of the stream of I/O requests is an *implicit* result of the combined activities of all users; this comprises, e.g., paging and swapping necessary to support the users' virtual address spaces. This implicit part of the stream of I/O requests is obviously caused by users but it is awkward to identify for each I/O activity the user requesting it.

To raise the level of confusion, the designers of the standard MVS tools System Management Facilities (SMF) and Resource Measurement Facility (RMF) have introduced a distinction between direct and indirect work which does not coincide with the distinction between explicit and implicit work. SMF and RMF classify all work executed in problem-program mode and all SVCs issued in that mode to be ***direct work*** and the remaining work to be ***indirect work***. By definition, all I/O requests issued when running in supervisor mode are considered as indirect activities and, consequently, are accumulated in the opaque set of ***system overhead***. Observations in production environments often show that some 50% of the START I/O (SIO) instructions are accounted for as overhead, while this fraction is sometimes even 70% in a TSO environment. These observations demonstrate the ambiguity introduced by the distinction between direct and indirect work. Obviously, modelling the disk-I/O subsystem is bound to fail when one attempts to found such a model on observational data collected by SMF and RMF. One of the principal objectives to develop locally the SYSTRAC software monitor was to obtain, by exploiting MVS System Trace, pertinent figures about the I/O load of individual user tasks. After implementation of SYSTRAC, this monitor demonstrated to be suitable to identify the cause of each I/O request and to pin-point the task responsible for that request, except for the fraction of paging I/O related to page stealing. Using this detailed information, one may construct an accurate model for disk I/O describing channel-busy and disk-access times.

Within MVS systems, one may distinguish among several types of disk-I/O - termed the I/O classes -, each with its typical behaviour. For instance, if a TSO user requests to access a data set specified by name, he has first to create a logical path to this data set by allocating it through the DYNALLOC SVC. The underlying SVC routine has to access the catalogs to find the name of the volume, then the Volume Table Of Contents (VTOC) to obtain the data set's attributes, and can only thereafter build the control blocks establishing the requested allocation. These I/O requests for system-data sets such as catalogs and VTOCs are issued by the DYNALLOC SVC routine, running in supervisor mode while processing the user's requests (and, hence, are accounted for as indirect work).

In the book, a distinction is made among twelve classes of I/O, most of them representing indirect I/O. Moreover, their attributes are discussed and the relation is demonstrated between operating-system functions requested by users and these I/O classes. These functional descriptions apply to both non-XA and MVS/XA systems.

12. MONITORING BY EVENT TRACING

The research presented in the book covers many in-depth investigations on the behaviour of system and application software in MVS systems. Evaluation of the important mechanisms in the operating system's kernel, such as the Dispatcher and the interrupt handlers, requires a monitor providing pertinent information about these mechanisms' behaviour and activities. At the start of the research, an evaluation showed that none of the commercially available monitors was suitable for supplying this information. For instance, the rejection of hardware monitors was dictated by the lack of appropriate wire-wrap pens on the back-planes of modern CPUs which formerly served to connect the monitors' probes. In addition, Generalized Trace Facility (GTF) had to be rejected due to its interference with the observation object, making CPU-time calculations meaningless. It was hence decided to develop a new monitor - termed SYSTRAC - based on MVS System Trace, in order to obtain pertinent information at a level of detail and accuracy not to be found in any of the commercially available tools. MVS System Trace collects data about some types of events associated with system activities (starting a device, handling an interrupt, dispatching a task, etc.), constructs 32-byte records and stores these records into the System Trace Table as Trace Table Entries (TTEs). The software monitor SYSTRAC samples this table and copies, in addition, some relevant fields of the MVS control blocks. This data-collection operation is exercised without interference with the object programs' activities. The data collected is recorded into data sets making it so available for further analysis and amenable to simulations. The types of TTEs recorded are:

- Start I/O operation
- external interrupt (timer, signal of other CPU, etc.)
- SuperVisor Call (SVC) interrupt
- program-check interrupt (page fault, etc.)
- dispatch of work under control of a Service Request Block (SRB)
- I/O interrupt
- redispatch of work under control of an SRB
- dispatch of work under control of a Task Control Block (TCB)
- return from SVC processing
- Program Call (invoking a program in a secondary address space)
- Program Transfer (returning to the primary address space)
- set Secondary Address Space Register

A set of programs has been developed to process and analyse this data. The method of operation, internals of the SYSTRAC monitor and sample output are presented in the book. The software monitoring technique of event tracing, as implemented in SYSTRAC, turned out to be capable of supplying ***all*** data relevant to performance research. However, there was one practical problem: upgrading SYSTRAC to keep pace with new releases of MVS turned out to be a severe bottle-neck, chiefly due to lack of skilled man-power at Delft University of Technology, where this research has been done. Within a few years time, SYSTRAC had been upgraded for the successive moves from MVS/non-SE to MVS with System Extensions version 1 (SE-1), SE-2, MVS with System Products version 1.1.1 (SP-1.1.1), SP-1.3.1 and SP-1.3.2. At that moment, just before the introduction of 31-bit addressing of MVS/XA, further upgrading has been renounced. Although the current implementation is still dedicated to non-XA, the monitoring method also applies to XA systems.

13. TRACING INSTRUCTION BY INSTRUCTION

The IBM System/370 architecture does not supply hardware facilities for ***instruction-by-instruction*** tracing. Some computer architectures, such as the PDP-11 and the earlier IBM Series 7000, contain dedicated hardware for tracing user software at the level of individual instructions, so supplying opcodes, addresses referred to, operand lengths and operand values. This data is useful for:

- debugging purposes,
- obtaining insight into the program's behaviour,
- optimization of user programs and applications,
- evaluation, by simulation or analytical modelling, of cache-memory performance and CPU throughput in existing and future systems,
- design of systems.

Because of the absence of hardware facilities in the Systems/370 architecture, a software monitor has been designed to obtain detailed information on the behaviour of programs in MVS systems. It acts as an interpreter or a virtual machine, traces software and records the opcodes executed, the addresses referred to, etc. Its principal application is to collect data suitable for evaluating the performance and throughput of the CPU and its components. This monitor, somewhat confusingly termed Problem Program Tracer (PPTRAC), is currently capable of tracing both problem-program-mode and supervisor-mode single-tasking software running with any key-in-PSW. With PPTRAC, routines of the MVS operating system have been observed such as the Dispatcher, Interrupt Handlers and SVC routines. The data collected is stored in a data set with a compact structure. In the scope of the research described in the book, several trace data sets has been created spanning a variety of programmers and languages. Five data-analysis programs (postprocessors) have been written to process the data collected; their functions are

1. simulating a single-CPU cache memory supporting the store-through and store-in-cache algorithms in direct-mapping and set-associative cache organizations,

2. reporting the distribution of the distances between instruction-fetch addresses and between storage-operand addresses,
3. reporting the number of instructions and the distributions of operand lengths arranged by instruction format and data type,
4. observing the amount of data stored in a cache in function of the time starting at a context switch (which, de facto, has the same effect as a reset of the cache),
5. reporting the use of instructions ordered by opcode, the number of first and second operand fetches, and the number of result-store operations.

The method of operation of PPTRAC and sample output is presented in the book. In this context, we introduce the notions *parent* for the tracing program (PPTRAC) and *child* for the traced program (a user program or a part of the operating system). PPTRAC fetches, just as the CPU's Instruction Unit, child instructions one by one and inspects their opcodes. After some verifications, PPTRAC let the CPU execute each child instruction or, in case of e.g. a branch, interprets it. Many precautions have to be taken in order neither to loose control nor addressability. Not only branches, but also SuperVisor Calls (SVCs) may disrupt the sequential instruction stream. Hence, SVCs such as LINK, PASS CONTROL (XCTL), OPEN, SPECIFY PROGRAM INTERRUPTION EXIT (SPIE) and END OF VOLUME (EOV) need special processing. Another problem is caused by the practice of System/370 to compute addresses as sum of a displacement and the contents of one or two registers. Since the child is allowed to use *all* registers, the parent has, during execution of a child instruction, *no* register at its disposal and, as a logical consequence, cannot address its own storage locations. Some software tricks had to be implemented in order to establish addressability for the parent and to guarantee control.

After successful completion of the problem-program-mode part of PPTRAC in 1982, it was decided to extend the monitor for single-tasking supervisor-mode software with a key-in-PSW less than eight (the system keys). This extension was required to trace parts of the operating system such as the Dispatcher, Interrupt Handlers, and SVC routines; it implied roughly a triplication of the monitor's size and caused many complications. For instance, parts of the operating system run on a CPU disabled for interrupts. Hence, during interpretation, PPTRAC also has to use this disabled CPU and therefore can neither issue SVCs nor start I/O to store the data collected on disk. Even after solving all problems, we never have dared tracing supervisor-mode software during production hours so as to avoid the risk of interfering deleteriously with other users.

14. RECORDING THE CPU'S INSTRUCTION EXECUTION TIMES

A Central Processing Unit (CPU) has only a single primary purpose: it has to process operands at programs' requests. Each unit of the CPU's processing effort is explicitly specified by an *instruction*, consisting of an operation code (opcode) and, optionally, a specification of operand(s), all located in virtual storage. A hardware pointer - termed the Program Counter - is located in the *instruction-address* field of a CPU's Program Status Word (PSW) and designates the next instruction to be executed. This pointer is *de facto* controlled by the program currently in execution; its contents are incremented during execution of a non-branching instruction or are, when branching, replaced by a new address. The opcode of the current instruction is interpreted by the CPU and the operation specified is executed by hardware, often in conjunction with microcode. One to three instructions may be prefetched and processed simultaneously with the current instruction; sophisticated mechanisms attempt to predict the outcomes of branch instructions prior to execution so as to minimize disruption of preprocessing by unexpected branches. The CPU time required depends on the complexity of the function requested and on the presence of all relevant data within the highest-speed circuits of the CPU (registers, pipeline and cache). All data not found there has to be accessed from the slower circuits of main memory. The factors affecting the CPU time are:

- the type of the instruction (e.g. LOAD, SUBTRACT DECIMAL),
- the length of the operands (e.g. 16 bytes for an ADD DECIMAL),
- the distance between the operands (e.g. in the special case of a MOVE CHARACTER, transferring 255 bytes over a distance of 1 byte causes a decelerating destructive overlap),
- the environment of the instruction: e.g. unexpected branches disturb the operation of prefetching and preprocessing mechanisms, decrease the degree of parallelism, and raise the instruction's execution time.

Usually, a CPU's capacity is expressed as a MIPS (Million Instructions Per Second) rate. This number is the reciprocal of the average Instruction Execution Time (IET, in microseconds), which equals the average CPU time per instruction. One should be aware that the average IET depends strongly on the software, specifically on the mix of instructions, their operands and the sequence of instructions. Some of the investigations described in the book require knowledge of IETs for individual instructions in function of their operands. For this purpose, a software monitor - termed *IETMON* - has locally been developed executing instructions in simple loops and recording the CPU time used. Combining observations for over eighty instruction sequences and for some 3000 combinations of their operands, the IETs are deduced. This data is included in the book in the form of tables. In spite of this monitoring technique's simplicity, the output of this monitor has proved to be highly reliable.

With the IETMON monitor, one is able to evaluate accurately the impact of hardware changes in a system such as the replacement or upgrade of a CPU. For instance, IETMON has been used to quantify the improvements caused by the upgrade of an IBM 3081-K32 to a 3081-KX32. At a first glance of these reports, one is struck by the reduction in the CPU's cycle time from 26 ns to 24.5 ns, which change was reflected in all those IETs being a multiple of the cycle time. In addition, such reports disclose many other speed-improving measures introduced by hardware and microcode upgrades.

15. THE ARTIFICIAL USER AS PERFORMANCE OBSERVER

From a user's point of view, both the host computers and the networks are black boxes. The user communicates with these boxes through his terminal and is *only* interested in the performance at his specific location. He does not know nor does he want to know how all components in the networks and the host systems operate and interact, neither is he interested in delay times per component nor in availability per network link. His interests in performance are limited to:

- availability,
- accessibility,
- number of service interrupts,
- responsiveness,

all as perceived at his terminal. These performance indicators are affected by the behaviour of a large number of components in the networks and hosts, and often cannot be recorded by any program running on a host. When one is interested in actual values and historical trends, the lack of intelligence in most terminals implies the need of some human beings recording by hand, through sampling, the performance indicators at their terminal and processing the observational results. This way of monitoring is obviously expensive in manpower. On closer examination, a *user* recording performance indicators may be considered a *generator* for transactions and a *recorder* for timestamps. As a generator, he is characterized by his rate, λi, of issuing transactions and by the type of these transactions. This generator does not work standalone, but is fed with messages created by the host; it should react to the contents of messages such as 'READY', 'CANCELLED', 'IKJ1234', 'TERMINAL LOCKED' and 'MAXIMUM NUMBER OF USERS ALREADY LOGGED ON, TRY LATER' by issuing appropriate transactions. This reaction mechanism con-

sists of a feedback from the message-receiving function (= terminal) to the transaction-generating function (= user). In addition, the user also acts as a recorder logging the timestamps of sending transactions and receiving the host's responses. Such a user may be replaced, with advantage, by a dedicated (micro)computer programmed to act as a message-controlled generator and as a recorder.

Based on this philosophy - replacing a user by a micro -, a number of monitoring aids have independently been developed by several universities and companies. Two implementations are discussed: the RESPMON monitor of Delft University of Technology and IBM's Automated Response Time System (ARTS). The architecture of this type of monitor - the ***artificial user*** - turns out to be simple-to-implement and, once implemented, easy-to-use and providing accurate figures about the performance as perceived by real users. During many years, the artificial users proved to be reliable and accurate observers, and, once implemented, are substantially cheaper than human beings. This type of monitor is very suitable for observing availability, accessibility, number of interrupts, and response times as perceived by the user at his terminal while he is interacting with the large black box containing the networks and hosts. In this context, the monitor provides the data required for defining Service Level Agreements, and also is used to verify compliance with the targets mentioned in these contracts between a computing centre and its users.

16. EPILOGUE

After writing all papers dedicated to performance, effective use and security of MVS systems, brought together in the current book, the author was confronted with the question "Is there still a future for large systems?". This question was inspired by the many similarities observed between the current evolution of mainframes and that of, e.g., species such as the dinosaur. The latter grew bigger and bigger while all their natural enemies disappeared or were, after a certain instant, too small to endanger these giants. And then, within a relatively short time, the entire population of dinosaurs dwindled. Are mainframes, also growing bigger and bigger, be doomed to the same destiny as the dinosaur?

On the one hand, data processing is being ***distributed***, rapidly moving parts from a few mainframes to large populations of stand-alone Personal Computers (PCs) and groups of PCs organized in Local Area Networks (LANs). Personal computing at one's desk provides many advantages to the endusers, has conquered a fast-growing market and has become very popular in many disciplines. However, there are still many problems to be solved before distributed processing reaches maturity: these problems lie, e.g., in the areas of security, data integrity, backups, maintenance of auxiliary storage, cataloging, performance and compatibility. On the other hand, many organizations are confronted by the necessity for ***large data bases*** with distributed data-entry and data-inquiry capabilities and with applications requiring large amounts of CPU and I/O power. These organizations still need mainframes and will at least continue to use these during the next decade. As a consequence, the mainframe market is still a growing market both in number of computers installed and in the CPU and I/O capacity of the individual systems.

In the author's opinion, we shall grow, during the years to come, to see groups of mutually connected mainframes, front-ended by many LANs and stand-alone PCs through their TP networks. Each organization will feel the need for central, large data bases parts of which are copied through the networks to PCs for local processing and are updated and maintained by PCs. As a consequence, the question "Is there still a future for large systems?" may be answered in the affirmative. At least during the next decade, systems programmers, application experts and, of course, people with network skills have not to fear unemployment.

CICS - DESIGNING FOR PERFORMANCE

Eric Emanuel
Candle Corporation

ABSTRACT

"CICS - Designing for Performance" is a soon to be published book providing a unique approach to CICS Performance management. Based on a real world practical approach to include operating systems and other subsystems that CICS may interface with. The major emphasis is on total system performance and how CICS best fits into the overall scheme of things. An example of this scenario would be the design of a CICS application using MRO, ISC, DB2, DL1, as well as a combination of other system components. Performance analysts, applications programmers, and capacity planners are the primary audience. Valuable information is provided for data processing and information systems managers as well.

INTRODUCTION

CICS is about to enter its 20th year as an IBM product. CICS evolution over these years has kept pace with the phenomenal growth of transaction processing. Business requirements coupled with technological advances have transformed CICS from "cost saving" back office applications, such as order entry and inventory control to "revenue earning" consumer direct service applications, such as home banking, and point of sale electronic funds transfers. The high visibility of CICS to the consumer marketplace coupled with the growing size and complexities of CICS networks certainly brings the subject of successful CICS performance management into the limelight. Managing CICS to successfully achieve service level objectives with maximum availability and reliability is the key item to the success of an organization that depends upon CICS as a revenue generator.

The book discusses CICS industry trends, requirements, performance objectives, along with CICS system design and performance analysis techniques to help ensure that your organizational requirements and objectives are met. "CICS - Designing for Performance" consists of seven parts, with a total of 20 chapters. These seven parts are:

- Part I - CICS Overview and Evolution
- Part II - CICS Performance Objectives
- Part III - Performance Management Tools and Techniques
- Part IV - CICS Performance Analysis Techniques
- Part V - Improving CICS Performance
- Part VI - Designing High Performance Applications
- Part VII - Planning for Future Growth

This paper is organized to present an overview of selected parts of this book, and is organized as follows:

- Section 1 - CICS Overview and Evolution
- Section 2 - CICS Performance Analysis Techniques
- Section 3 - Planning for the Future Growth

SECTION 1 - CICS OVERVIEW AND EVOLUTION

The introduction of the IBM System 360 in the mid 1960's revolutionized the computer industry. This new hardware and its associated software products created new capabilities and opportunities that were previously unavailable to the business community. From the mid to late 60's, various attempts were made to produce a good general purpose transaction processing system. This was not an easy undertaking.

Three basic requirements had to be met. First of all, support of a varied terminal network including both local and remote terminals was a key requirement. Secondly, relative ease of implementing applications had to be considered. And thirdly, the expenditure of people, processing, and dollar resources had to be minimized. In 1968, IBM in cooperation with a major utility company developed CICS systems primarily for the utilities industry. The first CICS systems to be implemented were used primarily by customer service representatives in the utilities industry to provide quick turnaround time on customer inquiries regarding utility service and billing. CICS at that time was supported by the OS 360 operating system, BTAM was used for data communications with the terminal network, and ISAM and BDAM were the supported file access methods. CICS application programs at that were supported file access methods. CICS application programs at that time were written in Assembler language with macro level calls to CICS services.

In 1969, IBM projected the total number of CICS users worldwide would be about 50. Boosted by the application language support of COBOL and PL1 in 1970, the use of CICS started to grow at a phenomenal rate. CICS support of COBOL and PL1 significantly bolstered the availability of application programmers for the development of CICS applications. The phenomenal growth of CICS was accelerated greatly with IBM's introduction of 370 processors and the VS operating system. As virtual systems evolved, CICS kept pace with support of VSAM and VTAM (Figure 1 illustrates the phenomenal growth of CICS over the years).

The introduction of CICS Release 1.5 in 1980 with Multi-Region Operation (MRO support) and Intersystem Communication (ISC support) proved to be a major milestone, providing a "single system image" to the end user. The ability of CICS to run as multiple logically connected regions within the same or within

remote processors removed many of the growth constraints that previously inhibited CICS from supporting very large terminal networks.

Today there are approximately 30,000 CICS installations worldwide. This number is growing quickly. CICS has evolved from "back office" applications such as inventory control and order entry in the '70's to "front office" applications such as electronic mail and automatic teller machine banking in the early '80's to today's support of consumer "direct service" applications, such as home banking and point of sale funds transfers. The "back office" applications of the '70's and "front office" appls of the early '80's certainly provided cost savings benefits to those companies that have implemented these applications. The addition of today's direct service applications where the consumer is in fact the CICS end user provides these companies with some excellent revenue generating opportunities. CICS's excellent support of other products such as DB2 helps to verify CICS as IBM's strategic transaction processing product well into the 1990's.

SECTION 2 - CICS PERFORMANCE ANALYSIS TECHNIQUES

The bottom line performance of CICS is measured by two factors, response time and throughput. When a computer installation defines its CICS service level objectives, what they are doing, in fact, is defining response time and throughput goals. These goals can only be achieved and maintained through constant system scrutiny and performance management and tuning.

This discussion will illustrate a logical top down tuning approach to achieve and maintain your CICS service level objectives. First of all, let's define what a top down performance tuning approach is. As we know, CICS executes within the operating system environment. The major objective of the top down tuning approach is to make sure that the operating system environment is well tuned to accommodate CICS before a tuning effort is embarked upon to tune CICS itself. One can vigorously tune CICS internally but if that operating system is not set up to best accommodate CICS, it won't run very well regardless of what you do internally to CICS because that operating system environment will serve as a key limiting factor to CICS performance. Therefore, the operating system must first be in tune, and then whatever changes are made within CICS will make a difference in performance.

Delving further into the top down tuning approach, we can categorize the top down performance tuning procedure into three general areas. Referring to Figure 2 we see operating system factors as the first step in our top down performance tuning effort. The operating system factors fall into three general categories. First and most importantly, DASD or I/O) contention; secondly, paging contention, that is, CICS contending with other jobs on the system for real storage; and thirdly, CPU contention and availability. We will address each of these areas in detail later on as we go through our performance tuning effort.

The second general area of our top down performance tuning approach are address space factors that affect CICS performance. Our scenario will profile a CICS system running under the MVS operating system. In address space area we will examine the various components of the C address space and optimize these components in order to provide ma CICS availability and performance. We will look at the Local Syst Queue Area, or LSQA, we'll examine the OSCOR area, the CICS nucleu and the Dynamic Storage Area, or DSA.

The objective of tuning the address space factors is to optimize the areas that comprise the CICS address space in order to assure maximum availability, reliability, response time, and throughput. Again, all these factors add up to achieving your service level goals. After the address space components are addressed, we will examine the third and last general area in top down performance tuning approach, and those are CICS internal factors. Firstly, we'll look at limits which are primarily CICS transaction control factors, and we'll see how these factors play a part in optimizing your CICS performance. We will then examine some timings which will affect not only CICS's communications with the operating system as well. Finally, we'll examine CICS priorities and we'll be viewing priorities in two ways. First of all, where CICS fits into the operating system, and secondly, transaction priorities within CICS itself. Let us now look at the top down performance tuning areas in depth.

OPERATING SYSTEMS FACTORS

I/O Contention

On most CICS system, I/O contention is the major CICS performance bottleneck. On the average, 75% of CICS performance problems are cause by I/O and DASD not being properly optimized. When we look at I/O contention, we have to examine two factors: the number of I/Os and the contention, we have to examine two factors: the number of I/Os and the duration of these I/Os. Let's first address how to reduce the number of physical I/Os within CICS. This is usually the greatest factor affecting response time and throughput. Since the vast majority of CICS data files are VSAM KSDS, you will generally

find two or three high level indexes, known as the control area, or CA. If a VSAM data record is requested by CICS to a file with three high level indices, and if none of those index records are already within a VSAM buffer in storage, then it would take five physical I/Os to retrieve that data record. That is, one I/O to each of the three high level indices, one I/O for the sequence set, and finally one I/O to retrieve the data record.

Let's assume that this VSAM file exists on a 3380 storage device. We could assume an average service time for each I/O of about 30 milliseconds. If each of your CICS transactions is doing multiple I/Os, this could seriously impact response time and throughput, and certainly cause you to fall short of achieving your service level objectives.

A CICS facility that should be used to address this issue is VSAM files that are to be included in LSR. The end result is having multiple VSAM files sharing relatively large buffer pools. One of the functions of VSAM is to do look aside processing. When a VSAM record is requested, before it does a physical I/O to the requested file, the buffer pools are searched to see if that record already resides in storage. If the record is found in storage, thus saving a physical I/O, this is called a successful look aside. This is especially important when retrieving index records because index record retrieval makes up the majority of VSAM I/Os; therefore, it is very important to define a sufficient number of index buffers within the LSR pool, so that the look aside hit rate would run around 90%. This will substantially cut down on the number of physical I/O's and greatly increase response time and throughput. However, there's no free lunch.

The trade off of saving physical I/Os is increasing CPU cycles because that particular buffer pool that corresponds with the record size that VSAM is trying to retrieve will be referenced by VSAM before the physical I/O is done. The net result is an increase in CICS overhead due to buffer referencing requirements. However, the trade off is usually very positive. (Figure 3 shows CPU time in seconds for 1,000 CICS transaction, each doing five reads. Figure 4 shows the corresponding decrease in response time.) As you can see, response time decreased by .9 seconds on the average to .4 seconds, a net savings in response time of more than 50%. And as you can see by these figures there's also a point of no return. On this particular system, there was not much improvement after specifying 100 LSR buffers in the index buffer pool. This is one of the major methods to reduce physical I/Os and, therefore, greatly improved response time and throughput.

Reducing Paging

Now let's look at one highly recommended method for reduction of CICS paging with an MVS. This method is known as storage isolation. The MVS system resource manager, or SRM, controls access to system resources. These resources include real storage. The control id done by swapping address spaces in or out of storage based on workload and allocation of resources. It's highly recommended that CICS be designated as non-swappable. Input to the SRM is specified in the installation performance specifications, or IPS member of SYS1.PARMLIB. The performance analyst divides the types of work in the IPS into distinct groups, assigns relative importance to each group, and provides performance characteristics for each address space within each group. the OPT member of SYS1.PARMLIB contains parameters that affect paging decisions by the SRM. Storage isolation is specified right here through the PPGRT parameter, PWSS. and the MVS/SA, PPGRTR. Therefore, through specifications within the IPS and OPT, CICS paging can be kept down to a minimum.

CPU Availability and Utilization

One of the common problems that cause CICS to have lack of CPU availability is the priority of CICS within the operating system scheme of things. It is recommended that CICS be placed high in priority within the operating system, right below VTAM but above JES. On a multi-region operation, or MRO CICS system, the terminal owning region should be placed higher in priority in the application owning region, which in turn should be placed higher in priority than the resource, or file owning region. This will cause the CICS terminal network to be serviced quicker, thus improving response time and throughput. If we examine an MVS address space with an MVS370 and MVS/XA below the 16 megabyte line, we'll find that approximately 8 megs or half that address space is being utilized by MVS common, or shared areas. These areas include the MVS nucleus, the MVS common systems are (or CSA), link pack area (or LPA), and System Queue Area (or SQA). The remaining portion of the address space in this example, 8 megabytes, is called the private area which is used by the individual job running within that address space. Looking at Figure 5, we can see the layout of an MVS address space and a typical CICS private area. We see in this particular instance that we have a CICS system running DL1, the bottom block shows an IMS nucleus.

The major components within this address space consists of LSQA, or Local System Queue Area, which is the difference between the high address of the private area, and the top of the region that is specified int he CICS job step. Technically, LSQA consists of MVS

subpools 253-255. However, there are two other areas that fall within this space, the System Work Area (or SWA) which are MVS subpools 236 and 237,and two other subpools, 229 and 230. One of the major users of subpool 229 and 230 is VTAM. VTAM uses this area for its buffering in CICS. The MAXPVT parameter can limit the amount of this buffering. A common symptom of running out of LSQA is an S40D abend. The way to remedy this situation is to effectively increase the size of the private area by either reducing MVS common area usage, such as removing modules from the link pack area, or decreasing the size of the CICS region. Looking at the CICS region itself, we can see that it is comprised of the CICS nucleus, which contains CICS management module s and tables, a resident application program area, OSCOR, and the dynamic storage area.

OSCOR is an areas set aside within the CICS region for MVS get-names after completion of CICS initialization. Running out of OSCOR will cause CICS to abend with an S90A. Be sure that you have enough OSCAR to accommodate your needs, but not too much OSCOR so that space is just being wasted within the CICS region. The objective here is to optimize both the size of LSQA and OSCOR to provide a sufficient amount of DSA so that your CICS system will almost never go short on storage and will also incur very few programs compressions. Let's now look at some of the CICS internal factors that will affect response time and throughput.

CICS Internal Factors

Let's examine two limiting factors within CICS: Active Maximum Tasks (or AMXT), and Max Tasks (or MXT). AMXT is the key system limiting factor within CICS. AMXT tells the CICS task control facility how far down the active task chain to interrogate before terminating its scan. This has a profound effect on a storage requirements and working set size. MXT is a limit for CICS as to how many total transactions may be running within CICS. It is AMXT, however, that is the key system limiting factor and AMXT should be used to control the throughput and storage requirements within CICS. After a total top down performance tuning procedure is followed, AMXT is the last parameter that should be set for the best response time and maximum throughput. Setting AMXT lower than it should be would be putting a false limit on overall CICS performance. As we raise the MXT limit, our throughput along with our working set size will increase, and then we'll reach a point where as we continue raising AMXT other system facts will start to degrade CICS performance, such as going short on storage. The AMXT setting should then be backed up to the point which will provide the best response time and throughput. One of the major timing factors that affect CICS performance is the region exit time interval (or ICV value). CICS waits on an ECB list to the operating system. One of these ECB's is a 'timer ECB, which is the ICV value. The other ECB's on CICS is waitlist to the operating system include file ECB's. If this ICV value, for example, is set in the system initialization table at one second, when CICS issues its wait to the operating system, this ICV timer starts to run. If no other event completes within this one second interval the ICV timer will expire, the ECB will be posted and CICS will request control back from the operating system. Specifying this ICV value at one second or less will assure that CICS gets control frequently enough from the operating system to have a positive impact upon response time and throughput. This is especially important on a lightly loaded CICS system where file I/Os may tend not to complete within a one second time frame. This will assure that CICS will have most of its working set resident and not be severely affected by page in operations when it receives control back from the operating system.

Finally, let's look in the example of priorities within CICS. There are three factors that make up dispatching priority of a CICS transaction., These three factors are transaction priority from the program control table (or PCT), operator priority from the signon table (or SNT), and terminal priority from the terminal control table (or TCT). Some of these factors add up to total dispatching priority and cannot exceed a priority of 255. It's important that high volume inquiry transactions that are in and out of the CICS system very quickly be given a higher priority than update transaction, which might take longer to run and have a lower transaction volume than inquiry transactions.

There are, of course, many more factors and parameters that impact CICS performance. The primary purpose of this article was to show a top down performance tuning methodology that should be followed in assuring optimum CICS performance.

SECTION 3 - PLANNING FOR FUTURE GROWTH

Looking forward towards the 1990's, we'll see an acceleration of the continuing evolution of system architectures. CICS, as IBM's strategic transaction processing system, will play an increasingly major role in this evolution. Let's examine some of the Information Processing industry trends, and how CICS strategies fit into the big picture.

As we more towards the '90's, 'direct service' applications such as home banking and point of sale funds transfers will comprise an increasing share of the transaction processing workload. (Figure 6

illustrates the trend toward direct service applications.) as you can see by 1990 approximately 70% of the total transaction processing workload will be comprised of 'direct service' applications. To facilitate this incredible growth both hardware and software, specifically CPU's and operating systems will evolve to handle this increase in terminal network growth. For example, in 1980, CICS was capable of supporting a 5,000 terminal network with a maximum throughput of approximately 30 transactions per second. IBM projects that in 1990 networks will be over 100,000 terminals with a transaction rate of greater than 500 transactions per second. Operating systems and processors will evolve to handle this workload. CICS systems, of course, must evolve as well. Some of the industry trends affecting the direction the direction that CICS will take are application evolution, along with decentralized operation and connectivity between like and unlike systems.

In the application area, we'll see a tremendous growth of revenue earning rather than just cost savings, 'direct service' applications. Because of these 'direct service applications, the typical end user will be a non-computer oriented consumer. Fourth generation languages (4GL) will help to provide the user friendly interface for these users. As the cost per MIP decreases, application development costs consume a higher percentage of the DP budget. We'll see an increasing use of packaged applications and application generators to help reduce these costs.

Decentralization operations which include local area networks, intelligent workstations, and departmental systems such as the 9370, are other factors in accelerating the growth of CICS. Working hand in hand with decentralized operations, is the need for connectivity between similar and unlike systems, we will see Open Systems Interconnect (OSI) become a standard in the industry. As CICS evolves to support these factors, protection of CICS customers existing applications must be considered. CICS will remain upward compatible from release to release, along with migration tools to ease the pain of change. As MIS gains more direct exposure to the consumer marketplace to 'direct service' applications, CICS performance, availability, and continuous operation factors become increasingly important.

CICS is continually evolving to provide high system availability as well as getting closer to the goal of continuous operation. CICS Release 2.1 wit the extended recovery facility (XRF) which allows a switch to a hot standby CICS system should the primary system run into availability problems. This is an excellent example of IBM's commitment to work toward a high availability and continuously operating CICS system. CICS will, of course, keep evolving to support new operating systems as well as CPU's, so that these high transaction volumes can be realized.

IBM's overall objective is to ensure that CICS is the major transaction processor for the 1990's. Because CICS plays such a major role in IBM's business projections, IBM is working hard to ensure that CICS provides the performance availability, continuous operation, capacity, and the functions to support their CICS customers future business requirements. And because of the heavy emphasis that IBM is placing upon CICS strategy, companies with heavy transaction process requirements should consider CICS as the only way to go.

In summary, we've seen some phenomenal growth in CICS systems over the last 20 years. However, these past 20 years growth will be dwarfed by the revolutionary advancements and achievements we can expect of CICS in the next ten years. The emphasis of CICS development will be on high availability and continuous operation, support of very large networks with high throughput interconnectivity for on like systems through OSI architecture, improved data recoverability and integrity, application development improvement, 4GL support, and CICS with DB2 as a viable production DB/DC system.

RULES OF THUMB

Computer Measurement Group (CMG) Ontario Inc.

Harry Zimmer
Amdahl Canada Limited

ABSTRACT

Performance and Capacity Planning Managers have three methods available to them on how to do and validate plans. (1) "The Benchmark", which is typically extremely expensive and time consuming. (2) "Back of the Envelope", guessing done in under ten minutes. (3) "Rules of Thumb", a middleground between benchmarking and guessing. Our experience in the Regional CMG Group in Ontario, is that given todays pressures of being fast, cheap and accurate, RULES of THUMB are the Planning Managers' best alternative.

1. Introduction

The purpose of this document is to:

1. Establish general and specific capacity guidelines.

2. Establish general and specific performance guidelines.

3. Establish several methods for estimating future processing workloads.

Contributions to this document were made by several CMG-Ontario members. A list of contributors appears on the next page. I would like to extend a special note of thanks to Mike Hurley for the help that he provided in the production of this document.

This document is an updated version of one published originally in September 1985, and updated in September 1986 and April 1987 (CMG Spring Transactions).

The material presented in this document should be used for planning purposes only. The rules are general in nature, and specific installations may experience large deviations in specific cases.

Submissions and updates for this document are welcomed - and encouraged. If you would like to make a submission, or if you have any questions or comments about this document, please contact me in writing:

2. General Rules of Thumb

2.1 Introduction

Here are some general points of reference which should be understood before using this document.

Users can be classified into one of the following major two categories:

1. Operational Systems

* TSO Primarily (ISPF)
* CICS/S2K, CICS/IMS, CICS/IDMS
* Batch Users
* Any combination of the above

2. Management or Decision Support Systems

* PROFS, Personal Services/370
* DB2, SQL
* SAS Family, APL, ADRS - 4GL's
* Any combination of the above

Each of these two user groups requires in depth investigation and attention from data processing performance and capacity planning departments. Here is a list of the critical issues:

* Business Objectives
* Availability
* Responsiveness
* Growth
* Cost Effectiveness
* Service Levels
* Stability
* Quality
* Productivity
* User Satisfaction

2.2 Performance

Processing performance is defined by the following components:

* Online Response Time
* Interactive User Response Time
* Batch Throughput
* Batch Deadlines (Turnaround Time)
* Backup and Recovery Window

These components are influenced by the following:

* Processor - CPU Utilization (Average and Peak), CPU Processing Speed.
* Main Storage - Storage Utilization and Paging Rate
* I/O Dasd Subsystem - Paging Rate, I/O Rate by Channel, I/O Rate by Device, and Wait State by Device.
* Data Communications - Protocol Complexity, Line Speed, Traffic Complexity, Network Topology, Geographical Distance, and Network Transmission Technology.
* Software Efficiency - Operating System, Program Products, Custom Designed Applications.

Some general performance rules of thumb are:

1. 80% of the improvement results from 20% of the work.
2. Left to themselves, things always go from bad to worse.
3. If there is the possibility of several things going wrong, the one that will go wrong is the one that will do the most damage.
4. All CPU's wait at the same speed.

2.3 Capacity

Workload processing capacity can be described by the following parameters:

* Processor (CPU) Speed - Number of Cycles Available, Number of Concurrent Engines at Work, and queue length.
* Main Storage Size - Number of Megabytes of Space Required vs Page Swap Rate. Main Storage, Expanded Storage and Secondary Storage relationships.
* I/O - DASD Subsystem Size and Throughput - Number of volumes of DASD, Number of Tape Drives, Number of Channels, and Number of Paths.
* Data Communications - Number and type of front end communications ports, Front End Processor Speed, Line Speeds, and remote device controller speed and memory size.

2.4 Forecasting Workloads

When forecasting workloads, the following factors should be considered:

* Growth/Reduction in Natural Business Units (eg. Growth in number of credit card transactions per month).
* System Enhancements (eg. Add three new transaction types.)
* Expansion (eg. Increase in the number of new users and number of locations. Of particular concern are mergers and acquisitions.)
* Change in hours of operation.
* Change in reporting frequency (eg. Change from monthly to weekly reporting, or with inquiry packages, from standard to ad hoc.)

For systems in production, future resource requirements should be extrapolated based on:

* Actual Resource Utilization (eg. Number of CPU hours per month.)
* Natural Business Units (eg. Number of Credit Card transactions per month.)

It is sometimes useful to do a forecast based on historical data. The most commonly used techniques are (please consult a statistics manual for the formulae):

* Simple Moving Averages
* Exponential Smoothing
* Classic Decomposition
* Simple Linear Regression
* Multiple Linear Regression
* The Box-Jenkins Method

There are 4 general trends which may be observed:

1. TREND data pattern - when the workload increases as a result of changes in the way the existing system is used. Eg. An increase in the number of transactions processed by a system.
2. CYCLICAL data pattern - which can be caused by a system change, such as the introduction of new applications and the elimination of others.
3. SEASONAL data pattern - which may be caused by periodic tasks that effect the overall system, such as year end or month end processing.
4. STATIONARY data pattern - when a time series behaves as random fluctuations around a mean value, and no trend can be identified.

2.5 General Rules of Thumb

1. The maximum number of active users on a system at any one time is equal to the number of user-id's divided by two.
2. Assume a peak to average ratio of 2.25 : 1.
   This is based on (a) Peak Hour to Average Hour Ratio being 1.5 : 1, and (b) Peak Day to Average Day Ratio being 1.5 : 1.
3. Peak utilization should never exceed 90% (therefore using a peak to average ratio of 2.25 : 1, the average utilization should never exceed 40%).
4. Personal Computers are assumed to behave as terminals, but will consume 25% more than terminals in CPU utilization.
5. Dial-Up users will, on average, consume 25% less in CPU utilization.
6. Prime Shift is defined as 07:00 to 19:00, excluding weekends and holidays. Work done in hours other than this period is classified as Non-Prime Shift Work. This definition is most applicable for company workloads which service Canada on a coast to coast basis.

7. Workload distribution of a system can be analyzed based on the number of programs a company runs:

# of Programs	% CPU Usage
2% of the total uses	50% of the resource
48% of the total uses	48% of the resource
50% of the total uses	2% of the resource

8. A commonly used measure of CPU usage and capacity is "the number of CPU hours consumed" versus the "number of CPU hours available" in a processing complex (CPU). A simple and fast method for calculating the capacity of a CPU is described by the following formula. This calculation is independent of the vendor, CPU model, and operating system:

Capacity # of CPU HRS = # of business days/month * # of hrs/day * % utiliz for good service * # of internal engines

Definitions:

# of business days/month	=	Depends on the month and the number of holidays. It generally averages out to 20 business days for an average Ontario company.
# of hours/day	=	Pick a measurement window - this is called the "Prime Shift". This is typically 7am to 7pm (12 hours).
% utilization for good service	=	80% is typically used by CMG-Ontario member installations.
# of internal engines	=	Today's CPU complex's typically have 1, 2, 3, 4 or 6 internal processors. (eg. 3090-200E 2 engines, and the 5890-190E has 1 engine.)

Sample Calculation #1

IBM 3081KX - 8 hrs/day - 20 business days - 80% utilization maximum. The 3081KX has 2 internal engines.

Max 256 Hours of 3081KX CPU = 20 days/month * 8 hrs/day * 0.8 * 2

Sample Calculation #2

Amdahl 5860 - 20 hrs/day - 18 business days - 90% utilization maximum. The 5860 has 1 internal engine.

Max 324 Hours of 5860 CPU = 18 days/month * 20 hrs/day * 0.9 * 1

2.6 Assumptions

1. The CPU is assumed to be the key resource.
2. All CPU estimates are expressed in TRUE CPU time (SMF with a capture ratio applied).
3. The system will be configured with no bottlenecks.
4. Online workload is the critical service to plan for.
5. The Prime Shift is the critical window to plan for in all operating environments. (ie. Use you company's peak processing window and plan around it.)
6. Network Response is defined as: Front End Communications Processor to Terminal Response. An average cross-network response time should always be planned for with the understanding that actual response times for locally attached and inter-city traffic may be faster.
7. The sources of the Rules of Thumb in this document are widespread and include:
   * Production Experience
   * Benchmarks
   * Simulations
   * Analytical Queuing Models

3. MVS

3.1 MVS General Rules of Thumb

For planning purposes, MVS users may be classified into one of four categories:

1. TSO Primarily (ONLINE)
2. CICS/IMS, CICS/IDMS, CICS/S2K, or CICS/DB2 Primarily (ONLINE)
3. Batch Primarily (BATCH)
4. Combination of Services (ONLINE+BATCH)

The basic data resources for doing MVS performance and capacity planning are SMF, RMF, and PA II data. In general a facility will produce 1,000,000 records of SMF data per CPU mips per month.

3.2 MVS Performance

Here is a list of the MVS performance monitor points, and some performance objectives:

Component	Objective
CPU	
CPU Busy	GT 85%
A.S. IN&READY ....see N1	N/A
A.S. OUT&READY	0
A.S. LOGICAL OUT&READY	0
Batch A.S. ....see N1	N/A
TSO A.S. ....see N1	N/A
STORAGE	
Minimum Available Frame Queue	GT 15
Average Available Frame Queue (Real Storage)	GE 4% of real storage
UIC - Over Committed	LE 2

MISCELLANEOUS

Number of Domains Defined	LT 10
RMF Reporting Interval ...(in minutes)	GE 15 & LE 30
RMF Sample Cycle	GE 250 msec & LE 1000 msec
DASD Block Size (Random)	up to 1/2 track size
DASD Block Size (Sequential)	up to full track (except 3380)
(a) Mixed Devices (3330/3350/3380)	About 6K (LE 6223)
(b) Mixed Devices (3350/3380)	About 9K (LE 9076)
VSAM Block Size	4K
Tape Block Size	8-12K minimum
6250bpi	up to 32K

MVS Performance Objectives Notes

N1 - Installation Dependent - can be useful for capacity planning
N2 - Sum of Non-VIO Reclaims + Non-swap, Non-VIO Page-Ins.
Installation and CPU Dependent - V/7B or 3083E assumed.
N3 - Sum of all Page-Ins + all Page-Outs.
Installation and CPU Dependent - V/7B or 3083E assumed.
N4 - 370-mode or No DPR assumed.
N5 - <Total Device Busy On Chan> divided by <Channel Busy>
N6 - <Device Busy> divided by <Activity Rate>
N7 - [<Device Busy> plus <Queue Length>] divided by <Activity Rate>
N8 - <Ended Time> - [<Avg Trans SVC Rate> * <Ended Time> divided by <Absorption rate>].
N9 - <Total Transactions> divided by <Report Interval>.

Acronym Definitions:

LE = "Less than or equal to"
LT = "Less than"
GE = "Greater than or equal to"
GT = "Greater than"
N/A = Not applicable

Note: Performance Values cited typically apply to 15 minute intervals. Care should be taken when trying to apply performance objectives over short periods of time.

DASD Controller Guidelines

* CACHED *	Interactive Workloads	Batch Workloads
I/O Rates <1>	< 160	< 180
Hits Ratio <2>	> 90 %	> 65 %
Read/Write Ratio	> 3:1	> 2:1
Read Hits/Stage	> 4	> 3
Read Misses/Stage	< 1	< 1

* UNCACHED *	Interactive Workloads	Batch Workloads
I/O Rates <1>	< 45	< 65

<1> Assumes 4K blocksize. Interpolate for blockings < and > 4K. I/O rates = I/O's per second per controller subsystem.
<2> This is Read Hit Ratio.

CACHE Guidelines

For Dedicated Cached Subsystems (i.e. only cached actuators in the subsystem):

(a) Should maintain hit ratios > 85%.
(b) For hit ratios < 85%, disqualify certain datasets or activities and/or Add more cache. Either move these data sets to another volume or out of the subsystem. Locality of reference analysis will be conclusive. (Note: Do not add more cache as the first step of tuning, since the read/write ratio and locality of reference may be the culprits of poor performance. Also see note (i) below.
(c) When hit ratios are consistantly high, channel utilizations can be allowed to increase significantly (up to 50%).

For Selective Cached Subsystems (i.e. 1 or more cached actuators in the subsystem):

(a) Keeping internal path utilization < 35% is critical, otherwise the uncached actuators service time will elongate unbounded, and will result in erratic response times.
(b) For hit ratios > 85%, the internal path utilization will be <= to the channel utilization. As the hit ratio decreases, the internal path utilization will become > the channel utilization.

Note (i): For erratic hit ratios, do the following on a volume basis:

i.1 * Determine Read:Write Ratio (would like this to be greater than or equal to 2:1).
i.2 * Locality of reference, is it good or bad? (Good means I/O's are clustered within a small range of tracks.)

If i.1 is high AND i.2 is good, then add more cache. If either i.1 or i.2 is unsatisfactory, uncache the data set or actuator.

Solid State Disk Guidelines

For 2 directors configured to two 3 megabyte channels:

a) The maximum paging rate is approximately 950 pages/second.
b) Configure one (maximum) page dataset per device address.
c) Configure one (maximum) swap data set per device address.
d) Configure the subsystem on dedicated channels if possible.
e) Two dedicated SSD swap paths will provide higher concurrency than 4 paths (dedicated or shared) to rotating 3380's. This is important for keeping swap-in delay low, and hence maintaining good response times.
f) Page response time: 3 msec.

Disk Guidelines

*** This section to be added in the next rules of thumb document.

3.3 MVS Capacity

The usage of MVS is directly dependent on the type of user making use of the service. In general, the following usage guidelines on a per user basis may be applied:

MVS Workload Forecasting

Type of User	# of CPU HRS/ Month 3081KX	# CYL DASD 3380	# Reels Tape 6250
TSO Primarily	0.250	15	3
CICS-IMS/IDMS/S2K	0.450	25	5
DB2	0.850	26	5
Batch Primarily	0.350	28	7
All Services	0.500	25	5

The CPU values presented in the above figure are totals per month, which includes all shifts (Prime + Non-Prime). The following guidelines may be applied for splitting these totals into prime and non-prime:

* TSO is split 90% prime, and 10% non-prime.
* CICS/IMS, CICS/IDMS, CICS/S2K is split 90% prime and 10% non-prime.
* DB2 is split 95% prime, and 5% non-prime.
* Batch is split 25% prime and 75% non-prime.
* Combination all Services is split 60% prime and 40% non-prime.

MVS CPU and MAIN MEMORY Rules:

For each MIP of installed processing capability, the system will require 4 to 6 megabytes of main memory. For specific dedicated situations:

(a) For IMS/CICS --- 4 megabytes / installed MIP.
(b) For TSO -------- 5 megabytes / installed MIP.
(c) For DB2 -------- 6 megabytes / installed MIP.

Online Workloads

The following information should prove to be of greatest help to systems development managers who require more precise figures for calculating the processing requirements for new ONLINE systems (ie. TSO, CICS/IMS based).

A transaction is defined to be one pressing of the ENTER key. A transaction may be classified as simple, medium or complex depending on the number of data base accesses done by the transaction. The following table defines the guidelines for CPU load forecasting on a transaction level basis:

MVS System Transactions and CPU Load
(In 3081KX CPU seconds)

Transaction Type	Simple	Medium	Complex
Number of I/O's	<=5	<=10	> 10
CICS-IMS/IDMS/S2K	0.038	0.071	0.143
VSAM/CICS	0.008	0.019	0.036
Non DB/DC	0.004	0.008	0.020

If the transaction mix is unknown, then assume 25% simple, 50% medium, and 25% complex.

Batch Workloads

Each online true CPU hour generates one hour of batch processing.

Systems Development

Where no detailed utilization information is available, development and production processing loads can be estimated based on planned development resources using the following guidelines:

Systems Development Workload Forecasting
Average Utilization Per Programmer Per Month

Type Development Tool Used	# of CPU Hours Per Month 3081KX CPU Hours
Conventional (Cobol, PL/I)	0.50
High Level (FOCUS,DB2,ACT/1)	1.00

* For systems which are developed using conventional development tools: one hour of development CPU per month will result in one hour of production CPU load per month twelve months later.
* For systems which are developed using high level development tools: one hour of development CPU per month will result in one hour of production CPU load per month six months later.
* For Online Systems, the resulting production load will be split 50% online and 50% batch.

To determine the prime and non-prime workload, the guidelines are:

* Development (test) and user direct processing load is split 80/20 between prime and non-prime.
* 80% of the online processing takes place during the prime shift.
* 80% of the batch processing takes pace during the non-prime shift.

3.4 MVS Data Bases

3.4.1 DB2

Buffer Manager: Use only one 4K bufferpool. One 4K bufferpool will be managed more effectively than 3 separate bufferpools.

VSAM Files: Use direct VSAM allocation for production tablespaces rather than storage groups. Direct allocation provides better control for tuning DASD devices.

Dispatching Priority: Set the dispatching priority of DB2 address spaces to the highest user priority, ie. higher than the IMS control region. Less than 10% of the DB2 code is executed under this priority and most of it is critical. Most DB2 work is dispatched under the primary address space, such as TSO or CICS.

Data Collection: Collect SMF record type 100 (statistics) and SMF record type 101 (Accounting) on a continual basis for DB2. The DB2 installation parameters SMFSTAT and SMFACCT should be set to collect these records by default. The global trace should not be active.

Resource Control: Release 2.1 of QMF features a user exit which can be used to restrict the resource consumption by user. If QMF is being used with large tables, the exit should be used to restrict the total CPU to avoid "runaway transactions".

3.4.2 IMS

Performance Targets:

IMS Control Region Page-Ins ..... Less than 2 per second

IMS Control Region Page-Faults ..... Less than 10 per second

IMS Message Processing Regions ..... Optimum usage at 60-75% per message region.

Tuning of IMS Systems should be done in the following order:

1. The DASD Subsystem,
2. Virtual Storage,
3. Paging Sybsystem, and finally,
4. Internal IMS Parameters.

3.4.3 IDMS

* Award IDMS the highest reasonable priority in the system (ie just below critical system components like JES and VTAM).
* Make IDMS non-swappable.
* Utilize the storage isolation functions of the SRM to reduce the number of page faults within the IDMS address space.
* Keep the total paging rate to a reasonable level for your paging configuration.

4. VM

4.1 VM General Rules of Thumb

There are three distinct types of VM users:

1. PROFS Primarily
2. Combination All Services
3. SQL Primarily

4.2 VM Performance

Here are the VM Performance monitor points, and some performance objectives:

VM Performance Objectives

Component	Description	Objective
Processor		
RAI	Resource Availability Index	GT 0.8
TOTCPU	Total System Processing	85-90%
TVRATIO	Total to Virtual Ratio	LT 2.0
ACTIVE	Active Users	LT 10%
Q1SEC	Time Between Q1 Drops - Seconds ..	0.10
Q2SEC	Time Between Q2 Drops - Seconds ..	0.50
PRIVOP	Privileged instructions	300 (for 4381-2)
Main Storage		
STGUTIL	Storage Utilization	LT 70%
STEALSCANS.....	Steal Scans	LT 0.10
PAGERATE	Paging Rate	20 pps (for 4381-2)
FREXTEND	Free Storage Extensions	LT 5 (Objective is 0)
I/O Dasd Subsystem		
IOINT	I/O Interrupts	N/A
CHANn	Channel 'n' Utilization	LT 30%
CTLUNIT	Control Unit Busy	LT 30%
DEVICE	Device Unit Busy	LT 30%

LE 5.0 SIO per sec 3350	:	LT 10% Devices with Queue
LE 5.5 SIO per sec 3375	:	LT 50% Seeks are Non-Zero
LE 6.0 SIO per sec 3370	:	LT 40 CYL Average Non-Zero Seek
LE 9.0 SIO per sec 3380	:	

4.3 VM Capacity

The following general capacity rules of thumb apply in the VM world:

* Prime Shift load does not exceed 75-80% of capacity.

* Total all Shifts does not exceed 85% of capacity.

Usage of VM is directly dependent on the type of user making use of the service. In general, the following usage guidelines may be applied:

VM Workload Forecasting

Type of User	# CPU HRS/ Month 3081KX	# CYL DASD 3380	# TAPE REELS 6250
PROFS Primarily	0.100	7	0.1
Comb. Services	0.200	10	0.1
SQL - Occasional	0.100	30	0.2
SQL - Moderate	0.300	30	0.2
SQL - Heavy	0.600	30	0.2

The CPU values presented in the above figure are totals (prime and non-prime shifts). These totals can be split into 90% prime and 10% non-prime.

SQL users have been broken into three classes (if the characteristics are unknown, assume the user to be of moderate type):

1. Occasional - One SQL/DS access per day or less - with minimal requests for summary reports of large data volumes.

2. Moderate - Regular use of an SQL/DS application - with a low to medium frequency of ad-hoc reporting.

3. Heavy - An application developer or end users with a high frequency of ad-hoc report development.

5. Tandem

5.1 Tandem General Rules of Thumb

* To take advantage of Tandem's hardware architecture, applications should be designed so that:

  1. Any application process can be moved to any CPU.

  2. Copies can be made of any application process, and workloads are spread across CPU's.

  3. Any data base file or program file can be moved to any disk drive.

  4. All transaction message-path-lengths are kept to a minimum.

* Based on measurements obtained by the XRAY/MEASURE software monitor, balance workloads across devices of the same type.

5.2 Tandem Performance

Parameter	Recommended MAX Value
CPU.CPU-BUSY-TIME	60% (TNSII), 70% (TXP) (not counting batch)
CPU.CPU-QTIME	1.0
CPU.DISPATCHES	180 per second (TNSII) 300 per second (TXP)
CPU.SWAPS	1 per second
DISC.REQUESTS-BLOCKED	5%
DISC.SEEK-BUSY-TIME	15 milliseconds per request
DISC.READS + WRITES + SEEKS	15 per second (TNSII) 25 per second (TXP)
DISC.READ-BUSY-TIME + WRITE-BUSY-TIME + SEEK-BUSY-TIME	25% (TNSII), 35% (TXP)
DISC.REQUEST-QTIME + PROCESS.REVC-QTIME (disc process)	3
PROCESS.VSEMS (disc process)	1 (DP1 only)
PROCESS.PAGE-FAULTS	2.0 per second

OLTP Performance:

* Standard ET1 (debit-credit banking) transaction
* Hardware: VLX CPU and B30 Operating System
* Pathway with TMF
* 3 random reads with updates (Account, Teller, Branch)
* 1 Sequential write (history)
* Data Base: 200 Million Bytes in size
* Throughput: 10 trans/sec per CPU
* Response Times with 95% less than 2 seconds

5.3 Tandem Capacity

* This section to be added in the next Rules of Thumb Document.

6. Data Communications

6.1 Response Time Analysis

The following guidelines may be used to estimate online response times for most operating environments:

* Response Time = Network Response + CPU Response + DASD Response

* Network Response can be fixed at 2.35 seconds. Before using this consider: line speed, topology & protocol complexity.

* CPU Response is equal to 10 times CPU Usage (eg. if CPU usage is 0.055 seconds, then CPU Response is 0.550 seconds).

* DASD Response is dependent on the number of I/O's. Each I/O takes 0.060 seconds on an IBM 3350, or 0.030 on an IBM 3380. (Eg. For a transaction that has 5 I/O's on an IBM 3380, then the DASD response time is 0.150 seconds).

6.2 Transmission Volumes

The following volumes can be used for planning purposes:

Data ..... 700 char/page
Text ..... 4,000 char/page
Image ..... 35-50,000 char/page
Graphics ..... 50,000 char/page
Voice Annotation ..... 32K - 64K bps

The following Terminal Device load rules of thumb are useful for planning purposes:

Data Communications - Terminal Load Guidelines

Application	Typical Complexity	Trans/Term/Person/Day
Data Entry	Simple	1,000
Inquiry	Medium	300
Update/Inquiry	Complex	500
Personal Computer	Complex	100
Word Processing	Complex	100

General Data Communications Rules of Thumb:

(1) For an SNA/SDLC environment:
A 9600BPS line can support 3 or 4 3270 type controllers. Each controller is assumed to be able to support up to 32 devices. Therefore a 9600BPS line can support from 96 to 128 devices. Use 96 as a maximum for high production traffic, and 128 as a maximum for lower development/test traffic.

(2) Error Rates: 1 error in every 10 to the power 5 bits is considered to be acceptable. Greater than this is considered to be unacceptable.

7. Printing

7.1 General Printing Rules of Thumb

Most printers have unique operating and capacity characteristics. In general, the following attributes may be applied to all users of printers:

(a) Average # of Lines Per Page ==========> 60

(b) Average # of Characters Per Line ==========> 120

(c) Average # of Characters Per Page ==========> 7,200

SPEED Comparisons

Lines/Minute (LPM)	Pages/Minute (PPM)
600	10
1200	20
2400	40
3600	60

7.2 Impact Printing Technologies

* Average forms mount time = 10 minutes.

7.3 Non-Impact Printing Technologies

* %'age of printed output that can be printed 2-up AND duplexed is 30% of total data centre print volume.

GOOD TOOLS AND MODELS ARE NOT ENOUGH: ON THE NECESSITY FOR BI-DIRECTIONAL COMMUNICATION

Ellen E. Robertson
Texas Utilities Services Inc.

Dottie Cunningham
Celanese Fibers Inc.

ABSTRACT

As the function of capacity management has evolved and matured, considerable attention has been directed towards what the capacity planner and performance analyst must provide management in terms of reporting, or in support of the corporation's decision making progress. A recent survey of CPE practitioners indicates concerns on their part relating to the information communicated to them by management in support of their activities, and to management's view of the CPE function in general. This panel of capacity planners and performance analysts will present these concerns to the audience and provide a forum for discussion on how issues resulting from these concerns might be resolved.

The following list provides a number of questions and issues that will be addressed by the panel. Attendees are encouraged to expand this list by presenting additional questions or issues to the panel during the course of the session.

1. As a CPE practitioner, how do you view your corporation's commitment to capacity planning and performance evaluation?
   - A. Are you properly positioned within the organization?
   - B. Is sufficient manpower devoted to the function?
   - C. Do you have a clearly defined career path?
   - D. Do you receive adequate tools and training?
   - E. Are you frequently assigned non related tasks and projects such that capacity planning and/or performance is really only a 'part time' job?
   - F. Is management willing to listen to problems you have doing your job?
2. Do you receive all the information necessary for you to perform your job properly?
   - A. Are management objectives and expectations clearly defined and communicated to you?
   - B. If there is a corporate strategic plan, do you receive it?
   - C. Do you have access to budget information that may impact the studies or recommendations you are asked to perform?
   - D. Are plans regarding new systems or products provided?
   - E. Do you have ready access to all levels of management across organizational lines?
3. Regarding the information you do receive:
   - A. Is it timely?
   - B. Is it pertinent?
   - C. What is most useful?
   - D. What is least useful?
4. What single piece of information which you do not currently receive, or do not receive on a timely basis, would be most useful to you in performing your job?
5. How do you view your ability to influence corporate plans?
   - A. Do you or your group participate in the formulation of strategic plans?
   - B. Are you free to make recommendations that may not agree with current policy or trends within your company?
   - C. Is the time and effort required to address speculative issues weighed against the potential benefits?
   - D. Are your recommendations generally accepted, and if not is the rational behind their rejection communicated to you?
   - E. Is the resulting net value to the company of actions taken based on your recommendations quantified?
6. What are the three major obstacles you encounter in performing your job?
7. What do you perceive as the most important communication problem between capacity planners/ performance analysts and executives?
8. If you could make one single request of your management relating directly to your job, what would it be?

Executive Views and Expectations of Capacity Planning

James A. Stanton
Morino Associates
Vienna, VA 22180

Abstract: Surveys of capacity management organizations have shown that some of the leading problems experienced by capacity planners are management related. Examples of problem areas include obtaining and keeping management credibility, communicating plans to management, and management support in terms of tools, education, etc. This session will provide a valuable opportunity for CPE practitioners to directly address questions of interest to a panel of executive level managers.

The following list provides a number of the questions and issues that will be addressed by the panel. Attendees are welcomed to expand this list by presenting additional questions or issues to the panel during the course of the session.

1. As a senior executive manager, how do you view the capacity planning (CP) function in your enterprise?
   a. What is the purpose of capacity planning in your enterprise?
   b. What do you think the purpose should be?
   c. What are the objectives of capacity planning?
   d. What is the importance of capacity planning?
   e. Who are the executive participants in the capacity planning process?
   f. What is the role of executive management in the capacity planning process?
   g. What role should the users play in the capacity planning process?

2. Does your organization have a formal CP program?
   a. Where does CP report in the organization?
   b. Where should it report in the organization?
   c. How long has the function been in existence?
   d. How many people are dedicated to the capacity planning process?
   e. What percentage of your DP budget is allocated to CP?

3. What are the three major obstacles to CP in your organization?

4. What formal reports does CP provide management? What should they provide? How often should the reports be provided?

5. Does your CP group participate in preparing the reports listed below? If so, how effective is this participation for the:
   a. Five year strategic plan?
   b. Two year business plan?
   c. Annual operating report?
   d. Quarterly assessment report?

6. How does your CP group translate CP methodology into reports presentable to I/S and executive management?
   a. What should the audit trail look like for CP recommendations?
   b. What kind of supporting information do you find essential in providing credibility to capacity plans?

7. How are user and corporate business forecasts used in your capacity planning process?

8. What do you expect from your CP function and staff?
   a. Why may it not be living up to your expectations?
   b. How is credibility best won and maintained by the capacity planners?
   c. What destroys the credibility of the capacity planners the quickest?
   d. What is the most important communication problem between executives and capacity planners?
   e. What does the executive manager typically want to know from the capacity planning process?
   f. What is the best form of presentation of capacity planning information?
   g. What skills does the executive look for in capacity planners?

9. How does your enterprise handle the management of the CP function?
   a. Should the executives explain their decisions or lack of capacity plan decisions to the capacity planners?
   b. What kinds of complaints are expressed in the executive suite regarding I/S service and how do the executives relate these complaints to CP issues?

10. How do you recommend the capacity planners relate to executive management concerning their careers and their future in your enterprise?
    a. Do executives want to hear about the problems capacity planners have in doing their jobs?
    b. What is your view of the career paths for capacity planners in your enterprise?
    c. What is the best way for the capacity planner to approach executive management to obtain approvals for training and CP tools?
    d. How would you describe the management support (in terms of tools, education, management involvement, and access to business management information) given to the capacity planning process in your enterprise?

11. What single recommendation would you make to the capacity planners in our audience as to how best to deal with executive management?

a. Capacity plannner should know the business of their key users?
b. Capacity planners must understand the primary business concerns, opportunities, areas of emphasis, and weaknesses?
c. I/S employees must bring opportunities to the attention of management?
d. The financial return of capacity plans should be clearly demonstrated?
e. The financial impact of capacity plan alternatives should always be clearly defined?
f. Capacity plan presentations should begin with statements of assumptions and should provide an opportunity for executives to ask and get answers to "what if the assumptions were different", types of questions?

SUCCESSFUL SOFTWARE PERFORMANCE ENGINEERING

MODERATOR: DR. CONNIE U. SMITH

At CMG86, a BOF session reviewed the evolution of Software Performance Engineering (SPE) and discussed recent experiences in applying it. SPE advocates building performance into new systems rather than tuning code after implementation. The BOF session revealed that there are, unfortunately, still problems in convincing managers and software developers of its vital importance. Once convinced, there are still many pitfalls that threaten successful SPE application.

This panel has two parts: the first addresses problems in convincing organizations to abandon the "fix it later" approach and adopt performance engineering. It begins with an overview of what it is, how it helps software development projects and capacity planning, who else is doing it, etc. Then panel members discuss SPE adoption considerations. The second part is on SPE experiences. Panel members will relay their project experiences, discuss pitfalls and offer advice for avoiding them, and highlight successful strategies and techniques. Both managers and practitioners are represented. Time is allocated for answering audience questions.

SPE DEFINITION

Software Performance Engineering (SPE) is a method for constructing software systems to meet responsiveness goals. With it, one models software requirements and designs, and evaluates whether predicted performance metrics meet the specified goals. If not, alternatives are proposed and assessed. The process continues through the detailed design, coding, and testing stages to develop more precise models of the software and its predicted performance.

SPE focuses on software development, but it is also an important part of a capacity management program. There are three major capacity management considerations: planning, growth, and control. Accurate planning requires data on new applications and data on the effect on resource requirements of growth in current work; SPE models provide both.

A passive capacity planning program anticipates growth and reacts to it. SPE advocates an *active* capacity management program that controls configuration requirements. Growth in workload demands may be inevitable, but growth due to resource requirements of software can be controlled through SPE.

SESSION 1:

SPE ADOPTION CONSIDERATIONS

Dr. Thomas E. Bell, Rivendel Consultants:

THE CHALLENGE OF PERFORMANCE ENGINEERING IS DESIGN IMPROVEMENT

Is Performance Engineering an analytical effort to expose the inadequacies of designers and implementors? Is it primarily a control effort involving reviews of designs so that errors can be caught and designers can be ordered to restart their efforts? Does it just involve projecting the amount of resources that will be required to support a new application -- but projecting it as early as possible? It is none of these. Instead it is an effort integral to the development project that contributes in the same way that database design contributes. With an expert understanding of the performance effects of various design alternatives, and the knowledge of how to quantify these effects, the Performance Engineer can suggest alternatives to the rest of the team. He or she can quantify the trade-offs and justify alternatives that, even if less elegant, are necessary to attain the project goals.

The obvious responsibilities of the Performance Engineer -- early projection, estimating equipment requirements, detection of performance bugs -- are less important than *getting* the performance requirements correct, *improving* the design, and *suggesting* improved implementations. Of course, the primary responsibilities are more difficult than the obvious ones; they require Performance Engineers to work cooperatively with other designers. They must use their design abilities, persuasive skills, and quantitative understanding rather than arrogance and power-plays to win over designers whose emphasis is on improved functionality or improved elegance.

Ken Kolence, Kolence Associates:

SOFTWARE PERFORMANCE ENGINEERING IS A JOINT EFFORT

There are several problems that hinder adoption of SPE:

1) it is difficult to quantify its value -- success is the absence of performance problems while only failures are obvious;

2) performance requirements for new systems are seldom explicit;

3) more products are needed to automate the difficult SPE tasks and better integrate SPE with other well-established development activities.

There are many ways to improve the situation. SPE should be more tightly coupled with capacity planning activities. We should be concerned not only with performance but also with workload characterization and forecasting. Success in these activities is easier to quantify. We also need to integrate instrumentation directly into software designs. This provides data for predicting response times under varying loads. It could also feed analytic models for determining required capacity allocation (setting SRM and performance group parameters. The ideal place for such features is within new CASE tools, but it is difficult to convince CASE developers to do it. We must first prove its value.

We must change the viewpoint of software developers. They need to be accountable for ***all*** requirements, including explicit performance goals. Often systems analysts are not aware of reasonable service level objectives, and developers are unaware of techniques for achieving them. We need to develop standards for goal specification. Products facilitate these tasks.

Many SPE tasks are labor intensive. It is difficult to obtain the data needed for SPE studies. Many organizations now use code generation tools and tools that add structure to old "spider web" programs. These products could be easily augmented to provide SPE data.

Finally, we need to generate more interest outside of CMG. In particular, we need to increase awareness of managers, developers, and software engineering researchers.

Ralph Terkowitz, Washington Post:

SOFTWARE PERFORMANCE AT THE WASHINGTON POST

The IBM computer complex at *The Washington Post* has about 20 MIPs of installed processing power with 30 Gigabytes of DASD. We are very proud of the performance of our online systems. Despite a relatively high transaction volume per installed MIP, we average completion of 85 - 90% of all tasks in under one second (compared to a Service Level Commitment of 75%). The unusual part of our environment is that we have accomplished these goals without any full-time analysts!

This juxtaposition of systems performance with lack of performance analysts may seem unusual; however, I believe it is directly related to our adopting Software Performance Engineering (SPE) techniques about five years ago. No one person on our staff is charged with the performance of our systems; rather, each of our senior analysts is responsible for the performance of his own system. Performance requirements and systems performance forecasts are routinely developed and confirmed by the applications staff. Why: Because they understand that developing a system to meet performance criteria is as important as having the system meet any other functional criteria.

The unusual empahsis on applications performance at The Post is not the result of any management revelation. In fact, senior management has no idea that our record of performance-oriented system implementation is not common in the data processing industry. Proposals have never been made to senior management to adopt the SPE technology. They don't even know what it is. SPE has become our method for applications development because of the successes we have had with it.

People often ask us for tips on starting or gaining management support for a SPE program. I believe that there is no one right way: there is nothing magic to do or tell senior management. I think that the key to developing a Software Performance Engineering program is recognizing that SPE is not in itself the goal of your development; rather, it is the means to the end of developing high performance systems -- *systems that consume no more than the forecast resources and deliver the expected performance.*

SPE is now a way of life at The Post. It is not in place due to management fiat, but rather because we have shown senior management that we can forecast, develop and build systems that operate at the expected cost with the expected performance. Management doesn't care about the method; they care about the results from it!

Dr. Connie U. Smith, L&S Computer Technology, Inc.:

STRUCTURED PROGRAMMING, HYBRID CORN, AND PERFORMANCE ENGINEERING

On the surface these appear to have little in common. However, recent software engineering studies have examined the process of technology transfer to understand what happens and to see if it can be hastened. They have found that it typically takes 15-20 years between the time that new technologies emerge and their widespread use in industry. The range holds for most new technologies whether they are software related, such as structured programming, or in other domains, such as hybrid corn. SPE is approximately 10 years old. Will it be commonplace in the next 5-10 years? Can the time be shortened? According to technology transfer research, you can play a role in its adoption.

Technologies are more readily adopted when they have a strong advocate who: persistently encourages and follows up on its use, serves as a two-way communication channel between technology users and technology developers, and helps to resolve problems that arise. Technologies are more likely to be adopted when they have a clear benefit; they are compatible with existing methods, experiences, and needs; they are easy to understand; easy to try; and they produce a measurable result. When an organization tries a new technology, it is more likely to be successful if an expert participates in the project and contributes to its success. These needs must be addressed if SPE is to be adopted and used. So, if you believe in SPE concepts and want to see them used in your organization:

- Learn what it is so you can explain it and its benefits to others
- Find or become a persistent advocate
- Document compatibility in your environment
- Apply it to a pilot project, then explain it and its results to others
- Quantify the results of using SPE (otherwise success is invisible)
- Alternatively, point out problems that occur without SPE and ***how*** they can easily be prevented.

Document experiences so others can point to its successful uses for justification, and learn from problems so they can be avoided.

SESSION 2:

SPE EXPERIENCES

Greg Fox, TRW Federal Systems Group:

TAKE PRACTICAL PERFORMANCE ENGINEERING STEPS EARLY

The following remarks address performance engineering in the context of a "large" system development. "Large" means hundreds of thousands of lines of software designed, coded, and tested by dozens of developers in a multi-year effort. The system performs complex transactions, with extensive algorithmic processing, on streams of data or messages received from sources external to the system.

The success of a performance engineering effort can be gauged by how well the finished system meets performance requirements ***and*** by how much disruption there was to the normal development process. Many complex, modern systems require some disruption; the goal is to keep it to acceptable levels.

Performance engineering has two phases: theoretical and practical. The success of the effort is determined by how and when the transition from theoretical to practical occurs. The theoretical aspects (analysis, modeling, and simulation) are valuable in the development of algorithms, an architecture free of unrecoverable bottlenecks, and realistic estimates of hardware resource requirements. The practical phase incorporates the performance features into the software. During integration it is unrealistic to expect that measured system performance will be as good as predicted by the models. The models have inherent limitations in accounting for the following factors: 1) the system environment, including the performance aspects of complex operating systems, and 2) inaccuracy of resource consumption estimates, including the effect of varying skill levels among programmers.

Practical performance engineering steps during design, code, and unit test narrow the gap between model predictions and initial measured performance. This reduces the amount of improvement needed during integration. By the time top-level design is completed, emphasis should shift from analysis and prediction to more practical activities, such as developing information for programmers to build the system in a performance-efficient fashion. A benchmark design and measurement activity should parallel coding and unit testing, and be an integral part of the development by the time integration is underway.

Experience shows that for many large systems, a factor of two performance improvement can be achieved from early integration benchmarks with relatively little disruption of the integration process. An additional improvement factor of two to three may be possible with moderate disruptions to cost and schedule. If measurement is left until late in integration, required performance improvements can cause major disruption to the completion of the development effort.

Norb Trohoski, General Electric:

ACCEPTANCE IS THE KEY ASPECT OF EFFECTIVE PERFORMANCE ENGINEERING

The key aspect of successful performance engineering in large computer system developments, where there are many pieces of software being developed involving hundreds of engineers and programmers, is its acceptance by both engineering and software development. This acceptance and commitment produces the proper team effort required to build in the performance.

The most common design and development methodology has been to develop the software programs so that they get the right results without concern for performance issues. Programmers do not intentionally write poor performing code, rather, runtime performance is not a major consideration in the design. Not until the programmer is in trouble with runtime does he become interested in performance analysis. This generally results in cost overruns, missed delivery schedules, and upset upper management and customers. Even when a performance engineering activity is in place, if the engineers and programmers do not believe in it, the information they provide on the proposed design is usually late, sketchy, and incomplete. This is because they are required to produce the data and, since they do not believe in performance engineering, they do as little as they can get away with and still meet their commitment. The worst part is when the data is incomplete. This may produce an analysis of the software that indicates the software will meet performance requirements, and then it is not discovered until test that the software will not.

If the developers give the performance engineering approach a try usually it will result in believers. Those who have experienced what performance engineering can do for them continually ask the performance engineering group for support. This makes the performance engineering activity easy, with resulting systems that are capable of meeting their performance requirements.

Thus it has been found that the key aspect to effective Performance Engineering is to get engineers and programmers to understand and believe in the importance of Performance Engineering; when this happens, successful software systems are produced.

Doug McBride, Hewlett Packard:

APPROPRIATE DECOMPOSITION AND MEASUREMENT ARE VITAL

There are, of course, a myriad of steps in software performance engineering. I would say, however, the two most troublesome areas for designers and implementors are:

- Decomposing the software system into components for subsystem performance measurement and tuning.

- Locating and/or creating software or hardware performance monitoring tools which give an accurate picture of how the software component is performing,and what system resources it is consuming.

As in solving any complex problem, decomposing the larger software system into components by breaking it into smaller parts typically aids in the solution of the overall problem. Decomposition focuses attention and resources on a smaller, more manageable subset of the entire problem. Three areas to consider when performing the decomposition include:

- Delineating component boundaries based on system resource consumption characteristics, as well as anticipated sensitivity to overall system performance parameters.

- Establishing meaningful performance budgets and goals for the particular component according to its functional relationship to the other components, and to overall system performance.

- Having measurement tools in place, or under development, to facilitate proper monitoring of the progress of the components being tested.

Without the tools that provide a window into the system to determine how well individual software components are performing and using system resources, it is virtually impossible to carry out the performance engineering function with any possibility of quantifiable success. Many ambitious performance efforts have failed due to the lack of proper monitoring tools - software or hardware - needed to meet performance goals and validate resource budgets. It is vital that these tools, which can take many forms, depending on prior experience and current need, be available, or their creation be budgeted during the design phase of the software. It is equally vital to explain and discuss the types of tools needed with project management, and how and when to acquire them.

PRELIMINARY CALL FOR PAPERS

CMG '88 INTERNATIONAL CONFERENCE

ON THE MANAGEMENT AND PERFORMANCE

EVALUATION OF COMPUTER SYSTEMS

December 12-16, 1988 **Loew's Anatole,** **Dallas, Texas**

It is not too soon to be thinking about the paper you are going to submit for presentation at the CMG '88 International Conference, held at the Loew's Anatole, Dallas, Texas. The Conference dates are December 12-16, 1988.

Although we're interested in receiving papers describing new ideas or techniques, we also want reports on experiences (either success or failure) in CPE areas. Papers, tutorials, new books, and BOF interest areas are encouraged in the following performance related areas:

Establishing a Capacity Management Program
Justification, Planning, and Control of Personal Computers in the corporation
Capacity planning and prediction
Management reporting
Workload characterization/forecasting
Distributed processing analysis
I/O subsystem performance analysis
User requirements and user service agreements
Office automation analysis
Installation management performance issues
UNIX
Artificial intelligence and expert systems
Establishing goals and measuring productivity
DP budgeting, cost accounting, charge-back, and financial management
Hiring and managing a CPE staff
Professionalism in the CPE field
Software performance: design, development, implementation, and production
Problem management and change control
Capacity management relationship to corporate staff
Network design and optimism

Preference will be given to papers and books that have not been previously published or presented. Authors of papers will be required to assign copyright for their papers to CMG for publication in the Conference Proceedings. It will be the authors responsibility to secure any release required by their employers for publication.

SCHEDULE

April 1, 1988	Abstracts due (10 copies)
June 1, 1988	Completed papers due (10 copies)
July 25, 1988	Notification of acceptance
Sept. 2, 1988	Final, camera-ready copy due

INQUIRIES

General Chairman, CMG '88
CMG Headquarters
6397 Little River Turnpike
Alexandria, VA 22312
(703) 354-3306

CMG OFFICERS AND DIRECTORS

PRESIDENT
Mel Boksenbaum
Amdahl Corporation
1250 E. Arques Avenue
P.O. Box 3470 MS 126
Sunnyvale, CA 94088
(408) 746-6761

VICE PRESIDENT
Marilyn T. Kanas
International Systems Services Corp.
Suite 201, 1 Greentree Centre
Marlton, NJ 08053
(609) 596-6700

TREASURER
Robert L. Morrison
IBM Corporation
Dept. 1P4 Bldg. 987
P.O. Box 390
Poughkeepsie, NY 12602
(914) 432-4713

SECRETARY
Jason Shane
Coldwell Banker Residential Group
nformation Services, Suite #200
23046 Avenida de la Carlota
Laguna Hills, CA 92653
(714) 859-5380

DIRECTORS
